Preface

The European Commission (EC) has highlight in different occasions the importance of mathematics in the resolution of the current societal challenges. Concerning the current EU Framework Programme for Research and Innovation, Horizon2020, in 2016 the EC launched an online consultation on mathematics in order to nourish the next Horizon2020 Work Programme (2018-20) with innovative mathematical content.

As a consequence of this importance, the diverse calls in the future Horizon2020 Work Programme demand the inclusion of mathematical partners. This fact is not mandatory, but the consortia with this component are more valuable. For example, the report of the online consultation includes the following paragraph:

"*Whereas mathematics is not a prerequisite in Horizon2020, the various areas covered by the programme rely on its development and its use; HPC, Big data, Quantum computing just to name a few. Without mathematical tools, future research will be severely hampered."*

This trend is being reflected in national and regional calls. Therefore, the Applied Mathematics is in a really key position. The traditional interaction with other important areas, such as Engineering, Physics, Chemistry, Computer Science, etc., has been fundamental for the consideration of the mathematics nowadays. For example, the use of mathematical tools in the well-known and actual Big Data problem, which has all kind of companies - small, medium and large - already plays and will continue playing a fundamental role in the resolution of this big problem of the XXI century. This is determinant in (ciber)security, recommendation in social networks, in productive processes, etc.

Thus, in this great framework, it is a pleasure to welcome you to the **17th International Conference on Computational and Mathematical Methods in Science and Engineering** (CMMSE 2017), which will be held at Rota, Cádiz (Spain), July 4^{th}-8^{th}, 2017. After seventeen editions, this is a consolidate international conference, which provide a comfortable environment in which researchers from different disciplines interact and create synergies focus on the achievement of new challenges and based on really breakthrough ideas. The current EU framework brings important funding opportunities for European partners, but also for important international research groups outside of Europe, in which the ideas developed during this conference can be funded.

The proceedings of CMMSE 2017, which contains the extended abstracts and papers accepted to the conference, is a perfect seed for this collaboration. In this edition, it has six volumes, the first five correspond to the articles typeset in LaTeX and the sixth to articles typeset in Word. The invited speeches given by renowned researchers will also be a starting point for the establishment of new challenges.

CMMSE 2017 covers a wide range of disciplines which have been divided into forty-five different symposia. High quality papers have been collected in each of these symposia. The first symposium entitled *High-Performance Computing (HCP)* focuses on computational problems appearing in many scientific and engineering applications. The second one, *mathematically modeling the future Internet and developing future Internet security technology*, is a self-explanatory session. The symposium *Computational finance*

deals with recent advances on modeling and computation in quantitative finance. *New educational methodologies supported by new technologies* is a session to discuss the use of new technologies and the possibility of developing new resources to improve the teaching and learning activities. In what regards *Mathematical models and information-intelligent systems on transport* session, it is dedicated to flow-modeling of particles framework whose applications are closely related to traffic flows, pedestrian flows, ecology, etc. *Computational Methods for Linear and Nonlinear Optimization* addresses some recent techniques and efficient methods to solve different type of optimization problems. New trends in the field of iterative methods for nonlinear problems are presented in *Numerical Methods for Solving Nonlinear Problems.* The 8th symposium entitled *Bio-mathematics* presents theoretical and practical applications associated with population dynamics, eco-epidemiology, epidemiology of infectious diseases and molecular and antigenic evolution. Modeling interesting problems arisen in Computer Science, considering algebraic and computational (fuzzy) techniques, is the main goal of *Mathematical Models for Computer Science*. The aim of the symposium *Mathematics meets Chemistry-Theorical Models at the Nanoscale* is to obtain a consistent description of the transition from clusters to the solid state, which is a major challenge in computational chemistry and physics.

The session *Hypercomplex methods in mathematics and Applied Sciences* includes new methods for modeling and solving of boundary value problems in fluid mechanics, elasticity theory and other related fields. Fixed-point theory has an enormous applicability in mathematics, engineering, chemistry, biology, economics, computer science, which justifies the great interest in *fixed point theory in various abstract spaces and related applications*. The 13th symposium *Industrial Mathematics* presents mathematical and computational researches related to corporate or government applications and problems arising from different economic sectors. C*omputational methods for fluid flow* are considered in this conference in order to discuss recent problems and advances in this area. A wide variety of topics related to pattern formation in animate and inanimate, patterns stationary, travelling or disordered in both space and time, is included in *Pattern formation in spatially extended systems.* Different research fields of fractal and fractional dynamics in theoretical and practical studies of Mathematics, Physics, and Engineering will be addressed in *Fractional calculus and applications.* The aim of *New Trends on Boundary Value Problems* is to present and discuss new trends in related fields such as variational methods and topological methods. *Estimation and control for stochastic systems: theory and applications* is a forum to discuss the latest approaches on this research topic from both theoretical and application perspectives. With respect to *Numerical Methods in Mathematics and Mechanics*, it is a session focused on the study of numerical methods and software capabilities related to multi-body system dynamics and equations of motion, structural and nonlinear control and modern vibrational methods. Machine Learning techniques are increasingly being used to tackle problems in bioinformatics and computational biology, hence the importance of the session *Mechanical Learning Techniques in Bioinformatics.*

The 21th symposium will put particular emphasis on algorithmic issues in the treatment of curves and surfaces from the symbolic and also from the numeric point of view: *Numerical Problems on Algebraic Curves and Surfaces.* The session *New advances in statistical methodologies* is intended to show theoretical, applied or computational techniques, which separately or in combination, have provide interesting achievements to a broad spectrum of statistical methods. Taking into account that *Non Newtonian Calculus, Theory and Applications* is a very novel research topic, the goal of this session is to gather the scientific community working on this framework in order to discuss and exchange

ideas. Different techniques to determine effective properties in elasticity and conductivity of heterogeneous materials such as homogenization and micromechanic are given in the symposium: *Homogenization of Partial Differential Equations. Micromechanics. Elasticity and conductivity of composite materials.* The stability, growth and prosperity of an economy as well as the wellbeing of society is affected by the increasing frequency and severity of natural and human-caused disasters. This fact justifies the great significance of the symposium entitled *Mathematical modeling of Man-made Natural disasters: forest fire & environmental pollution.* The session, *Recent trends in the analysis and computations of nonlinear partial differential equations and systems,* will pay special attention the investigation of analytical features of the solutions of nonlinear problems and the analysis of approximation techniques to simulate them. *Control and estimation for Cyberphysical and Distributed parameter systems* aims at processing problems corresponding to this topic in a unified manner and to propose generic and widely applicable solutions for robotics, transportation and socioeconomic systems, etc.

Current theoretical and computational advances concerning the numerical treatment of rank structured matrices and their applications will be introduced in *Rank structured matrices: recent developments and new perspectives.* Novel trends in the field of computational intelligence methods such as genetic algorithms, evolutionary strategies and ant colony optimization, among others, will be analysed in the session *Computational intelligence methods for solving complex optimization problems.* An interesting discussion about the latest findings in nonlinear wave theory will be carried out during the symposium *Dynamics and stability of nonlinear wave patterns.* New research developments to push flow control understanding and applications, as well as the study different devices capable of interacting with the fluid boundary layer, will be presented in the conference session entitled *Flow Control, Active/Passive*. The main purpose of the symposium *Numerical Linear Algebra Methods for Large Scale Scientific Computing* is to collect methods for solving linear algebra problems derived from the discretization of partial differential equations and optimization problems. *Mathematics, Science and Engineering Education* analyzes the use of new ICT tools in teaching methods corresponding to different educational levels. *Recent trends in the development of meshless or meshfree methods and applications* is a session which offers the opportunity to discuss current progresses in this area. The 35th symposium entitled *Contemporary Approaches in Multivariate Representations and Approximation Methods for Discrete and Continuous Mathematical Objects* is designed to focus on mostly multivariate problems encountered in science and engineering.

Lie Symmetry Analysis and Conservation Laws for Nonlinear Differential Equations and Applications covers the modelization of real world problems by means of nonlinear differential equations. *Statistical Modeling and Applications* are considered in this conference in order to show the new theoretical steps on this research line and on its applications. All topics related to orthogonal polynomials and their use in solving real-life problems will be covered in *Orthogonal Polynomials and Applications*. *Complex Networks* covers general phenomena which can be modelled as networks where a number of individuals interact over a complex networked structure. *Data Analysis and Modeling Science and Engineering: Numerical Methods and Computational Approaches* aims to discussing recent trends in data analysis, forecast and modeling focusing on the numerical aspects and computational approaches for the analysis and classification of large data sets. *Multiscale modeling of solid/fluid systems with focus on structures, thermodynamic properties and industrial applications* presents new results and developments within this fascinating area. The session *Theoretical and computational of the free boundary problems* considers results obtained from the both theoretical and computational view of a free

boundary problems which include the stationary and evolutionary variational, quasi-variational inequalities and Hamilton-Jacobi-Bellman. The 43rd symposium *Processing, modeling, and describing time series* offers an international forum for the presentation of original results in this field. *Data mining and engineering* aims at joining the contemporary innovations about data mining and the related area of data engineering. Finally, the last symposium, *Metaheuristics in science and engineering* deals with contemporary approaches in the context of metaheuristics focusing on applications in real problems or simulated scenarios.

We would like to finish this preface expressing our deepest gratitude to the plenary speakers for their outstanding contributions to research and leadership in their respective fields. We are also most grateful to the special session organizers and scientific committee members. Working with an efficient and capable team has been fundamental in the execution of CMMSE 2017. Finally, it is important to mention that this conference would not have been possible without the interest and enthusiasm of all participants. Therefore, we can only conclude this preface giving them thanks and a cordial welcome. We hope you enjoy the conference.

Linear-time solvers for linear systems with sparse and structured matrices of interest in applications.

J. Abderramán Marrero[1]

[1] *Department of Mathematics Applied to Information Technology, School of Telecommunication Engineering, UPM - Technical University of Madrid (Spain)*

emails: jc.abderraman@upm.es

Abstract

Some recent results on linear-time solvers, e.g. based on incomplete or full Givens reduction, for determined linear systems with matrix coefficient having a particular sparse or low-rank structure are pointed out. These results have motivated its possible application to matrices of related interest.

Key words: Linear-time solvers, large-order linear systems, Givens reduction, low-rank structured matrices.

1 Extended abstract

Fast algorithms have been proposed recently for both linear systems and inversion methods, where particular kinds of large-order matrices arising in applications are involved. More precisely, for general k-tridiagonal [1, 2], bordered tridiagonal [3], bordered k-tridiagonal [4], opposite-bordered tridiagonal [5], and comrade matrices [6], where different approaches were applied.

A sequential numerical algorithm based on tridiagonal solvers to manage comrade linear systems was introduced in [6]. In [1], a direct algorithm was design for inverting k-tridiagonal matrices based on symbolic computation. This symbolic approach is based on the following known fact. Let $A(\lambda)$ be the matrix obtained from A by changing the entry $a_{i,j}$ by $a_{i,j}(\lambda)$, such that, when $\lambda \to 0$, $a_{i,j}(\lambda) \to a_{i,j}$. Thus $\lim_{\lambda\to 0} A(\lambda) = A$, component-wise. Therefore, if A is nonsingular, there exists δ, with $0 < |\lambda| < \delta$, satisfying $lim_{\lambda\to 0}A^{-1}(\lambda) = A^{-1}$, component-wise. Also, such symbolic strategy has been applied for inverting other related matrices and to solve linear systems, e.g. the opposite-bordered tridiagonal ones [5].

 ISBN: 978-84-617-8694-7

The solution of the determined linear system, formulated by using the vector linear equation

$$Ax = b; \quad \text{with } A \in \mathcal{GL}_n(\mathbb{R}), \text{ and } \quad x, b \in \mathbb{R}^n, \tag{1}$$

with $\mathcal{GL}_n(\mathbb{R})$ the general linear group of the $(n \times n)$ real matrices and the matrix A nonsingular bordered tridiagonal, shortly GNBT, was computed in [3] using a sequential numerical solver. It was based on an incomplete or full Givens reduction of the GNBT matrix A, depending on whether the tridiagonal submatrix associated with A is nonsingular or singular, respectively. Therefore, the GNBT linear system (1) was transformed in an equivalent, but simpler, nonsingular bordered triangular system and the vector solution x was computed using the useful Sherman-Morrison formula or an adapted back substitution. Using a similar procedure, this numerical procedure was also extended on the bordered k-tridiagonal, shortly GNBkT, matrices in [4].

As a result, when the tridiagonal (k-tridiagonal) matrix, associated with the GNBT (GNBkT) matrix A, is singular, then a linear-time solver for the corresponding linear system was obtained independently of the LU factorizations of such matrices. Nevertheless, as was advised in [3], when such associated matrix is singular, the Givens reduction of A can give a dense triangular matrix, or having rows with full nonzero entries. It can generate numerical instability. Infrequently, the Sherman-Morrison formula can generate also instabilities. To avoid these drawbacks, specialized subroutines should be used, e.g. the basic linear algebra subroutines, BLAS.

The (unique) QR factorization of a nonsingular k-tridiagonal matrix [1, 2], a particular type of GNBkT matrix, is sparse, independently of the existence of its LU factorization. Therefore, the determined linear systems (1) with such matrix coefficient can be solved in linear time using Givens reduction of the k-tridiagonal matrix coefficient and an adapted back substitution [2].

Since the speedup and reliability of the numerical solvers from [2], [3], and [4], when the correspondent matrices, or associated submatrices, have a sparse and unique QR factorization, we ask about their applications on vector, or matrix, equations involving opposite-bordered tridiagonal [5], comrade [6], and other sparse and low-rank structured matrix coefficients arising in applications. Some preliminary results on opposite-bordered tridiagonal and also on comrade linear systems have given support for a positive answer.

The search of necessary as well as sufficient conditions to obtain linear-time solvers for these classes of linear systems, related with the structure of the matrix coefficients, or that of some of its associated submatrices, and its correspondent QR (or LU) factorization, can be a challenging line.

This numerical approach should be extended to find fast algorithms for linear systems with dense but low-rank structured matrices, e.g. on particular subclasses of generalized Hessenberg matrices [7].

OpenCL Code Generation for Mobile Devices

Sergio Afonso[1], Alejandro Acosta[1] and Francisco Almeida[1]

[1] *Department of Computer Engineering, Universidad de La Laguna, Spain*

emails: safonsof@ull.es, aacostad@ull.es, falmeida@ull.es

Abstract

The efficient exploitation of the computational capabilities of mobile devices is still a challenge. The heterogeneity of Systems on Chip (SoC) requires specific knowledge of their hardware in order to harness their full potential. OpenCL is a standard for cross-platform access to accelerator devices. By following an annotation-based approach we can automatically translate a program written in a high-level language into OpenCL. This helps to reduce the cost of development of OpenCL code for mobile devices. With our approach, the programmer can select from different target languages the one that is better suited to implement each section of an application. Our automatically-generated OpenCL code can outperform Renderscript in many cases.

Key words: parallelizing compiler, source-to-source translation, annotation based, opencl, android, heterogeneous architecture

1 Introduction

Modern SoCs now integrate technologies previously only available in servers and desktop computers, such as multicore CPUs, GPUs and DSPs, in a reduced form factor and under higher energy consumption constraints. The architecture of these devices is composed of a set of heterogeneous processors and a single memory that is shared between them. Some of the most relevant SoCs in the market today are Samsung Exynos, Qualcomm Snapdragon, Apple Ax and Nvidia Tegra, which are all based on ARM technology.

Due to these features, a software developer looking for the fastest or most energy-efficient way of running an algorithm on mobile devices, usually needs to develop parallel code to run on the best fitting processor available. Even though companies behind the most widely used mobile operating systems, such as Android or iOS, provide development frameworks that ease the creation of applications for their platforms, their support for high

 ISBN: 978-84-617-8694-7

performance computing is still limited. They provide programming languages, like Renderscript and Metal, that provide a higher-level view on the hardware and a way to accelerate parallel algorithms. However, learning these languages and developing applications with them require a non-trivial effort from programmers.

Lower-level computing APIs, such as CUDA [4] or OpenCL [5], can provide the best performance because of the finer control they provide, but that requires taking the specific hardware architecture of each device into consideration and spending a much larger amount of time fine-tuning the code. In the context of mobile architectures, the existing heterogeneity makes this prohibitely expensive. The key to achieving high performance at a low development cost has to come from powerful abstractions that let an automated system make use of these lower-level APIs in a cross-platform and efficient way.

Paralldroid [1, 2, 3] is a development framework that allows the automatic generation of Native C and Renderscript code for Android devices. This system defines a reduced set of annotations that, applied to the main components of a Java class, indicate the required memory movements and parallel methods of that class. It always creates a Java class with the API of the original class and some additions, enabling a seamless integration with the rest of the application. It is an evolution over other annotation-based approaches such as OpenACC or OpenMP, because it defines higher level anotations, and it is better suited to the object-oriented programming paradigm.

The main contributions of this paper are:

- The OpenCL programming model, whose importance is well known in desktop systems, is introduced to mobile devices by allowing transparent execution from Android Java applications.
- OpenCL support opens the possibility to develop accelerated Java applications for platforms other than Android using Paralldroid. The only requirements for these platforms are Java and OpenCL support.
- Our new approach lets high-level Java developers take advantage of more efficient GPU executions without modifying the annotated Java code. Performance improvements come from the use of a lower-level library for heterogeneous computing and, therefore, an increase in the code generation process complexity.

2 Methodology

In Android, applications are written mainly in Java, but it is also possible to use the Java Native Interface (JNI) to implement methods in C/C++, and Renderscript to accelerate parallel algorithms.

Paralldroid is embedded in the compilation process of OpenJDK, and is able to process the Abstract Syntax Tree (AST) of the Java code detecting a custom set of annotations,

 ISBN: 978-84-617-8694-7

summarized in Table 1. Depending on the target language selected for each class, a set of translator classes will be created and used to process them. These translators turn the original code and annotations into another AST that will be converted into code.

Annotation	Applied to	Parameters	Scope
@Target	Classes	value	—
@Map	Fields, method parameters	value	@Target
@Declare	Fields, methods	size	@Target
@Parallel	Methods	—	@Target
@Input	Method parameters	—	@Parallel
@Output	Method parameters	—	@Parallel
@NumThreads	Methods, method parameters	field	@Parallel
@Index	Method parameters	—	@Parallel

Table 1: Paralldroid annotations

For OpenCL support we implemented three translators. The Java translator generates a modified Java code that interfaces with the Java application, keeping the same interface as the original class, while forwarding the code execution to a native context. The native translator generates C code that handles communications with the Java context through JNI and with the OpenCL context, acting as the OpenCL host code that sets up memory buffers and enqueues commands. The OpenCL C translator generates the parallel kernels and support functions that get embedded as a string constant into the native source code and compiled at runtime. A native support library implements error handling routines and manages shared OpenCL resources, such as the context, platform, command queue, etc.

This way, developers do not have to modify the rest of the application when testing different backends, and they can improve the generated code by hand if necessary. This greatly simplifies the process of accelerating parallel algorithms in Android.

3 Computational results

In Figure 1 we show the results we obtained by running a set of image processing algorithms implemented in Java and Paralldroid-generated Renderscript and OpenCL, in the Sony Xperia Z (labelled SXZ) and Odroid XU3 (labelled XU3) devices. In the XU3, we found that OpenCL execution was slower than Renderscript due to our limitation to use only one GPU, whereas in this device the GPU is partitioned and reported as two separate GPUs by the OpenCL driver. Furthermore, all Renderscript executions are performed by the CPU, which turned out to be faster than the GPU in this platform. However, when Renderscript and OpenCL run on the same hardware, we find that our OpenCL code runs faster in most cases.

Energetic BEM for soft and hard scattering of 2D damped waves by open arcs

Alessandra Aimi[1], Mauro Diligenti[1] and Chiara Guardasoni[1]

[1] *Dept. of Mathematical, Physical and Computer Sciences, University of Parma, Italy*

emails: alessandra.aimi@unipr.it, mauro.diligenti@unipr.it,
chiara.guardasoni@unipr.it

Abstract

The analysis of damping phenomena, that occur in many physics and engineering problems, reformulated in terms of boundary integral equations and solved via the boundary element method is a novelty. In this context, we develop here an extension of the so-called energetic boundary element method, recently proposed in literature, for soft and hard scattering of 2D damped waves by open arcs, directly in space-time domain. The presented numerical results confirm accuracy and stability of the proposed technique, already proved for the numerical treatment of undamped wave propagation problems in several dimensions and for the 1D damped case.

Key words: Damped wave equation, scattering, energy, boundary element method
MSC 2000: 65M38

1 Introduction

Wave propagation and scattering are two of the most studied physics phenomena that can be well described by mathematical models, leading to the problem of solving linear hyperbolic partial differential equations (PDEs) in two or three dimensional space [1, 2]. These problems are normally considered in an unbounded homogeneous domain and a method to tackle them can be the reformulation of the PDE as a boundary integral equation (BIE) on the usually bounded boundary of the domain, which then is numerically solved using the boundary element method (BEM) [3].
In the context of wave propagation, while the elastic forces tends to maintain the oscillatory motion, the transient effect dies out because of energy dissipations. The process of energy

 ISBN: 978-84-617-8694-7

dissipation is generally referred to as damping. The analysis of damping phenomena that occur, for example, in fluid dynamics, in kinetic theory and in semiconductors, is of particular interest: the dissipation is generated by the interaction between the waves and the propagation medium and can be also closely related to the dispersion, as in the interactions between water streams and surface waves or in ferromagnetic materials. On the other side, in mechanical systems, in general, damping has the effect of reducing the amplitude of vibration and, therefore, it is desirable to have some amount of damping in order to achieve stability in a faster way. Hence, damping is whether an unavoidable presence in physical reality or a desired characteristic in design.

The use of advanced numerical techniques to solve the related PDEs, such as finite element (FEM) and the finite difference (FDM) methods is well established and it is standard in this framework, even if the research of a numerical method that could reproduce the expected damping decay is an actual argument in literature [4, 5, 6]. On the other hand, in the context of BEMs, the analysis of dissipation through damped wave equation rewritten as a BIE is a relatively new topic, because it has been scarcely investigated until now. Since wave propagation phenomena are often observed in infinite media (domain) where Sommerfeld radiation condition holds, a suitable numerical method has to ensure that this condition is not violated. For example, FEMs need the application of special techniques to fulfill this condition that, on the contrary, is implicitly fulfilled by BEM.

In principle, both frequency-domain and time-domain BEM can be used for hyperbolic initial-boundary value problems [7, 8, 9, 10]. Space-time BEM has the advantage that it directly yields the unknown time-dependent quantities. In this last approach, the construction of the BIEs, via representation formula in terms of single and double layer potentials, uses the fundamental solution of the hyperbolic partial differential equation and jump relations [11, 12]. The mathematical background of time-dependent boundary integral equations is summarized by M. Costabel in [13].

For the numerical solution of the damped wave equation in 1D unbounded media, we have already considered in [14, 15, 16] the extension of the so-called energetic BEM, introduced for the undamped wave equation in several space dimensions [17, 18, 19]. Energetic BEM is based on a weak formulation directly expressed in the space-time domain, thus avoiding the use of the Laplace transform and of its inversion suggested in [11].

The analysis carried out for 1D damped wave propagation problems allowed to fully understand the approximation technique for what concerns marching on time, avoiding space integration with BEM singular kernels and it was considered as a touchstone for the extension to higher space dimensions, which is done here for the 2D case. In particular, we will treat soft and hard scattering of damped waves by open arcs. Also in this context, the energetic approach gives consistent approximations and accurate numerical solutions.

The paper is structured as follows: at first, we present the differential model problem outside an open arc in the plane, equipped by Dirichlet boundary conditions (soft scattering),

 ISBN: 978-84-617-8694-7

and we introduce the corresponding boundary integral weak formulation. Then, we illustrate the consequent energetic BEM discretization. Further, to complete the presentation, we describe an analogous model problem equipped by Neumann boundary condition (hard scattering), always discretized by energetic BEM. At last, some numerical benchmarks are introduced and discussed, showing, from a numerical point of view, stability and accuracy of the obtained numerical solutions.

2 Model problem for soft scattering and its weak boundary integral formulation

We consider a Dirichlet problem in a bounded time interval $[0,T]$ for the damped wave equation exterior to an obstacle, given by an open arc $\Gamma \subset \mathbb{R}^2$:

$$\left[\Delta u - \frac{1}{c^2}\, u_{tt} - \frac{2D}{c^2} u_t - \frac{P}{c^2} u\right](\mathbf{x},t) = 0, \qquad \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma,\ t \in (0,T] \tag{1}$$

$$u(\mathbf{x},0) = u_t(\mathbf{x},0) = 0, \qquad \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma, \tag{2}$$

$$u(\mathbf{x},t) = \bar{u}(\mathbf{x},t), \qquad \mathbf{x} \in \Gamma,\ t \in (0,T]\,, \tag{3}$$

where c is the propagation velocity of a perturbation inside the domain, D and P are the viscous and material damping coefficients, respectively. Equation (1) appears in different contexts, from electric transmission to sound propagation, from primary or secondary seismic wave propagation in presence of intrinsic attenuation to quantum field theory.
When $D = P = 0$ the given PDE collapses to the classic wave equation. The boundary datum $\bar{u}(\mathbf{x},t)$ represents the value of the excitation field over Γ.
Since we want to discretize the above problem using BEM, we have to rewrite it in a boundary integral form. This can be done using classical arguments and the knowledge of the fundamental solution of the 2D damped wave operator. Hence, we start writing the single-layer representation of the solution of (1)-(3):

$$u(\mathbf{x},t) = \int_\Gamma \int_0^t G(\mathbf{x}-\boldsymbol{\xi}, t-\tau)\phi(\boldsymbol{\xi},\tau)\, d\tau\, d\gamma_{\boldsymbol{\xi}}, \qquad \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma, t \in (0,T], \tag{4}$$

where the unknown density $\phi = \left[\dfrac{\partial u}{\partial \mathbf{n}}\right]_\Gamma$ represents the time history of the jump of the normal derivative of u along Γ and

$$G(\mathbf{x},t) = \begin{cases} \frac{c}{2\pi}\, e^{-Dt}\, \dfrac{\cos\left(\frac{\sqrt{P-D^2}}{c}\sqrt{c^2t^2-\|\mathbf{x}\|^2}\right)}{\sqrt{c^2t^2-\|\mathbf{x}\|^2}}\, H[c\,t-\|\mathbf{x}\|]\,, & P \geq D^2 \\ \\ \frac{c}{2\pi}\, e^{-Dt}\, \dfrac{\cosh\left(\frac{\sqrt{D^2-P}}{c}\sqrt{c^2t^2-\|\mathbf{x}\|^2}\right)}{\sqrt{c^2t^2-\|\mathbf{x}\|^2}}\, H[c\,t-\|\mathbf{x}\|]\,, & P \leq D^2 \end{cases} \tag{5}$$

 ISBN: 978-84-617-8694-7

is the forward fundamental solution of the 2D damped wave operator, with $H[\cdot]$ the Heaviside distribution. Definition (5) switches from $\cos(\cdot)$ to $\cosh(\cdot)$ depending on the reciprocal magnitude of P and D^2: when $P > D^2$ we are in the so-called *underdamping* configuration, when $P < D^2$ we are in *overdamping* configuration, while the separation state $P = D^2$, referred to the vanishing of both $\cos(\cdot)$ and $\cosh(\cdot)$ arguments, is called *critical damping*. Note that in the limit for D, P tending to 0, $G(\mathbf{x}, t)$ tends to the fundamental solution of the 2D undamped wave operator.
Now, it is clear that if we want to recover the solution of the differential problem at any point outside the obstacle and at any time instant, we have to proceed with a post-processing phase provided that we know the density function $\phi(\mathbf{x}, t)$. Hence, since the extension of u in (4) for $\mathbf{x}$ tending to Γ is continuous, the unknown density ϕ can be determined via the assigned Dirichlet boundary condition (3). This results in the space-time BIE

$$\int_\Gamma \int_0^t G(\mathbf{x} - \boldsymbol{\xi}, t - \tau)\phi(\boldsymbol{\xi}, \tau)\, d\tau\, d\gamma_{\boldsymbol{\xi}} = \bar{u}(\mathbf{x}, t), \qquad \mathbf{x} \in \Gamma, t \in [0, T], \tag{6}$$

which can be written with the compact notation

$$V\phi = \bar{u}. \tag{7}$$

The energetic weak formulation of problem (7) is defined similarly as in [18] and it can be deduced observing that, multiplying the PDE (1) by u_t, integrating over $[0, T] \times (\mathbb{R}^2 \setminus \Gamma)$ and using integration by parts in space, one obtains that the energy $\mathcal{E}(u, T)$ of the solution u at the final time of analysis T, defined by

$$\frac{1}{2}\int_{\mathbb{R}^2\setminus\Gamma} \Big[\|\nabla_{\mathbf{x}} u(\mathbf{x}, T)\|^2 + \frac{1}{c^2}u_t^2(\mathbf{x}, T) + \frac{P}{c^2}u^2(\mathbf{x}, T) + \frac{4D}{c^2}\int_0^T u_t^2(\mathbf{x}, t)dt\Big] d\gamma_{\mathbf{x}} \tag{8}$$

can be rewritten as

$$\mathcal{E}(u, T) = \int_\Gamma \int_0^T u_t(\mathbf{x}, t)\left[\frac{\partial u}{\partial \mathbf{n}}\right]_\Gamma (\mathbf{x}, t)\, dt\, d\gamma_{\mathbf{x}}\,. \tag{9}$$

Hence, remembering the nature of our BIE which is expressing the time history of u over Γ, we can derive it w.r.t. time and write down the energetic weak problem associated to (7) as:
find $\phi \in L^2([0, T]; H^{-1/2}(\Gamma))$ *such that*

$$\int_\Gamma \int_0^T (V\phi)_t(\mathbf{x}, t)\psi(\mathbf{x}, t)\, dt\, d\gamma_{\mathbf{x}} = \int_\Gamma \int_0^T \bar{u}_t(\mathbf{x}, t)\psi(\mathbf{x}, t)\, dt\, d\gamma_{\mathbf{x}}\,, \tag{10}$$

where ψ is a suitable test function, belonging to the same functional space of ϕ.
With an integration in the sense of distributions, we can equivalently write

$$\int_\Gamma \int_0^T (V\phi)(\mathbf{x}, t)\psi_t(\mathbf{x}, t)\, dt\, d\gamma_{\mathbf{x}} = \int_\Gamma \int_0^T \bar{u}(\mathbf{x}, t)\psi_t(\mathbf{x}, t)\, dt\, d\gamma_{\mathbf{x}}\,. \tag{11}$$

 ISBN: 978-84-617-8694-7

The theoretical analysis of the quadratic form coming from the left-hand side of (10) was carried out for $P = D = 0$ in [18] where, under suitable hypothesis, coercivity was proved with some technicalities. This allowed us to deduce stability and convergence of the related Galerkin approximate solution, which here, for the case of non-trivial damping coefficients, will be verified from a numerical point of view.

3 Energetic BEM discretization

We consider on the obstacle Γ, a boundary mesh constituted by $M_{\Delta x}$ straight elements $\{e_1, \cdots, e_{M_{\Delta x}}\}$, with $length(e_i) \leq \Delta x$, $e_i \cap e_j = \emptyset$ if $i \neq j$ and such that $\bigcup_{i=1}^{M_{\Delta x}} \overline{e}_i$ coincides with $\overline{\Gamma}$ if the obstacle is (piece-wise) linear, or is a suitable approximation of $\overline{\Gamma}$, otherwise. The functional background compels one to choose space shape functions belonging to $L^2(\Gamma)$, although higher degree shape functions can be used. Hence we use standard piece-wise constant polynomial boundary element functions $w_j(\mathbf{x})$, $j = 1, \cdots, M_{\Delta x}$, suitably defined in relation to the introduced mesh over Γ.
For time discretization we consider a uniform decomposition of the time interval $[0, T]$ with time step $\Delta t = T/N_{\Delta t}\,, N_{\Delta t} \in \mathbb{N}^+$, generated by the $N_{\Delta t} + 1$ instants

$$t_k = k\,\Delta t, \quad k = 0, \cdots, N_{\Delta t}\,, \tag{12}$$

and we choose piece-wise constant time shape functions. Note that, for this particular choice, our shape functions, denoted with $v_k(t)$, $k = 0, \cdots, N_{\Delta t} - 1$, will be defined as

$$v_k(t) = H[t - t_k] - H[t - t_{k+1}]\,. \tag{13}$$

Hence, the approximate solution of the problem at hand will be expressed as

$$\phi(\mathbf{x}, t) \simeq \sum_{k=0}^{N_{\Delta t}-1} \sum_{j=1}^{M_{\Delta x}} \alpha_j^{(k)}\, w_j(\mathbf{x})\, v_k(t). \tag{14}$$

The Galerkin BEM discretization coming from energetic weak formulation (11) produces the linear system

$$A\,\alpha = b\,, \tag{15}$$

of order $M_{\Delta x} \cdot N_{\Delta t}$, where matrix A has a block lower triangular Toeplitz structure. Each block has dimension $M_{\Delta\, x}$. If we indicate with $A^{(\ell)}$ the block obtained when $t_h - t_k = \ell\,\Delta t$, $\ell = 0, \ldots, N_{\Delta t} - 1$, the linear system can be written as

$$\begin{pmatrix} A^{(0)} & 0 & 0 & \cdots & 0 \\ A^{(1)} & A^{(0)} & 0 & \cdots & 0 \\ A^{(2)} & A^{(1)} & A^{(0)} & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & 0 \\ A^{(N_{\Delta t}-1)} & A^{(N_{\Delta t}-2)} & \cdots & A^{(1)} & A^{(0)} \end{pmatrix} \begin{pmatrix} \alpha^{(0)} \\ \alpha^{(1)} \\ \alpha^{(2)} \\ \vdots \\ \alpha^{(N_{\Delta t}-1)} \end{pmatrix} = \begin{pmatrix} b^{(0)} \\ b^{(1)} \\ b^{(2)} \\ \vdots \\ b^{(N_{\Delta t}-1)} \end{pmatrix} \tag{16}$$

 ISBN: 978-84-617-8694-7

where

$$\alpha^{(\ell)} = \left(\alpha_j^{(\ell)}\right) \quad \text{and} \quad b^{(\ell)} = \left(b_j^{(\ell)}\right), \quad j = 1, \ldots, M_{\Delta x}\,. \tag{17}$$

The solution of (16) is obtained with a block forward substitution, i.e. at every time instant $t_\ell = \ell\,\Delta t$, $\ell = 0, \cdots, N_{\Delta t} - 1$, we solve a reduced linear system of the type

$$A^{(0)}\alpha^{(\ell)} = b^{(\ell)} - (A^{(1)}\alpha^{(\ell-1)} + \cdots + A^{(\ell)}\alpha^{(0)}). \tag{18}$$

Procedure (18) is a time-marching technique, where the only matrix to be inverted is the symmetric positive definite diagonal block $A^{(0)}$, while all the other blocks are used to update at every time step the right-hand side. Owing to this procedure we can construct and store only the blocks $A^{(0)}, \cdots, A^{(N_{\Delta t}-1)}$ with a considerable reduction of computational cost and memory requirement.
Further, matrix elements are generated by suitable quadrature schemes, already used in [18], taking into account kernel singularity.

4 The case of hard scattering

Here, the scattered wave $u(\mathbf{x}, t)$ satisfies problem (1)-(2), equipped now by Neumann boundary conditions:

$$q(\mathbf{x}, t) := \frac{\partial u}{\partial \mathbf{n}}(\mathbf{x}, t) = \bar{q}(\mathbf{x}, t), \qquad \mathbf{x} \in \Gamma,\ t \in (0, T]\,, \tag{19}$$

where the datum $\bar{q}$ represents the opposite of the normal derivative of the incident wave along Γ, i.e. $\bar{q} = -\frac{\partial u^I}{\partial \mathbf{n}}$.
In order to obtain a boundary integral reformulation of the problem at hand, we consider the double-layer representation of the solution :

$$u(\mathbf{x}, t) = \int_\Gamma \int_0^t \frac{\partial G}{\partial \mathbf{n}_{\boldsymbol{\xi}}}(\mathbf{x} - \boldsymbol{\xi}, t - \tau)\varphi(\boldsymbol{\xi}, \tau)\, d\tau\, d\gamma_{\boldsymbol{\xi}}, \qquad \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma, t \in (0, T], \tag{20}$$

where the unknown density $\varphi = [u]_\Gamma$ represents the time history of the jump of u along Γ and G is given in (5).
Again, it is clear that if we want to recover the solution of the differential problem at any point outside the obstacle and at any time instant, we have to proceed with a post-processing phase provided that we know the density function $\varphi(\mathbf{x}, t)$, which can be determined applying the normal derivative w.r.t. $\mathbf{x}$ to (20) and using the assigned Neumann boundary condition (19). This results in the hyper-singular space-time BIE

$$\int_\Gamma \int_0^t \frac{\partial^2 G}{\partial \mathbf{n}_{\mathbf{x}} \partial \mathbf{n}_{\boldsymbol{\xi}}}(\mathbf{x} - \boldsymbol{\xi}, t - \tau)\varphi(\boldsymbol{\xi}, \tau)\, d\tau\, d\gamma_{\boldsymbol{\xi}} = \bar{q}(\mathbf{x}, t), \qquad \mathbf{x} \in \Gamma, t \in [0, T], \tag{21}$$

 ISBN: 978-84-617-8694-7

which can be written with the compact notation

$$D\phi = \bar{q}. \tag{22}$$

For this model problem, the energy (8) can be rewritten as

$$\mathcal{E}(u,T) = \int_\Gamma \int_0^T [u_t]_\Gamma(\mathbf{x},t)\, \frac{\partial u}{\partial \mathbf{n}}(\mathbf{x},t)\, dt\, d\gamma_{\mathbf{x}}\,. \tag{23}$$

Hence, remembering the nature of our BIE which is expressing the time history of $\frac{\partial u}{\partial \mathbf{n}}$ over Γ, we can write down the related energetic weak problem as:
find $\varphi \in H^1([0,T]; H_0^{1/2}(\Gamma))$ *such that*

$$\int_\Gamma \int_0^T (D\varphi)(\mathbf{x},t)\psi_t(\mathbf{x},t)\, dt\, d\gamma_{\mathbf{x}} = \int_\Gamma \int_0^T \bar{q}(\mathbf{x},t)\psi_t(\mathbf{x},t)\, dt\, d\gamma_{\mathbf{x}}\,. \tag{24}$$

where ψ is a suitable test function, belonging to the same functional space of φ.

Also in this case, the theoretical analysis of the quadratic form coming from the left-hand side of (24) was carried out for $P = D = 0$ in [21] where, under suitable hypothesis, coercivity was proved with some technicalities. This allowed us to deduce stability and convergence of the related Galerkin approximate solution, which here, for the case of non-trivial damping coefficients, will be verified from a numerical point of view.

For what concerns the energetic BEM discretization, we consider on the obstacle Γ, the boundary mesh already described at the beginning of Section 3. The functional background compels one to choose space shape functions belonging to $H_0^1(\Gamma)$, although higher degree shape functions can be used. Hence we use standard piece-wise linear polynomial boundary element functions $w_j(\mathbf{x})$, $j = 1, \cdots, M_{\Delta x} - 1$, suitably defined in relation to the introduced mesh over Γ.
For time discretization we consider a uniform decomposition of the time interval $[0,T]$ with time step $\Delta t = T/N_{\Delta t}\,, N_{\Delta t} \in \mathbb{N}^+$, generated by the $N_{\Delta t} + 1$ instants (12) and we choose piece-wise linear time shape functions. Note that, for this particular choice, our shape functions, denoted with $v_k(t)$, $k = 0, \cdots, N_{\Delta t} - 1$, will be defined as

$$v_k(t) = R(t - t_k) - 2\, R(t - t_{k+1}) + R(t - t_{k+2})\,, \tag{25}$$

where $R(t - t_k) = \frac{t - t_k}{\Delta t}\, H[t - t_k]$ is the ramp function. Hence, the approximate solution of the problem at hand will be expressed as

$$\varphi(\mathbf{x},t) \simeq \sum_{k=0}^{N_{\Delta t}-1} \sum_{j=1}^{M_{\Delta x}-1} \alpha_j^{(k)}\, w_j(\mathbf{x})\, v_k(t). \tag{26}$$

The Galerkin BEM discretization coming from energetic weak formulation (24) produces a linear system analogous to (15) and with the same properties. Matrix elements are generated by suitable quadrature schemes, already used in [21], taking into account kernel singularity.

 ISBN: 978-84-617-8694-7

5 Numerical results

In the following, we will present and discuss numerical results obtained by energetic BEM applied to for 2D Dirichlet or Neumann damped wave propagation exterior problems.
At first, we consider the problem (1)-(2)-(3) with $\Gamma = \{\mathbf{x} = (x, 0) \,|\, x \in [-0.5, 0.5]\}$ and the Dirichlet boundary datum

$$\bar{u}(\mathbf{x}, t) = -H[t] f(t)\, x, \quad \text{where} \quad f(t) = \begin{cases} \sin^2(4\pi\, t)\,, & \text{if} \quad 0 \le t \le \dfrac{1}{8} \\ 1\,, & \text{if} \quad t \ge \dfrac{1}{8}\,, \end{cases} \tag{27}$$

taken from [18]. The velocity is fixed as $c = 1$.
We choose a uniform decomposition of Γ in 40 straight elements ($\Delta x = 0.025$) and we set $\Delta t = 0.025$. In Figure 1, we show the time history of the approximate solutions $\phi(x, t)$ of BIE (6), on the straight element e_{10} and on the time interval $[0, T] = [0, 2]$, for $P = 0$ varying $D = 0, 1, 2, 5, 10, 20$ (left) and for $D = 0$ varying $P = 0, 1, 10, 20$ (right). Note the effects of increasing viscous and material damping, which substantially change the aspect of the solution related to the classical wave equation, visible in the graphs for trivial parameters.

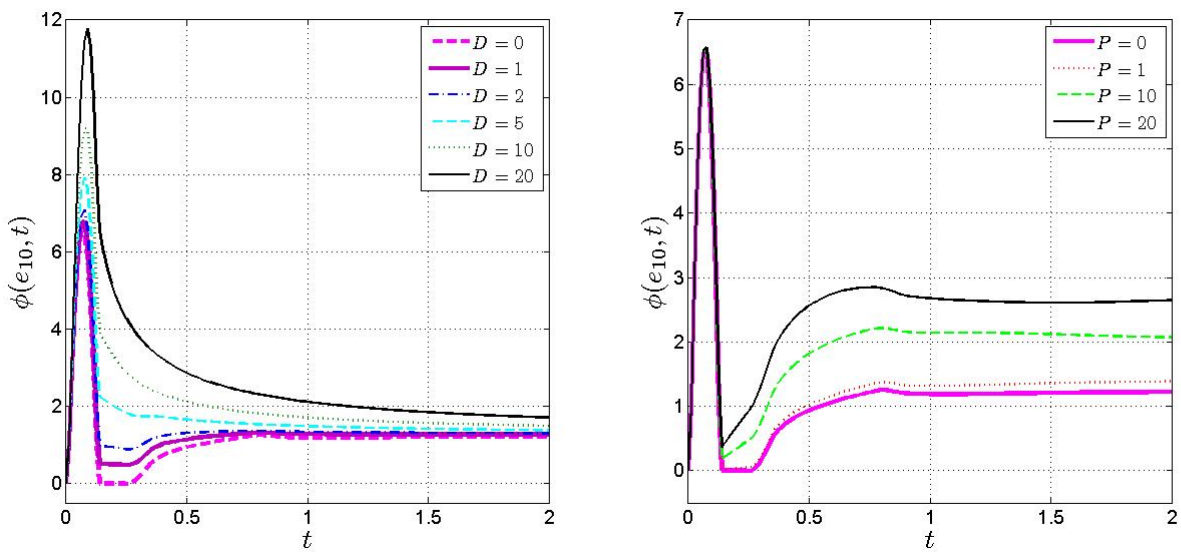

Figure 1: Time history of $\phi(x, t)$ on element e_{10}, for $P = 0$ (left) and $D = 0$ (right).

Since the Dirichlet datum becomes independent of time, it has been numerically checked on the time interval $[0, T] = [0, 60]$ that, for $P = 0$, the BIE transient solution $\phi(x, t)$ on

 ISBN: 978-84-617-8694-7

Γ tends to the stationary one $\phi_\infty(x)$, i.e. the solution of the BIE related to the following Dirichlet problem for the Laplace equation:

$$\begin{array}{ll} \Delta u_\infty(\mathbf{x}) = 0, & \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma \\ u_\infty(\mathbf{x}) = -x, & \mathbf{x} \in \Gamma \\ u_\infty(\mathbf{x}) = O(1), & \|\mathbf{x}\| \to \infty \end{array} \tag{28}$$

while, for $P > 0$, the transient solution $\phi(x,t)$ on Γ tends to the stationary one $\phi_{\infty,k}(x)$, i.e. the solutions of the BIE related to the following Dirichlet problem for the Helmholtz equation:

$$\begin{array}{ll} \Delta u_{\infty,k}(\mathbf{x}) + k^2 u_{\infty,k}(\mathbf{x}) = 0, & \mathbf{x} \in \mathbb{R}^2 \setminus \Gamma \\ u_{\infty,k}(\mathbf{x}) = -x, & \mathbf{x} \in \Gamma \\ u_{\infty,k}(\mathbf{x}) = O(\|\mathbf{x}\|^{-1}), & \|\mathbf{x}\| \to \infty \end{array} \tag{29}$$

with wave number $k = \sqrt{-P}/c^2$.

For the case of hard scattering, we consider the model problem (1)-(2)-(19) fixing $\Gamma = \{\mathbf{x} = (x,0) \,|\, x \in [0,1]\}$, $c = 1$, $[0,T] = [0,5]$ and Neumann boundary datum coming from an incident plane linear wave $u^I(\mathbf{x},t)$ propagating in direction $\mathbf{k} = (\cos\theta, \sin\theta)$, i.e.

$$\bar{q}(\mathbf{x},t) = -\frac{\partial}{\partial \mathbf{n}_\mathbf{x}} f(t - \mathbf{k}\cdot\mathbf{x})\Big|_\Gamma. \tag{30}$$

with $f(t) = 0.5\, t\, H[t]$. In this case, the Neumann datum (30) tends to the constant value $\bar{q}_\theta = 0.5 \sin\theta$, when t tends to infinity, so we expect that the approximate transient solution $\varphi(x,t)$ of BIE (21) on Γ will tend to the BIE solution of the corresponding Laplace ($P = 0$) or Helmholtz ($P > 0$) problems, equipped with the same Neumann datum $\bar{q}_\theta$.

For an incident angle of $\pi/3$, in Figure 2 on the left we present for $D = 1$ and $P = 0$, the transient solution $\varphi(x,T)$ on Γ at the final time instant of analysis, which can be compared with the corresponding static solution shown in the same Figure on the right. A similar comparison can be done looking at Figure 3, having fixed $\pi/3$, $D = 0$ and $P = 1$.
In both cases, the approximate solutions obtained by energetic BEM with discretization parameters fixed as $\Delta x = 0.05$ and $\Delta t = 0.05$ show an optimal accuracy.

Abstract

A new method, the so-called SABO (Semi-Analytical method for pricing of Barrier Options), recently introduced in literature for the evaluation of barrier options, is here described. The method, already applied in the context of European options, is now extended to Asian options with geometric mean.

Key words: Boundary Element Method, Geometric Asian Options, Barrier Options.
MSC 2000: 91G60, 65M38

1 Introduction

The variety of financial products in recent years grew much quicker than ever before. The recent financial crisis has highlighted the need for a more scientific approach to the problem of pricing of these products, taking advantage of more advanced statistical and mathematical skills and of the availability of numerical techniques and faster computer systems.
In particular in this paper we will illustrate a new algorithm, the so-called SABO (Semi-Analytical method for pricing of Barrier Options), to evaluate Asian options with barriers. Asian options are derivative contracts whose payoff at maturity depends on the (geometric or arithmetic) average value of an underlying asset over some time interval; in the case of "barrier option", these contracts get into existence or extinguish when the underlying asset reaches a certain barrier value. With respect to European vanilla option, the buyer has a reasonable protection against inconvenient fluctuations in the underlying price and the issuer can attain a better forecasting of the terminal position.
For standard Asian options with geometric mean equipped with floating or fixed strike price, closed formula solutions are available [7] but if the contract involves non standard

  ISBN: 978-84-617-8694-7

payoffs or arithmetic mean or barriers, numerical techniques are unavoidable. The pricing is then traditionally based on Monte Carlo methods [7] or on domain methods, such as Finite Volume Methods [9] and Finite Difference methods [2], but Monte Carlo methods are affected by high computational costs and inaccuracy due to their slow convergence and domain methods have some troubles particularly in unbounded domains.
Barrier options are largely exchanged as they are good products for hedging and investment and they are cheaper than vanilla options but, for Asian options, we found in literature only the analysis of [1] which provides rigorous bounds in the arithmetic mean case.
SABO has been recently introduced for the computation of European barrier options within various differential models ([4], [5] and[6]). This new approach, based on Boundary Element Method turns out to be stable and efficient especially when the differential problem is defined in an unbounded domain and the data are assigned on a limited boundary (which is the case of the "barrier options"). The method is particularly advantageous for its high accuracy, for the implicit satisfaction of the far-field behavior of the solution and for the low discretization costs. Moreover it provides a straight hedging computation. The essential requisite, that makes it not as general as other numerical methods is that, for its application, we need the knowledge of the transition probability density related to the vanilla option problem at least in an approximated form.
The method is here extended to Asian barrier options evaluated with geometric mean that, although not common among practitioners, give some information also about the evaluation of Asian barrier options with arithmetic mean. This work can be conceived as an intermediate and preparatory step in this last direction.

2 The model problem

A geometric Asian option V is an option depending on the evolution of the stock price S_t and on the geometric average of the stock price over some time interval

$$A_t := \int_0^t \log(S_t)dt\,.$$

If the stochastic process S_t is modeled by the usual geometric Brownian motion

$$dS_t = rS_t dt + \sigma S_t dW_t$$

where r denotes the risk free interest rate, σ the volatility and W_t a standard Wiener process, then, A_t is a lognormal stochastic process too.
With the classical hedging arguments applied in the Black-Scholes framework, it is possibile to conclude that the Asian option value $V(S, A, t)$ solves the following partial differential equation (PDE):

$$\frac{\partial V}{\partial t} + \frac{\sigma^2}{2}S^2\frac{\partial^2 V}{\partial S^2} + rS\frac{\partial V}{\partial S} + \log(S)\frac{\partial V}{\partial A} - rV = 0 \qquad S \in \mathbb{R}^+,\, A \in \mathbb{R},\, t \in [0, T)\,. \tag{1}$$

 ISBN: 978-84-617-8694-7

Different final boundary conditions (payoffs) define different types of contract, such as:

$$\begin{aligned}
\text{floating strike call} \quad & V(S,A,T) = \max\left(S - \exp\left(\frac{A}{T}\right), 0\right) \\
\text{floating strike put} \quad & V(S,A,T) = \max\left(\exp\left(\frac{A}{T}\right) - S, 0\right) \\
\text{fixed strike call} \quad & V(S,A,T) = \max\left(\exp\left(\frac{A}{T}\right) - E, 0\right) \\
\text{fixed strike put} \quad & V(S,A,T) = \max\left(E - \exp\left(\frac{A}{T}\right), 0\right)
\end{aligned}$$

for $S \in \mathbb{R}^+$, $A \in \mathbb{R}$ and E the strike price.
Some boundary conditions are implicitly satisfied by V through its payoff behavior and they are such to assure existence and uniqueness of the Cauchy partial differential problem solution. The exact solution can be defined by an integral form as payoff expected value and it can be therefore employed also with more general payoff contracts:

$$V(S,A,t) = \int_{-\infty}^{+\infty} \int_{0}^{+\infty} V(\widetilde{S},\widetilde{A},T) G(S,A,t;\widetilde{S},\widetilde{A},T) d\widetilde{S}\, d\widetilde{A}\,. \tag{2}$$

The function $G(S,A,t;\widetilde{S},\widetilde{A},\widetilde{t})$ is the *transition probability density function* (PDF), also known as *Green's function* or *fundamental solution* of the partial differential operator. As a function of $(S,A,t) \in \mathbb{R}^+ \times \mathbb{R} \times [0,T)$ the PDF solves (1) and, as a function of $(\widetilde{S},\widetilde{A},\widetilde{t})$, it solves the *backward Kolmogorov equation* adjoint of (1):

for each $(S,A,t) \in \mathbb{R}^+ \times \mathbb{R} \times [0,T)$

$$\begin{cases}
-\dfrac{\partial G}{\partial \widetilde{t}} + \dfrac{\sigma^2}{2}\widetilde{S}^2 \dfrac{\partial^2 G}{\partial \widetilde{S}^2} + (2\sigma^2 - r)\widetilde{S}\dfrac{\partial G}{\partial \widetilde{S}} - \log(\widetilde{S})\dfrac{\partial G}{\partial \widetilde{A}} + (\sigma^2 - 2r)G = 0 & \widetilde{S} \in \mathbb{R}^+,\ \widetilde{A} \in \mathbb{R},\ \widetilde{t} > t \\
G(S,A,t;\widetilde{S},\widetilde{A},t) = \delta(S-\widetilde{S})\delta(A-\widetilde{A}) & \widetilde{S} \in \mathbb{R}^+,\ \widetilde{A} \in \mathbb{R}
\end{cases} \tag{3}$$

where $\delta(\cdot,\cdot)$ represents the Dirac distribution. The solution of problem (3) must satisfy opportune boundary conditions assuring that the Green identity is verified.

 ISBN: 978-84-617-8694-7

We can prove, thanks to results in [8], that the closed form solution of problem (3) is

$$\begin{aligned} G(S,A,t;\widetilde{S},\widetilde{A},\widetilde{t}) &= \frac{\sqrt{3}\,H[\widetilde{t}-t]}{\pi\sigma^2(\widetilde{t}-t)^2}\exp\left\{-\frac{2}{\sigma^2(\widetilde{t}-t)}\log^2\left(\frac{S}{\widetilde{S}}\right)\right. \\ &+ \frac{6}{\sigma^2(\widetilde{t}-t)^2}\log\left(\frac{S}{\widetilde{S}}\right)\left(A-\widetilde{A}+(\widetilde{t}-t)\log(S)\right) \\ &- \frac{6}{\sigma^2(\widetilde{t}-t)^3}\left(A-\widetilde{A}+(\widetilde{t}-t)\log(S)\right)^2 \\ &- \left.\left(\frac{2r+\sigma^2}{2\sqrt{2}\sigma}\right)^2(\widetilde{t}-t)\right\}\left(\frac{\widetilde{S}}{S}\right)^{\frac{2r-\sigma^2}{2\sigma^2}}\frac{1}{\widetilde{S}} \end{aligned} \tag{4}$$

denoting by $H[\cdot]$ the Heaviside step function.
When considering fixed strike options or floating strike options, the exact solution can be evaluated also by other more efficient closed-formulas of Black-Scholes type [10].
To Asian options we can apply some barriers, as often done with European options, in order to reduce their price and to ward against excessive fluctuations of strike price. For this kind of geometric Asian options neither closed form solutions are available nor we have found some analysis in literature.
As example, a geometric Asian up-and-out barrier call option is an option that is extinguished when the price of the underlying asset grows up enough to breach an assigned upper barrier B before the expiry date T. Its value is modeled by the differential boundary value problem:

$$\frac{\partial V}{\partial t}+\frac{\sigma^2}{2}S^2\frac{\partial^2 V}{\partial S^2}+rS\frac{\partial V}{\partial S}+\log(S)\frac{\partial V}{\partial A}-rV=0 \quad S\in(0,B),\ A\in\mathbb{R},\ t\in[0,T) \tag{5}$$

$$V(S,A,T) \quad \text{assigned} \quad S\in(0,B),\ A\in\mathbb{R} \tag{6}$$

$$V(B,A,t)=0 \quad A\in\mathbb{R},\ t\in[0,T) \tag{7}$$

$$\text{asymptotic conditions of vanilla option} \quad \{(S,A): S=0\vee A\to-\infty\vee A\to+\infty\}. \tag{8}$$

The method, that we will illustrate in the following section for the solution of (5)-(8), is rather flexible; it therefore can be easily extended also to Asian call options with other types of barrier, that widen or contract (moving barriers), and to put options, too.

3 The SABO approach

SABO is the acronym of **S**emi-**A**nalytical method for the pricing of **B**arrier **O**ptions and substantially it is the application of Boundary Element Method (BEM) to barrier option problems. The method is based on the below listed steps.

 ISBN: 978-84-617-8694-7

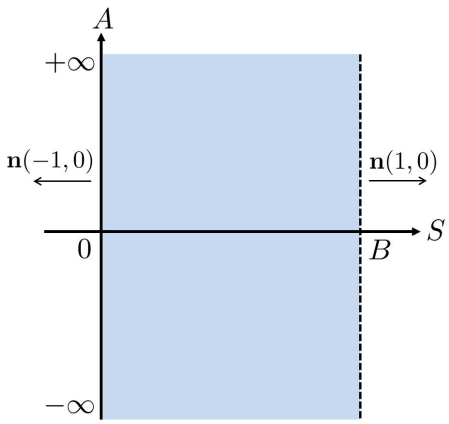

Figure 1: $(S, A) \in \Omega := (0, B) \times \mathbb{R}$, spatial domain of the differential problem (5)-(8) modeling an Asian option with up-and-out barrier.

3.1 The integral representation formula in the domain of the differential problem

Let us start from the differential problem (5) for an up-and-out barrier call option: the domain of investigation for $V(S, A, t)$ is now $\Omega \times [0, T)$, defining $\Omega := (0, B) \times \mathbb{R}$, as represented in Fig. 1.
Recalling some theory in [3], we proved that a new integral formulation holds: it is obtained adding one more term to the basic integral formulation (2) restricted to the actual domain, i.e.

$$\begin{aligned} V(S,A,t) &= \int_{-\infty}^{+\infty}\int_{0}^{B} V(\widetilde{S},\widetilde{A},T)G(S,A,t;\widetilde{S},\widetilde{A},T)d\widetilde{S}\,d\widetilde{A} \\ &+ \int_{t}^{T}\int_{-\infty}^{+\infty}\frac{\sigma^2}{2}B^2\frac{\partial V}{\partial \widetilde{S}}(B,\widetilde{A},\widetilde{t})G(S,A,t;B,\widetilde{A},\widetilde{t})d\widetilde{A}\,d\widetilde{t}\,. \end{aligned} \tag{9}$$

3.2 The boundary integral equation (BIE)

In the integral formula (9), $\frac{\partial V}{\partial \widetilde{S}}(B, \widetilde{A}, \widetilde{t})$ is unknown. If we succeed in computing it, formula (9) gives us the solution of problem (5)-(8) over the whole domain $\Omega \times [0, T)$.
With this purpose, we take the limit for $S \to B$ in (9) and, using boundary condition (7), we obtain

$$\begin{aligned} 0 = V(B,A,t) &= \int_{-\infty}^{+\infty}\int_{0}^{B} V(\widetilde{S},\widetilde{A},T)G(B,A,t;\widetilde{S},\widetilde{A},T)d\widetilde{S}\,d\widetilde{A} \\ &+ \int_{t}^{T}\int_{-\infty}^{+\infty}\frac{\sigma^2}{2}B^2\frac{\partial V}{\partial \widetilde{S}}(B,\widetilde{A},\widetilde{t})G(B,A,t;B,\widetilde{A},\widetilde{t})d\widetilde{A}\,d\widetilde{t}\,. \end{aligned} \tag{10}$$

 ISBN: 978-84-617-8694-7

in the sole unknown $\frac{\partial V}{\partial \widetilde{S}}(B, \widetilde{A}, \widetilde{t})$.
The idea implemented by SABO is to approximate $\frac{\partial V}{\partial \widetilde{S}}(B, \widetilde{A}, \widetilde{t})$ numerically solving (10) and then, inserting it in the representation formula (9), to recover the solution V at every desired point of the domain Ω and at every desired time instant.

3.3 The numerical approximation of the BIE solution

The approximation of the BIE unknown $\frac{\partial V}{\partial \widetilde{S}}(B, \widetilde{A}, \widetilde{t})$ is found by collocation method as in [6] and it is structured as follows:
- introduction of a uniform decomposition in the time interval $[0, T]$

$$\Delta t := \frac{T}{N_t}, \quad N_t \in \mathbb{N}^+, \qquad t_k := k\Delta t, \quad k = 0, \ldots, N_t$$

and time representation of the BIE unknown by piecewise constant basis functions

$$\varphi_k(\widetilde{t}) := H[\widetilde{t} - t_{k-1}] - H[\widetilde{t} - t_k], \quad k = 1, \ldots, N_t\,;$$

- introduction of a uniform decomposition in the unbounded A-domain $\equiv \mathbb{R}$ suitably truncated by $[A_{\min}, A_{\max}]$

$$\Delta A := \frac{A_{\max} - A_{\min}}{N_A}, \quad N_A \in \mathbb{N}^+, \qquad A_h := A_{\min} + h\Delta A, \quad h = 0, \ldots, N_A$$

and representation of the BIE unknown in the independent variable A by piecewise constant basis functions

$$\psi_h(\widetilde{A}) := H[\widetilde{A} - A_{h-1}] - H[\widetilde{A} - A_h], \quad h = 1, \ldots, N_A\,;$$

- approximation of the BIE (10) unknown as

$$\frac{\partial V}{\partial \widetilde{S}}(B, \widetilde{A}, \widetilde{t}) \approx \sum_{k=1}^{N_t} \sum_{h=1}^{N_A} \alpha_h^{(k)} \psi_h(\widetilde{A}) \varphi_k(\widetilde{t})\,; \tag{11}$$

- definition of the collocation points: as usual when considering piecewise constant trial functions, they are the centers of intervals $[A_{i-1}, A_i]$ and $[t_{j-1}, t_j]$, i.e.

$$\overline{A}_i = \frac{A_i + A_{i-1}}{2}, \quad i = 1, \ldots, N_A\,; \qquad \overline{t}_j = \frac{t_j + t_{j-1}}{2}, \quad j = 1, \ldots, N_t\,;$$

- evaluation of (10) at the collocation points $(\overline{A}_i, \overline{t}_j)$ building a linear system of $N_A \times N_t$ equations:

 ISBN: 978-84-617-8694-7

for $i = 1, \dots, N_A$, $j = 1, \dots, N_t$

$$\begin{aligned} 0 &= \int_{-\infty}^{+\infty} \int_0^B V(\widetilde{S}, \widetilde{A}, T) G(B, \overline{A}_i, \bar{t}_j; \widetilde{S}, \widetilde{A}, T)\, d\widetilde{S}\, d\widetilde{A} \\ &+ \int_{\bar{t}_j}^T \int_{-\infty}^{+\infty} \frac{\sigma^2}{2} B^2 \sum_{k=1}^{N_t} \sum_{h=1}^{N_A} \alpha_h^{(k)} \psi_h(\widetilde{A}) \varphi_k(\widetilde{t}) G(B, \overline{A}_i, \bar{t}_j; B, \widetilde{A}, \widetilde{t})\, d\widetilde{A}\, d\widetilde{t}\,. \end{aligned}$$

- resolution of the linear system

$$\mathcal{A}\alpha = \mathcal{F} \tag{12}$$

whose unknowns are the coefficients of linear representation in (11)

$$\alpha = (\alpha^{(k)}|_{k=1,\dots,N_t}) = \big((\alpha_h^{(k)}|_{h=1,\dots,N_A})|_{k=1,\dots,N_t}\big).$$

The rhs entries are:

for $i = 1, \dots, N_A$, $j = 1, \dots, N_t$

$$\mathcal{F}_i^{(j)} = -\int_{-\infty}^{+\infty} \int_0^B V(\widetilde{S}, \widetilde{A}, T) G(B, \overline{A}_i, \bar{t}_j; \widetilde{S}, \widetilde{A}, T)\, d\widetilde{S}\, d\widetilde{A}\,. \tag{13}$$

The matrix entries are:

for $i, h = 1, \dots, N_A$, $j, k = 1, \dots, N_{\Delta t}$

$$\begin{aligned} \mathcal{A}_{ih}^{(jk)} &= \frac{\sigma^2}{2} B^2 \int_{\bar{t}_j}^T \int_{-\infty}^{+\infty} \psi_h(\widetilde{A}) \varphi_k(\widetilde{t}) G(B, \overline{A}_i, \bar{t}_j; B, \widetilde{A}, \widetilde{t})\, d\widetilde{A}\, d\widetilde{t} \\ &= \frac{\sigma^2}{2} B^2 H[t_k - \bar{t}_j] \int_{\max(t_{k-1}, \bar{t}_j)}^{t_k} \int_{A_{h-1}}^{A_h} G(B, \overline{A}_i, \bar{t}_j; B, \widetilde{A}, \widetilde{t})\, d\widetilde{A}\, d\widetilde{t} \\ &= \frac{\sigma^2}{2} B^2 H[t_k - \bar{t}_j] \int_{\max(t_{k-1}, \bar{t}_j)}^{t_k} \int_{A_{h-1}}^{A_h} \frac{\sqrt{3}}{\pi \sigma^2 (\widetilde{t} - \bar{t}_j)^2 B} \\ &\quad \exp\left\{ -\frac{6\big(\overline{A}_i - \widetilde{A} + (\widetilde{t} - \bar{t}_j)\log(B)\big)^2}{\sigma^2 (\widetilde{t} - \bar{t}_j)^3} - \left(\frac{2r + \sigma^2}{2\sqrt{2}\sigma}\right)^2 (\widetilde{t} - \bar{t}_j) \right\} d\widetilde{A}\, d\widetilde{t} \end{aligned}$$

and, since equation (5) has constant parameters in time, they depend only on the difference between time instants so, defining $\ell = k - j$, $\ell = 0, \dots, N_t - 1$ and performing the change of variable $\widetilde{t} = \Delta t(\tau + k - 1)$, we get $\widetilde{t} - \bar{t}_j = \Delta t(\tau + k - j - 1/2) = \Delta t(\tau + \ell - 1/2)$ and

 ISBN: 978-84-617-8694-7

therefore

$$\begin{aligned}\mathcal{A}_{ih}^{(jk)} &= \frac{\sigma^2}{2}B^2\int_{\frac{1}{2}-\frac{1}{2}H[\ell]}^{1}\int_{A_{h-1}}^{A_h}\frac{\sqrt{3}}{\pi\sigma^2\Delta t(\tau+\ell-1/2)^2B}\\ &\quad\exp\left\{-\frac{6\big(\overline{A}_i-\widetilde{A}+\Delta t(\tau+\ell-1/2)\log(S)\big)^2}{\sigma^2\Delta t^3(\tau+\ell-1/2)^3}-\left(\frac{2r+\sigma^2}{2\sqrt{2}\sigma}\right)^2\Delta t(\tau+\ell-1/2)\right\}d\widetilde{A}\,d\tau\\ &=: \mathcal{A}_{ih}^{(\ell)}\,.\end{aligned} \tag{14}$$

Observe that, by consequence, $\mathcal{A}$ is a block upper triangular matrix with Toeplitz structure: the upper triangularity is due to the fact that the fundamental solution is defined by (3) only for $\widetilde{t}>t$ implying that the matrix entries are non trivial only for $k\geq j$; the Toeplitz structure is due to the dependence on time differences. Therefore it holds:

$$\mathcal{A}=\begin{bmatrix} A^{(0)} & A^{(1)} & A^{(2)} & \cdots & A^{(N_t-1)}\\ 0 & A_{(0)} & A^{(1)} & \cdots & A^{(N_t-2)}\\ 0 & 0 & A_{(0)} & \ddots & \vdots\\ \vdots & \vdots & \ddots & \ddots & A_{(1)}\\ 0 & 0 & \cdots & 0 & A_{(0)}\end{bmatrix}. \tag{15}$$

This allows to compute only last blocks column and to solve the linear system by block backward substitution.

3.4 The numerical approximation of option price

Once system (12) is solved, the knowledge of α, that determines the approximation of BIE solution, implies the possibility of computing $V(S,A,t)$ at any point $(S,A,t)\in\Omega\times[0,T)$, introducing (11) in the integral representation formula (9):

$$\begin{aligned}V(S,A,t) &\approx \int_{-\infty}^{+\infty}\int_0^B V(\widetilde{S},\widetilde{A},T)G(S,A,t;\widetilde{S},\widetilde{A},T)d\widetilde{S}\,d\widetilde{A}\\ &+ \frac{\sigma^2}{2}B^2\sum_{k=\mathrm{floor}[\frac{t}{\Delta t}]+1}^{N_t}\sum_{h=1}^{N_A}\alpha_h^{(k)}\int_{\max(t,t_{k-1})}^{t_k}\int_{A_{h-1}}^{A_h}G(S,A,t;B,\widetilde{A},\widetilde{t})d\widetilde{A}\,d\widetilde{t}\,,\end{aligned} \tag{16}$$

where floor$[\cdot]$ is the function that rounds its argument to the nearest integers towards minus infinity.
The main advantage of this method is that we can avoid to evaluate the solution over a grid, considering only the evaluation at the points of interest.

Abstract

The confusion matrix is the standard way to report on the thematic accuracy of geographic information data. Two widely adopted indices for thematic accuracy controls upon error matrix are the overall accuracy and the Kappa coefficient. Both indices are global and do not allow for a category-wise control. Provided that a multinomial sampling, this work proposes a new method for testing the homogeneity of two independent thematic classifications which is based on whole error matrices. Specifically, a test function is proposed that uses as a test statistic the discrete Hellinger distance. A simulation experiment is carried out to evaluate the goodness of the proposal and an application to a real data set is included.

Key words: thematic accuracy, confusion matrix, hellinger distance

1 Introduction

Geographic Information (GI) supports decision making in several fields as climate change, crop forecasting, forest fires, national defense, civil protection or spatial planning. The quality of the GI is essential to ensure that decisions based on it are technically the best. There are different components to describe this quality. One of them is the thematic quality, as is established by the international standard ISO 19157. This thematic quality is usually quantitatively assessed by means of the so called confusion matrix or error matrix (i.e. when classification correctness has to be assessed). The confusion matrix is a contingency table established by the cross-reference of a set of categories. The true categories or reference data are located in columns, whereas in rows are located the categories for the classification

 ISBN: 978-84-617-8694-7

	Reference Data			
Observed Data	Category 1	Category 2	...	Category M
Category 1	n_{11}	n_{12}	...	n_{1M}
Category 2	n_{11}	n_{12}	...	n_{1M}
...	...	...	...	...
Category M	n_{M1}	n_{M2}	...	n_{MM}

Table 1: Contingency table associated with a confusion matrix.

process. So, the elements in the diagonal are correctly classified items, and the off diagonal elements contain the number of confusions, the errors due to omissions or commissions.

The control of a confusion matrix is usually carried out by using two widely adopted indices like the overall accuracy (OA) and the Kappa coefficient (κ). The first is the ratio between the account of elements that are correctly classified and the total amount of elements in the matrix. The Kappa coefficient is a measure based on the difference between the agreement indicated by the values of the main diagonal (OA) and the chance agreement estimated by the marginal values. If M represents the number of classes under consideration and $k = M \times M$ the number of cells in the error matrix, assuming a multinomial sampling model, n_{ij} represents the number of elements in the class j of the reference data that are classified in class i of the observed data and n stands for the total number of elements classified. Table 1 shows a general way to present a confusion matrix.

The kappa coefficient (Cohen, [3]) is defined as

$$\hat{\kappa} = \frac{OA - P_c}{1 - P_c}$$

where the overall accuracy is $OA = \frac{1}{n}\sum_{i=1}^{M} n_{ii}$ and $P_c = \sum_{i=1}^{M} p_{i+}p_{+i}$, represents the proportion of agreement expected by chance agreement; $p_{i+} = \frac{n_{i+}}{n}$, $p_{+i} = \frac{n_{+i}}{n}$ being the proportions in the ith row and in the ith column, respectively. Banerjee et al. [2] gave an estimate of the variance of $\hat{\kappa}$ by means of

$$\hat{V}(\hat{\kappa}) = \frac{P_c + P_c^2 - \sum_{i=}^{M} p_{+i}p_{i+}(p_{i+} + p_{+i})}{n(1 - P_c)^2}. \tag{1}$$

The Kappa coefficient is asymptotically normally distributed and this fact provides a means for testing the significance of the Kappa coefficient for a single confusion matrix in order to determine if the agreement between the observed data and the reference data is significantly greater than 0. However, some authors have criticized the use of OA and κ because they only use the account of elements that are correctly classified, the marginal values, and the total number of elements in the matrix (Gwet, [5], Stehman, [8], among many others), that is, they do not incorporate the off-diagonal information of the error matrix.

 ISBN: 978-84-617-8694-7

In the same way, it is possible to determine if two independent Kappa values, associated with two confusion matrices, are significantly different. So, it can be compare two analysts, two strategies, the same analyst over time, etc.

The null hypothesis $H_0 : \kappa_1 - \kappa_2 = 0$ can be rejected if $Z > Z_\alpha$, with

$$Z = \frac{|\hat{\kappa}_1 - \hat{\kappa}_2|}{\sqrt{\hat{\sigma}_1^2 + \hat{\sigma}_2^2}}$$

where $\hat{\kappa}_1$, $\hat{\kappa}_2$ are the estimate of kappa coefficient for both confusion matrices, $\hat{\sigma}_1^2$, $\hat{\sigma}_2^2$ their estimated variances, and Z_α is the $1-\alpha$ percentile of $N(0,1)$.

For example, for the confusion matrices A and B,

Matrix A	
50	0
20	30

Matrix B	
50	10
10	30

However, the use of the Kappa coefficient for this purpose can lead us to incoherent results. In this case, $Z = 0.12$ and at signification level of 5%, the null hypothesis can not be rejected, the conclusion should be that, globally, both confusion matrices reveal the same information although it is easily to observe that this assertion is not true for the matrices. Our proposal is to take advantage of the underlying sampling model and to deal with a confusion matrix as a multinomial distribution. This way, by testing the homogeneity of the associated confusion matrices, it is possible to determine if two photointerpretation works, two different classification works, or a test work and a product reach the same conclusion.

2 The homogeneity test

Let X, Y be two independent random vectors whose values have been grouped into $k = M \times M$ classes $C_1, C_2, \ldots, C_k$, or equivalently, taking values in $\Upsilon = (1, 2, \ldots, k)$ with probabilities $P = (p_1, p_2, \ldots, p_k)$ and $Q = (q_1, q_2, \ldots, q_k)$, respectively. Our task is to test the following null hypothesis

$$H_0 : P = Q. \tag{2}$$

Several test statistics can be chosen for testing H_0, but not all of them can be applied when empty cells are present, as in the confusion matrices. Here, we are going to consider a test statistic based on the Hellinger distance. So, let $(X_1, \ldots, X_n)$ and $(Y_1, \ldots, Y_m)$ be two independent random samples from X and Y, with sizes n and m, respectively. For testing (2), we consider the following test function

$$\Psi = \begin{cases} 1, & \text{if } T_{n,m} \geq t_{n,m,\alpha}, \\ 0, & \text{otherwise,} \end{cases}$$

 ISBN: 978-84-617-8694-7

where $T_n = 2(n+m)\sum_{i=1}^{k}(\sqrt{\hat{p}_i} - \sqrt{\hat{q}_i})^2$ and $t_{n,m,\alpha}$ is the $1-\alpha$ percentile of the null distribution of $T_{n,m}$.

A reasonable test for testing H_0 should reject the null hypothesis for large values of $T_{n,m}$. To decide when to reject H_0, that is, to calculate $t_{n,m,\alpha}$ or, equivalently, to calculate the p-value of the observed value of the test statistic, we need to know the null distribution of $T_{n,m}$, which is clearly unknown, so one has to approximate it. Asymptotically, the null distribution of T_n is a chi-square variate with $k-1$ degrees of freedom. However, for small and moderate sample sizes, the behaviour of the asymptotic null distribution is rather poor (Alba et al. [1], Kim et al. [6]). To overcome this problem, we approximate the null distribution of the test statistic by means of a bootstrap estimator. It is proved the bootstrap provides a consistent estimator of the null distribution of $T_{n,m}$.

3 Simulation study

The bootstrap approximation is valid for large samples. To evaluate the goodness of the proposal for small and moderate sample sizes, a simulation experiment is carried out. All computations have been performed using programs written in the R language [7].

To study the goodness of the bootstrap approximations to the null distribution of the test statistic $T_{n,m}$, we first generated two independent samples with equal sample sizes $n = m = 50$ from the multinomial with $P_1 = (0.5, 0.2, 0, 0.3)$ ($k = 2 \times 2$) and calculated $\hat{p}$ with $B = 1000$ replications. This was repeated 5000 times and we calculated the fraction of $\hat{p}$s less than or equal to 0.05 and 0.10 (f05 and f10 in tables), which are the estimated type I error probability for $\alpha = 0.05, 0.10$. The whole experiment is repeated for $n = 100, 300, 500$ and for $P_2 = (0.3, 0, 0.15, 0, 0.15, 0, 0.1, 0.15, 0.15)$ ($k = 3 \times 3$). Table 2 shows the results obtained. According to these results, it can be highlighted that the estimated type I error probabilities are quite close to the nominal values in all the tried cases. It means the proposal behaves properly when the null hypothesis is true.

Now, the simulation experiment is completed with a power study. Now, we generated two independent samples with sizes n and m from two multinomials with P_1 and $Q_1 = (0.50, 0.16, 0.02, 0.32)$ and calculated $\hat{p}$ in the same conditions as before. Now, the fraction of $\hat{p}$s less than or equal to 0.05 and 0.10 are the estimated powers associated with the nominal values $\alpha = 0.05, 0.10$, respectively. The whole experiment is repeated for $n = 50, 100, 200, 300$ and $Q_1^{\dagger} = (0.52, 0.16, 0.02, 0.30)$. The whole experiment was repeated for P_2, $Q_2 = (0.32, 0, 0.13, 0, 0.17, 0, 0.06, 0.15, 0.17)$ and $Q_2^{\dagger} = (0.3, 0, 0.15, 0.02, 0.17, 0, 0.06, 0.13, 0.17)$. Table 3 and 4 show the results obtained.

According to the results in tables 3 and 4, the procedure is able to detect if two photointerpretation works, two different classification works, or a test work and a product reach the same conclusion.

Abstract

Encouraged by the success of applying metaheuristics algorithms to other ranking-based problems (Kemeny ranking problem and parameter estimation for Mallows distributions), in this paper we deal with the rank aggregation problem (RAP), which can be viewed as a generalization of the Kemeny problem to arbitrary rankings.

In particular, we perform a comparative study among some local-based search metaheuristics: hill climbing (HC), iterated local search (ILS), variable neighborhood search (VNS) and greedy randomized adaptive search procedure (GRASP).

We provide a complete analysis of the experimental study regarding accuracy and number of iterations required to reach the best solution.

Key words: Ranking, Rank aggregation problem, Metaheuristic algorithm, Kendall distance, Permutation, Partial ranking.

1 Introduction

In the last decades, the *Rank Aggregation Problem* (RAP) [1] has gained popularity in several fields as statistics and machine learning because of its significant applications in many real-world problems, including information retrieval and recommender systems.

Rankings represent preferences in a natural way. Given a set of items $[n] = \{1, 2, \ldots, n\}$, a ranking π is an ordering of (some of) these items. The case when the rankings are permutations (complete rankings without ties) has received a great attention in the literature (see [2] and references therein). However, many real world problems usually deal with incomplete rankings, that is, those where only p items are ranked, $2 \leq p < n$, and/or with rankings where some items are equally preferred or tied.

Given a sample of arbitrary rankings, the solution to the RAP is the *consensus* permutation, that is, the permutation which best summarizes the rankings in the sample. When all the rankings in the sample are permutations, this problem is known as the *Kemeny ranking problem* [3]. Both are NP-hard problems when the number of rankings to aggregate is greater than 3.

The RAP has been widely studied and several proposals have arisen in the last years. However, they only focus in particular cases of the problem, incomplete rankings or rankings with ties, but not both of them simultaneously. Recently, metaheuristics algorithms have been used to approach several ranking-based problems [4, 5].

In this paper we deal with problem instances of the RAP containing any kind of rankings (complete, incomplete, with and without ties). In a recent paper [6], the authors have developed a version of the greedy Borda algorithm tailored to this problem, which clearly outperforms the standard Borda method. Now, we go one step further, and with the goal of obtaining better solutions (closer to the global optimum) we propose the use of more complex search engines. Since local search-based metaheuristics have shown a good trade-off between efficiency and accuracy in related problems (e.g. the traveling salesman problem, the routing-packing problem, the vertex separation problem, the linear ordering problem, etc.), in this study we focus on this family of metaheuristics. Specifically, we perform a comparative study among the following algorithms:

- *Hill climbing (HC)* algorithm. It is a local search algorithm which iteratively tries to improve a given solution by moving at each iteration to the neighbor representing the biggest increase (decrease) in the evaluation or objective function with respect to the current solution.

- *Iterated local search (ILS)* method. It is a multi-start local search algorithm based on the HC algorithm, which tries to escape from the local optimum by perturbing it, and use the resulting configuration to seed a new HC iteration.

- *Variable neighborhood search (VNS).* It is also a multi-start local search algorithm which, instead of modifying the starting point at each iteration, changes to a different neighborhood.

- *Greedy randomized adaptive search procedure (GRASP)* It is a multi-start local search algorithm which, at each iteration, constructs a randomized informed solution and locally improves it.

Thus, the main contribution of this paper is to provide a comparative study among the selected MHs. We consider different neighborhoods and allowed resources (number of fitness evaluations). The results show the influence of the starting point and the selected neighborhood in the performance of the (local) search algorithms. Regarding the trade-off between goodness of the solution and number of evaluations, we get that the VNS is the best

 ISBN: 978-84-617-8694-7

choice under limited resources, while the GRASP performs better when more evaluations are allowed.

Hermite finite element method for nonlinear Black-Scholes equation governing European options

Rui M.P. Almeida[1], Teófilo D. Chihaluca[1] and José C.M. Duque[1]

[1] *Center of Mathematics and Applications, University of Beira Interior, Covilhã, Portugal*

emails: ralmeida@ubi.pt, teofilo.chihaluca@ubi.pt, jduque@ubi.pt

Abstract

We develop a numerical algorithm for solving a generalized Black-Scholes partial differential equation, which arise in European option pricing considering transaction costs. The Crank-Nicolson method is considered to discretize in the temporal direction and the Hermite cubic interpolation method in the spatial direction. The efficiency and accuracy of the proposed method are tested numerically, the results confirm the theoretical behaviour of the solutios, and they are with good agreement with the exact solution.

Key words: Non-linear Black-Scholes, Finite Element Method, Crank-Nicolson, Hermite Polynomials.

1 Introduction

The valuation of options based on stochastic processes dates back to 1877, when Charles Castelli wrote the book entitled "The Theory of Option in Stocks and Shares". Two decades later, Louis Bachelier, in his dissertation "Théorie de la spéculation", presented the first analytical way of calculating the price of an option. Subsequently, in 1955, in an unpublished manuscript entitled "Brownian Motion in the Stock Market", a professor at the Massachusetts Institute of Technology (MIT), Paul Samuelson, 1970 Nobel Prize in Economics, showed that the asset price can be modeled by a stochastic process called Brownian Geometric Motion. In 1962, A. James Boness presented a dissertation entitled "Theory and Measurement of Stock Option Value", where he announced an option evaluation model that represented a great step forward from his predecessors and served as the basis for the work later developed by Black and Scholes. The Black-Scholes [5] model is a well-known

 ISBN: 978-84-617-8694-7

popular model which is used to calculate the price of European options. Since its inception in 1973 by Fischer Black and Myron Scholes, it remains one of the most preferred models and provides the basis for the theory of financial options. The linear Black-Scholes equation is given by

$$0 = V_t + \frac{1}{2}\sigma^2 S^2 V_{SS} + rSV_S - rV, \qquad S > 0, \qquad t \in]0, T[, \tag{1}$$

where V is the option value, T the expiry date, S the underlying asset price, σ the volatility and r the riskless interest rate.
Equation (1) permit the evaluation of the price of a European option under the assumptions listed below:

- the value of the financial asset underlying the option can be modeled by a geometric Brownian motion;
- there are no transaction costs associated with the management of financial asset portfolios, nor fees payable in the market;
- the market does not allow arbitrage opportunities;
- you can do *short selling*;
- there is a risk-free rate that is constant throughout the life of the option, to which it is possible to lend and borrow at that same rate any financial asset;
- the volatility of the underlying asset is known and remains constant throughout the option lifespan;
- the transaction of the financial asset is made on a continuous basis and changes in its price are also on a continuous basis;
- fractional parts of an asset can be obtained;
- the financial asset does not pay dividends during the option lifespan.

The classical Black-Scholes model is notable for its explicit closed form solution of European style options (call and put options). Many researchers have attempted to obtain the solution of the Black-Scholes Equation analytically and/or numerically, thereby adopting and using various direct and iterative methods, respectively.

J. Ankudinova and M.Ehrhardt [3], make a comparative study between models with transaction costs and the linear model. The influence of transaction costs modeled by the volatilities given by the Leland, Barles and Soner and Krakta models was calculated by the Crank-Nicolson method in time and by the finite difference method in space.

 ISBN: 978-84-617-8694-7

In [11] a study of the linear Black-Scholes equation for European and American call options was made. The finite element method was used in the space dimension and explicit Euler method in the time discretization. The analytical solution was obtained by applying the Fourier transformation, while the numerical solution was obtained by the finite element method. The results were them compared using the finite difference method.

Almeida et al., in ([2],[1],[6]), established convergence, properties and error bounds for the fully discrete solutions of a class of nonlinear equations of reaction-diffusion nonlocal type, using a linearised Crank-Nicolson-Galerkin finite element method with polynomial approximations of arbitrary degree.

The remainder of this paper is organized as follows. In Section 2 the problem is described considering some transaction cost models for European options. In Section 3, we define the problem as a general non-linear partial differential equation in non divergent form. In Section 4, we construct the discretization in spatial direction with the Hermite interpolation method in a uniform mesh and, in Section 5, we discretize in temporal direction with the Crank-Nicolson method. In Section 6, we obtain and compare the approximate numerical solutions. Finally, in Section 7, we draw some conclusions.

2 Non-linear Black-Scholes Model

The Black-Scholes model requires a portfolio adjustment in order to protect a "hedge" risk free. In the presence of transaction cost, this adjustment is likely to be more expensive, since an infinite number of transactions is required [12]. But the hedger needs to find the balance between the transaction costs that are needed to rebalance the portfolio and the implicit costs of hedging errors. As a result of this "imperfect" coverage, the option can be overly underestimated, where the risk-free profit obtained by the arbitrator is offset by the transaction cost so that there is no single equilibrium price plus a viable price range. It has been demonstrated that in a transaction market there is no replicator portfolio for a European type call option and the portfolio is required to dominate rather than replicate the option value (see [4]). Soner, Shreve and Cvitanič have proved in [10] that the minimum coverage portfolio of a financial option is trivial, so efforts have been made to ease the condition coverage criterion to better replicate *pay-off* of derivative securities. Because of the presence of transaction costs (see [4], [5], [9]) the classical model results in a strongly or wholly non-linear and possibly degenerate parabolic type diffusion equation where the volatility σ may depend on the time t, the price S or on other derivatives of the option price V. In this work, we study the non-linear Black-Scholes equation with some transaction cost models for European options, with σ a non-constant modified volatility function

$$\tilde{\sigma}^2 := \tilde{\sigma}^2(t, S, V_S, V_{SS}).$$

 ISBN: 978-84-617-8694-7

In this way equation (1) becomes the following non-linear Black-Scholes equation, which we will consider for European options

$$0 = V_t + \frac{1}{2}\tilde{\sigma}^2(t, S, V_S, V_{SS})S^2V_{SS} + rSV_S - rV, \qquad S > 0, \qquad t \in (0, T). \tag{2}$$

A European call option allows buying an asset of value S for a value of K on the maturity date T, while a European put allows selling an asset of value S for a value K at the maturity date T. Since the option can only be exercised at maturity and, in order to avoid arbitrage, we complement equation (2) with the following conditions:

European call option:

$$V(S, T) = \max\{S - K, 0\}, \qquad \text{when } S \geq 0 \tag{3}$$

$$\lim_{S\to\infty} \frac{V(S, t)}{S - Ke^{-r(T-t)}} = 1, \qquad \text{for } t \in [0, T] \tag{4}$$

$$V(0, t) = 0, \qquad \text{for } t \in [0, T] \tag{5}$$

$$\lim_{S\to\infty} V_S(S, t) = 1, \qquad \text{for } t \in [0, T] \tag{6}$$

European put option:

$$V(S, T) = \max\{K - S, 0\}, \qquad \text{when } S \geq 0 \tag{7}$$

$$V(0, t) = Ke^{-r(T-t)}, \qquad \text{for } t \in [0, T] \tag{8}$$

$$\lim_{S\to\infty} V(S, t) = 0, \qquad \text{for } t \in [0, T] \tag{9}$$

$$\lim_{S\to\infty} V_S(S, t) = 0, \qquad \text{for } t \in [0, T] \tag{10}$$

2.1 Leland's model

In [9], Leland deduces that the option price is the solution of the non-linear Black-Scholes equation (2), with the modified volatility given by

$$\tilde{\sigma}^2 = \sigma^2\Big(1 + Le \times sign(V_{SS})\Big). \tag{11}$$

In equation (11) Le is Leland's number, which is given by

$$Le = \sqrt{\frac{2}{\pi}}\left(\frac{k}{\sigma\sqrt{\delta t}}\right) \tag{12}$$

 ISBN: 978-84-617-8694-7

where δt is the interval between two successive revisions of the portfolio, k is the round trip transaction cost per transacted monetary unit and σ represents the historical volatility. By a different process, Boyle and Vorst deduced a similar modified volatility, given by

$$\tilde{\sigma}^2 = \sigma^2 \left(1 + Le\sqrt{\frac{\pi}{2}} sign(V_{SS})\right). \tag{13}$$

However, δt in Leland's definition (12) represents the interval between two successive portfolio reconstructions and not the transaction frequency as in (13) (see [4]).

2.2 Barles and Soner's model

Barles and Soner obtained the most complex model. Following the Hedges and Neuberger [7] utility function approach, they propose, to simplify the calculations, the volatility model

$$\tilde{\sigma}^2 = \sigma^2 \left(1 + e^{r(T-t)} a^2 S^2 V_{SS}\right), \tag{14}$$

where σ is the historical volatility and $a = \frac{k}{\sqrt{\varepsilon}}$. Barles and Soner in [4] proved the existence of a viscosity solution for the European option with the volatility given by (14). Their numerical results indicate an economically significant price difference between the standard Black-Scholes model and the non-linear model with transaction costs.

2.3 Kratka's model

The model proposed by Krakta in [8] minimizes the sum of the rate of the transaction costs and the rate of the risk from an unprotected portfolio. In this way, the portfolio is well protected with the Risk Adjusted Pricing Methodoly (RAPM) and the modified volatility is given by

$$\tilde{\sigma}^2 = \sigma^2 \left(1 + 3(\frac{C^2 M}{2\pi} S V_{SS})^{\frac{1}{3}}\right), \tag{15}$$

where $M \geq 0$ is the measure of the transaction cost and $C \geq 0$ the risk premium.

It should be noted that the non-linear transaction cost models described above are all consistent with the linear model if the additional parameters for the transaction cost are zero.

3 Non-linear General Equation

In this work, we study equations of the form:

$$u_t = c_0 u_{xx} + c_1 u_x + c_2 u + f, \qquad \text{with} \qquad a < x < b, \qquad 0 < t < T, \tag{16}$$

 ISBN: 978-84-617-8694-7

under the initial and boundary conditions

$$u(x,0) = u_0(x), \qquad a < x < b, \tag{17}$$

$$\begin{cases} u(a,t) = g_1(t) \\ u(b,t) = g_2(t) \end{cases} \quad \text{and} \quad \begin{cases} u_x(a,t) = g_3(t) \\ u_x(b,t) = g_4(t) \end{cases} \quad 0 < t < T, \tag{18}$$

where $c_0 = c_0(x,t,u,u_x,u_{xx})$, $c_1 = c_1(x,t,u,u_x)$, $c_2 = c_2(x,t,u)$, $f = f(x,t)$, $g_1(t)$, $g_2(t)$,$g_3(t)$,$g_4(t)$ e $u_0(x)$ are known real bounded functions.
Note that (16)-(18) is a general model which includes the problem under study. The transformation $u(x,t) = V(S, T-t)$ transforms (2) into (16) with $c_0 = \frac{1}{2}\tilde{\sigma}^2 x^2$, $c_1 = rx$, $c_2 = -r$ and $f = 0$, and the initial condition becomes

$$u(x,0) = \max\{K - x, 0\} \quad \text{or} \quad u(x,0) = \max\{x - K, 0\}$$

by (3) and (7).
For a call option, condition (5) is satisfied considering $g_1(t) = 0$. For b sufficient large conditions (4) and (6) can be approximated by $g_2(t) = b - Ke^{-rt}$ and $g_4(t) = 1$.
Since we need another condition, motivated by the behavior of the solution for the linear equation, we consider $g_3(t) = 0$.
For a put option, (8), (9) and (10) implies that $g_1(t) = Ke^{-rt}$, $g_2(t) = 0$, $g_3(t) = 1$ and $g_4(t) = 0$.

Let w be a test function. Multiplying (16) by w and integrating in]a,b[, we obtain

$$\int_a^b u_t w\, dx - \int_a^b c_0 u_{xx} w\, dx - \int_a^b c_1 u_x w\, dx - \int_a^b c_2 u w\, dx = \int_a^b f w\, dx. \tag{19}$$

Since c_0 depends on u_{xx}, the integration by parts is useless. For relation (19) to make sense, u, u_t, u_x and $u_{xx} \in L_2(a,b)$, that is, u must be in $C^1(a,b)$, for $t \in]0,T]$. According to the conditions in (18), we choose the test function space to be

$$V_0 = \{w, w_x, w_{xx} \in L_2(a,b) : w(a) = w(b) = w_x(a) = w_x(b) = 0\},$$

and for the space solution we consider

$$V = \{u, u_t, u_x, u_{xx} \in L_2(a,b) : v(a,t) = g_1(t), v(b,t) = g_2(t), v_x(a,t) = g_3(t), v_x(b,t) = g_4(t) \\ \forall t \in [0,T]\},$$

 ISBN: 978-84-617-8694-7

4 Discretization in Space

Considering the discretization $a = x_0 < x_1 < \cdots < x_{m+1} = b$ of $[a, b]$, with spacing h and requiring continuity in C^1, we define for each node x_i, two Hermite interpolation polynomials, $\varphi_i(x)$ and $\psi_i(x)$. The Hermite interpolation polynomials have support $[x_{i-1}, x_{i+1}]$, and are defined by

$$\varphi_i(x) = \begin{cases} 2\left(\frac{x-x_i}{h}\right)^3 - 3\left(\frac{x-x_i}{h}\right)^2 + 1, & x \in [x_{i-1}, x_i], \\ \frac{(x-x_i)^3}{h^2} - \frac{2(x-x_i)^2}{h} + (x - x_i), & x \in [x_i, x_{i+1}] \end{cases} \tag{20}$$

and

$$\psi_i(x) = \begin{cases} -2\left(\frac{x-x_i}{h}\right)^3 + 3\left(\frac{x-x_i}{h}\right)^2 + 1, & x \in [x_{i-1}, x_i], \\ \frac{(x-x_i)^3}{h^2} - \frac{(x-x_i)^2}{h}, & x \in [x_i, x_{i+1}] \end{cases} \tag{21}$$

The Hermite cubic polynomials satisfy the following interpolation properties:

$$\varphi_j(x_i) = \begin{cases} 1 & , i = j \\ 0 & , i \neq j \end{cases}, \quad \varphi_j'(x_i) = 0, \tag{22}$$

$$\psi_j(x_i) = 0, \quad \psi_j'(x_i) = \begin{cases} 1 & , i = j \\ 0 & , i \neq j \end{cases}, i, j = 0, \ldots, m+1 \tag{23}$$

and hence they satisfy the required continuity conditions.
Let $T > 0$ and $\mathcal{H} = \langle \varphi_0, \psi_0, \varphi_1, \psi_1, \cdots, \varphi_{m+1}, \psi_{m+1} \rangle$, the vector subspace generated by the $2m + 2$ elements of the Hermite base. Let us consider the test function in

$$V_{0m} = \{w_m(x) \in \mathcal{H} : w_m(a) = w_m(b) = (w_m)_x(a) = (w_m)_x(b) = 0\} \subset V_0$$

and the approximate solution in

$$\begin{aligned} V_m = \{u_m(x,t) \in \mathcal{H} : u_m(a,t) = g_1(t),\ u_m(b,t) = g_2(t), \\ (u_m)_x(a,t) = g_3(t),\ (u_m)_x(b,t) = g_4(t), \quad \forall t \in [0,t]\} \subset V. \end{aligned}$$

A function $u_m \in V_m$ is said to be an approximate solution of (19) if, for each $t \in]0, T]$, it satisfies

$$\begin{aligned} &\int_a^b (u_m)_t w_m \, dx - \int_a^b c_0 (u_m)_{xx} w_m \, dx - \int_a^b c_1 (u_m)_x w_m \, dx \\ &- \int_a^b c_2 (u_m) w_m \, dx = \int_a^b f w_m \, dx, \qquad \forall w_m \in V_{0m}. \end{aligned} \tag{24}$$

 ISBN: 978-84-617-8694-7

Any function $w_m \in V_{0m}$ can be written as

$$w_m(x) = \sum_{i=1}^{m} W_i \varphi_i(x) + Z_i \psi_i(x), \tag{25}$$

and any function $u_m \in V_m$ can be written as

$$\begin{aligned} u_m(x,t) \quad &= \varphi_0(x) g_1(t) + \psi_0(x) g_3(t) + \sum_{i=1}^{m} \varphi_i(x) U_i(t) + \psi_i(x) V_i(t) \\ &+ \varphi_{m+1}(x) g_2(t) + \psi_{m+1}(x) g_4(t), \end{aligned} \tag{26}$$

Substituting (25) and (26) in equation (24) and simplifying the expressions, we obtain a system of ordinary differential equations, which can be written in matrix form:

$$MU(t)' - A(U(t))U(t) - B(U(t))U(t) - C(U(t))U(t) = F(t) + D(t), \tag{27}$$

with the unknown

$$U(t) = [U_1, ..., U_m, V_1, ..., V_m]^T.$$

In general, the solution $U(t)$ is not explicitly known for all $t \geq 0$, so it is necessary to use a numerical method to obtain an approximate solution.

5 Discretization in Time

Let us now consider the partition $0 = t_0 < t_1 < \cdots < t_N = T$, with step δ, of $[0, T]$. By the Cranck-Nicolson method, evaluating (27) in $t_{n+\frac{1}{2}} = \frac{t_n + t_{n+1}}{2}$ and using the approximations

$$U'(t_{n+\frac{1}{2}}) \approx \frac{U(t_{n+1}) - U(t_n)}{\delta} = \frac{U_{n+1} - U_n}{\delta} \tag{28}$$

and

$$U(t_{n+\frac{1}{2}}) \approx \frac{U(t_{n+1}) + U(t_n)}{2} = \frac{U_{n+1} + U_n}{2}, \tag{29}$$

we obtain

$$\begin{aligned} &(2M + \delta\,(A_{n+1} + B_{n+1} + C_{n+1})U_{n+1} = (2M - \delta\,(A_{n+1} + B_{n+1} + C_{n+1}))U_n \\ &+2\delta F_{n+1/2} - 2\delta D_{n+1/2}, \quad n = 0, 1, \cdots, N-1. \end{aligned} \tag{30}$$

Since the function $f(x,t)$ is known, $F_{n+1/2} = F(x, t_{n+1/2})$ is also known for all n. Then, for each $n = 0, 1, \cdots, N-1$, we have to solve the nonlinear system (30) and thus determine the solution $u(x,t)$ at discrete times $t_n = n\delta$.

 ISBN: 978-84-617-8694-7

For the system of algebraic equations (30), we propose the fixed point scheme:

$$\begin{aligned}&\left[2M+\delta\left(A_{n+1}^{(k)}+B_{n+1}^{(k)}+C_{n+1}^{(k)}\right)\right]U_{n+1}^{(k+1)}=(2MU_n\\&-\delta\left(A_{n+1}^{(k)}+B_{n+1}^{(k)}+C_{n+1}^{(k)}\right))U_n+2\delta F_{n+1/2}-2\delta D_{n+1/2}\end{aligned}\tag{31}$$

$$U_{n+1}^{(0)}=U_n\quad and\quad n=1,2,\ldots,N\quad k=1,2,\ldots.$$

6 Numerical results

In this section, we present the results of a Matlab implementation of the theory. First we validate the code by simulating the linear equation and calculating the error. Then we compare the solutions of the nonlinear equation obtained with the different modified volatilities presented.

Example 1: The analytical solution of the linear Black-Scholes equation in (1), where r and σ are constant and satisfying conditions (3), is given by the well-known formula [5]

$$V(S,t)=SN(d_1)-Ke^{-r(T-t)}N(d_2)\tag{32}$$

where $N(x)=(1/2\pi)\int_{-\infty}^{x}e^{\frac{-y^2}{2}}dy$, $x\in\mathbb{R}$ is the cumulative distribution function of $N(0,1)$, $d_1=\{\log(S/K)+\left(r+\sigma^2/2\right)(t-T)\}/\left(\sigma\sqrt{t-T}\right)$ and $d_2=d_1-\sigma\sqrt{(t-T)}$. Knowing the exact explicit solution permitted us to calculate the exact error of the approximations. We simulated equation (16) using the parameters $T=1$, $r=0.1$, $\sigma=0.2$, $a=0.4$, $b=1$, $K=0.4$, $T=1$, $g_1(t)=0$, $g_2(t)=1-0.4e^{rt}$, $g_3(t)=0$, $g_4(t)=1$ and $u_0(x)=\max\{x-0.4,0\}$.
In Figure (1), we present the solution obtained with $h=0.01$ and $\delta=0.001$, in some instants. We may observe that the behaviour is similar to the behaviour of the exact solution. In figure (2), the convergence error for h is studied, that is, we establish a fixed value $\delta=0.001$ and different values of $h=0.1,0.01,0.001$. For each value of h, we calculated the error in the $L_2(a,b)$ norm and we collected the results in the graph represented.
From the figure presented we may conclude that the convergence is only of order 2. We suspect that this behaviour is due to the lack of regularity of the solution.

Example 2: In order to compare the behaviour of the solution for the different models presented, we simulated Equation (16) for each model. In Figure 3, we represent the solution and the first derivative of the non-linear Black-Scholes equation for the different transaction costs models at $t=0$. The parameters used are: $r=0.2$, $\sigma=0.2$, $Le=0.6$, $M=30$, $C=0.01$, $a^2=0.4$, $K=0.4$, $T=1$, $h=0.1$, $\delta=0.001$, $g_1(t)=0$, $g_2(t)=1-0.4e^{rt}$, $g_3(t)=0$, $g_4(t)=1$ and $u_0(x)=\max\{x-0.4,0\}$.

 ISBN: 978-84-617-8694-7

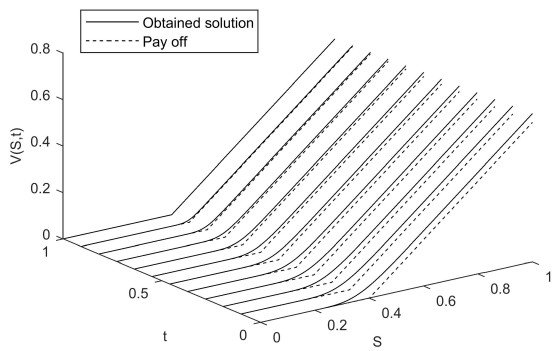

Figure 1: Obtained solution in example 1.

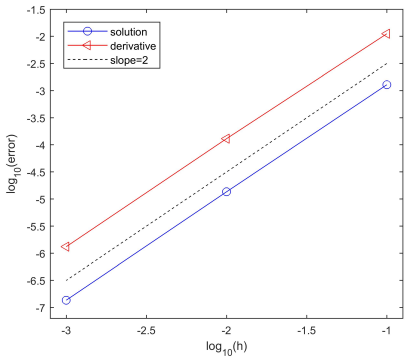

Figure 2: Convergence analysis for h in example 1.

The chart shows that the difference is not significant for all the transaction cost models. At this point, with the given parameters, the Leland model provides the highest price, followed by the Barles and Soner model, the Kratka model, and finally the linear model with constant volatility without transaction costs. An analysis from the initial to the maturity date permits us to conclude that the difference between the various models decreases as the expiration date approaches. This is an expected consequence of the decreasing necessity of portfolio adjustment and hence lower transaction costs closer to expiry. The difference is bigger at the beginning of the year, where the non-linear price is higher than the linear price.

7 Conclusions

A finite element method based on Hermite polynomials, to solve the non-linear problem in the non-divergent form, in a domain with fixed boundaries, was presented. The program resulting from the implementation of this method in Matlab code was tested with the linear equation. The error and convergence analysis was done in Example 1. The Crank-Nicolson method presents a convergence order of 2, for both solution and its derivative, while the finite element method has a convergence order of approximately 2 for the solution and 2 for its derivative, which does not fit the methods applied in this work. In Example 2, the solution and the derivative of the non-linear Black-Scholes equation were simulated with the different transaction cost models, taking into account the European-type call option. The study shows that the difference is not significant for all transaction cost models and it decreases the closer we are from the expiration date. As future work, we will carry out a similar study for American options.

Abstract

This paper describes the highlights of our algorithm implementation for the computation of the trigonometric functions sine and cosine of a matrix. This algorithm is based on a Taylor series approximation, which is characterized from the computational point of view because is very rich in matrix multiplications. We have used this feature to develop an implementation that can use one or two GPUs if available. In addition, our implementation can be easily used in the MATLAB environment.

Key words: Matrix Trigonometric functions, GPU computing, MATLAB, mex MATLAB.

1 Introduction

The trigonometric matrix functions *sine* and *cosine* arise in many engineering processes that are described by second order differential equations. Several state-of-the-art algorithms have been provided recently for computing these matrix functions using polynomial and rational approximations with scaling and recovering techniques [3, 5, 1]. One of the last and most competitive proposals in both accuracy and performance to obtain the cosine of a matrix

A ($\cos(A)$) is [2], which is a Taylor based algorithm. This paper addresses the challenge of performing the computation suggested in [2] as fast as possible on a computer composed by a multicore CPU and two NVIDIA GPUs. The challenge is twofold since the aim is also to develop an easy-to-use interface that allows the user to execute our algorithm from MATLAB.

2 Matrix Cosine Computation

The matrix cosine can be defined for all $A \in \mathbb{C}^{n\times n}$ by

$$\cos(A) = \sum_{i=0}^{\infty} \frac{(-1)^i A^{2i}}{(2i)!} ,$$

and let

$$T_{2m}(A) = \sum_{i=0}^{m} \frac{(-1)^i B^i}{(2i)!} \equiv P_m(B), \tag{1}$$

be the Taylor approximation of order $2m$ of $\cos(A)$, where $B = A^2$. We have implemented an "accelerated" version of the algorithm in [2] that computes a Taylor approximation $P_m(B)$ (1). The approximation of $\cos(A)$ is recovered by means of the double angle formula $\cos(2X) = 2\cos^2(X) - I$. By using the fact that $\sin(A) = \cos(A - \frac{\pi}{2}I)$, the same algorithm can also be used to compute the matrix sine.

3 The Accelerated Version

In our implementation, just like in [2], we have used a technique called Paterson-Stockmeyer's method [4] that allows to reduce the number of matrix products. But still the number of matrix products can be large. The fact that the computational cost is based on matrix products is a good reason to use GPUs since the matrix product is a very optimized operation in GPU. Using one or two GPUs is thus a logical step forward in reducing the execution time required to compute (1). Our implementation is efficient because it highly exploits the capabilities of the underlying existing GPUs.

The *accelerated* version was developed with the aim of being not only efficient but also easy to use and easy to modify. This is accomplished by keeping the MATLAB interface and syntax of the original algorithm [2]. The strategy consists of executing those parts of the MATLAB function that are good candidates to be accelerated using MATLAB *mex functions* implemented in CUDA and C++, and leaving the remaining operations to the host.

Data in both host and device memories must be persistent all along the time a MATLAB function is executing. A key point of our implementation is the use of only one `mex` function

 ISBN: 978-84-617-8694-7

to implement all the different operations because some data must remain in the device memory between consecutive calls, and this can be realized calling repeatedly to the same `mex` function. The `mex` function implemented, called `call_gpu`, has a string as its first argument (we name it the *command tag*) that labels the action to do. The rest of the arguments depend on the action to be performed. For example, `call_gpu('init',A))`, which actually is the first call that must be written in the code, allocates memory into the device to host some matrices like, e.g. matrix A and the resulting matrix, among others. Under this command, matrix A is also transferred from the MATLAB working space in the host memory to the device memory. Other operations implemented for the GPU are called with labels `'scale'`, `'unscale'`, `'power'`, `'norm1'`, and `'finalize'`.

This solution provides ease to the user. The original MATLAB code is modified with very few commands, i.e. only replacing few lines in the code with calls to the `mex` function with the appropriate *command tag*. This can be carry out by a non expert user on GPUs and/or on CUDA programming. However, the user who implements the MATLAB code must be aware that once matrix A has been uploaded to the GPU, this matrix and the derived ones, e.g. (B_1, B_2, ...), will be stored only into the device.

4 Experimental Results

The experimentation has been performed on a host computer, equipped with an Intel Quad-Core i7-3820 (3.6Ghz) processor, and with two NVIDIA GPU of type K20c (Kepler architecture) attached. Each GPU has 13 multiprocessors with 192 cores each, resulting in a total of 2496 CUDA cores. The two devices jointly make available to the user a total of 4992 CUDA cores for processing. Each device features 4800 MBytes of RAM memory.

The experiment shown in Figure 1 compares the execution time using the host CPU, one GPU or two GPUs. In general, it can be stated that the overhead incurred by data transference through the PCIe bus in implementations that use GPUs makes inadequate its use for small problem sizes. The raw MATLAB implementation for CPU is the best option when the problem size is less than $n \approx 520$ in case there are two GPUs available, or $n \approx 640$ when there exists just one GPU within reach. The use of two GPUs is always better than using only one for problems larger than ≈ 60.

5 Conclusions

This contribution describes the two key features of our implementation of the Taylor series approximation algorithm proposed in [2] to calculate the sine (or cosine) of a matrix. Our implementation can use one or two GPUs. The application is easy to use since the commands provided to the user can be easily integrated into a MATLAB code.

 ISBN: 978-84-617-8694-7

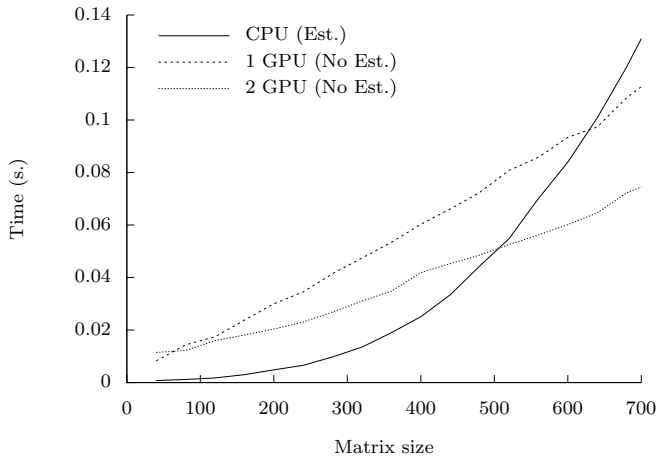

Figure 1: Execution time to obtain $\cos(A)$ using the CPU, 1 GPU, and 2 GPUs.

Our solution outperforms MATLAB in the sense that, though currently MATLAB provides with some functions that allow to use one GPU, it is not possible yet to use two GPUs at the same time.

Abstract

Several pivoting strategies for Neville elimination of almost strictly sign regular matrices are recalled and compared. They are also compared with Gauss elimination with partial pivoting. Some optimal properties of two-determinant pivoting are presented.

Key words: pivoting strategies, almost strictly sign regular matrices
MSC 2000: 65F05, 65F15, 65F35

1 Introduction

Numerical methods adapted to structured classes of matrices have been studied recently. A very important class of structured matrices due to its applications is the class of *sign regular* (SR) matrices. A matrix is SR if all its minors of the same order have the same sign. The importance of nonsingular SR matrices comes from their characterization as variation diminishing transformations. This property has played a crucial role in the applications to Statistics, Economy or Computer-Aided Geometric Design (see [5, 6, 15]).

A relevant subclass of SR matrices is formed by *totally positive* (TP) matrices, that is, matrices such that all their minors are nonnegative. The study of TP matrices began in 1930 with the work of Schoenberg (see [17]). The exhaustive research carried out in the field of TP matrices is reflected in books written several decades ago, such as Gantmacher and Krein, whose original was published in Russian in 1941 and has an English version of 2002 (see [9]), or Karlin's 1968 book (see [14]). There are also more recent texts such as that edited by Gasca and Michelli in 1996 (see [10]) and more recently Pinkus' book (see [16]) and Fallat and Johnson's book (see [8]). In contrast, the knowledge about the class

of SR matrices is much smaller. This is due, above all, to the much greater difficulties that arise from their study.

The goal of this work is the study of another subclass of SR matrices: the *almost strictly sign regular* (ASSR) matrices (see [1]). These matrices have all their nontrivial minors of the same order with the same strict sign and this subclass contains the nonsingular *almost strictly totally positive* (ASTP) matrices, introduced by Gasca, Miccheli and Peña (see [11]). A nonsingular matrix is ASTP if a minor with consecutive rows and columns is positive if and only if it has positive diagonal entries. Hurwitz matrices and B-splines collocation matrices are examples of ASTP matrices. In general, problems with ASSR matrices are much more difficult to deal with than the corresponding problems for ASTP matrices.

This work analyzes several aspects about the application of some pivoting strategies to ASSR matrices using Neville elimination (NE) or Gaussian elimination (GE). NE is an elimination procedure alternative to GE, very useful when dealing with SR matrices and their subclasses.

In [12] the scaled partial pivoting with respect to the l_∞-norm and Euclidean norm are studied for GE and NE applied to totally positive linear systems. It is proved that in exact arithmetic row exchanges are not necessary. In [2] a backward error analysis of Neville procedure is presented (with and without pivoting strategy). In the case of TP matrices, the error bounds are similar to those obtained previously by other authors for GE. In 2007 a pivoting strategy called two-determinant pivoting (see [7]) is analyzed. The application of NE with two-determinant pivoting strategy to ASSR matrices is studied in [3]. It is shown that this procedure preserves the almost strict sign regularity and that the associated Wilkinson-type growth factor is optimal.

This work is organized as follows. In Section 2 we present several pivoting strategies for NE. In Section 3 we compare, these pivoting strategies and GE with partial pivoting, using an illustrative example. Moreover, we announce the better properties of the two-determinant pivoting strategies under several points of view.

2 Some pivoting strategies for Neville elimination

In this section we briefly present the NE and several row pivoting strategy associated to this method.

NE is a very convenient procedure when working with ASSR matrices and other related types of matrices. If A is a nonsingular $n \times n$ matrix, NE consists of at most $n-1$ successive major steps, resulting in a sequence of matrices as follows:

$$A = \widetilde{A}^{(1)} \to A^{(1)} \to \cdots \to \widetilde{A}^{(n)} = A^{(n)} = U \tag{1}$$

where U is an upper triangular matrix.

 ISBN: 978-84-617-8694-7

For each t, $1 \leq t \leq n$, $A^{(t)} = \left(a_{ij}^{(t)}\right)_{1\leq i,j\leq n}$ has zeros in the positions $a_{ij}^{(t)}$, for $1 \leq j \leq t$, $j \leq i \leq n$. Besides it holds that

$$a_{it}^{(t)} = 0,\ i \geq t \Rightarrow a_{ht}^{(t)} = 0,\ \forall h \geq i. \tag{2}$$

The matrix $A^{(t)}$ is obtained from $\widetilde{A}^{(t)}$ reordering rows t, $t+1$, ..., n according to a row pivoting strategy that satisfies (2).

To obtain $\widetilde{A}^{(t+1)}$ from $A^{(t)}$ we produce zeros in the column t below the main diagonal by subtracting a multiple of the ith row from the $(i+1)$th, for $i = n-1,\ n-2,\ \ldots,\ t$, according to the following formula:

$$\widetilde{a}_{ij}^{(t+1)} = \begin{cases} a_{ij}^{(t)}, & 1 \leq i \leq t, \\ a_{ij}^{(t)} - \frac{a_{it}^{(t)}}{a_{i-1,t}^{(t)}} a_{i-1,j}^{(t)}, & \text{if } a_{i-1,t}^{(t)} \neq 0, \quad t+1 \leq i \leq n, \\ a_{ij}^{(t)}, & \text{if } a_{i-1,t}^{(t)} = 0, \quad t+1 \leq i \leq n, \end{cases} \tag{3}$$

for all $j = 1, 2, \ldots, n$.

The element

$$p_{ij} = a_{ij}^{(j)}, \quad 1 \leq j \leq i \leq n \tag{4}$$

is called the (i,j) *pivot* of NE of A and the number

$$m_{ij} = \begin{cases} \dfrac{a_{ij}^{(j)}}{a_{i-1,j}^{(j)}} \left(= \dfrac{p_{ij}}{p_{i-1,j}} \right), & \text{if } a_{i-1,j}^{(j)} \neq 0, \\ 0, & \text{if } a_{i-1,j}^{(j)} = 0, \end{cases} \tag{5}$$

the (i,j) *multiplier*. Note that $m_{ij} = 0$ if and only if $p_{ij} = 0$ and, by (2),

$$m_{ij} = 0 \implies m_{hj} = 0,\ \forall h > i. \tag{6}$$

Now we present some pivoting strategies for NE, using row exchanges with similar purposes to those of the pivoting strategies for GE. Recall that $A^{(t)}$ is obtained by reordering the rows of matrix $\widetilde{A}^{(t)}$ by an adequate pivoting strategy with a criterion for the choice of the pivots p_{ij}. GE with partial pivoting chooses the pivots so that all multipliers have absolute value not greater than 1. With a similar purpose, one can define *NE with partial pivoting*. We interchange the rows of $\widetilde{A}^{(t)}$ so that $A^{(t)}$ satisfies

$$|a_{tt}^{(t)}| \geq |a_{t+1,t}^{(t)}| \geq \cdots \geq |a_{nt}^{(t)}|$$

and from $A^{(t)}$ we construct $\widetilde{A}^{(t+1)}$ as in (3).

 ISBN: 978-84-617-8694-7

To improve the previous strategy we will incorporate an adequate scaling, thus arising the scaled partial pivoting, if we use the standard $\|\cdot\|_\infty$, or the Euclidean scaled partial pivoting if the norm used is Euclidean $\|\cdot\|_2$ (see [12]).

We will denote by $r_i^{(t)}$ to the ith row of the submatrix $A^{(t)}[1,\dots,n|t,\dots,n]$, with $i=t,t+1,\dots,n$ and $t=1,\dots,n-1$, and with $s_i^{(t)}$, $S_i^{(t)}$ to the amounts

$$\begin{aligned} s_i^{(t)} &= \|r_i^{(t)}\|_\infty = \max_{t\le j\le n} |a_{ij}^{(t)}|, \\ S_i^{(t)} &= \|r_i^{(t)}\|_2 = ((a_{it}^{(t)})^2+\cdots+(a_{in}^{(t)})^2)^{1/2}. \end{aligned} \tag{7}$$

In the *scaled partial pivoting for NE*, for each value of t, the rows of $A^{(t)}$, from the row tth to the nth are ordered according to a permutation $(i_1,i_2,\dots,i_{n-t+1})$ of the elements $(t,t+1,\dots,n)$, so that

$$\frac{|a_{i_1,t}^{(t)}|}{s_{i_1}^{(t)}} \ge \frac{|a_{i_2,t}^{(t)}|}{s_{i_2}^{(t)}} \ge \cdots \ge \frac{|a_{i_{n-t+1},t}^{(t)}|}{s_{i_{n-t+1}}^{(t)}}. \tag{8}$$

Then, $A^{(t)}$ has been obtained by substituting the tth row of $\widetilde{A}^{(t)}$ for the i_1th, $(t+1)$th for the i_2th and so on.

For the case of the Euclidean scaled partial pivoting strategy, we can obtain an analogous expression to (8) simply replacing in it $s_i^{(t)}$ for $S_i^{(t)}$.

In [7] a row pivoting strategy associated to NE for nonsingular SR matrices is introduced. It will be called two-determinant pivoting strategy due to the special role played by some 2×2 determinants of some matrices appearing along the Neville procedure. Besides, the authors also study the scaled partial pivoting in NE.

The criterion of the *two-determinant pivoting* strategy to obtain $A^{(t)}[t,\dots,n]$ from a reordering of the rows of $\widetilde{A}^{(t)}[t,\dots,n]$ is the following:

- If $\widetilde{a}_{tt}^{(t)} = 0$: then we reverse the ordering of the rows, that is, $A^{(t)}[t,\dots,n] := P_{n-t+1}\widetilde{A}^{(t)}[t,\dots,n]$.
- If $\widetilde{a}_{nt}^{(t)} = 0$: then we do not perform rows exchanges, that is, $A^{(t)} := \widetilde{A}^{(t)}$.
- If $\widetilde{a}_{tt}^{(t)} \neq 0$ and $\widetilde{a}_{nt}^{(t)} \neq 0$, then we compute the determinant $d_1 = \det \widetilde{A}^{(t)}[t,t+1]$.
  - If $d_1 > 0$ then $A^{(t)} := \widetilde{A}^{(t)}$.
  - If $d_1 < 0$ then $A^{(t)}[t,\dots,n] := P_{n-t+1}\widetilde{A}^{(t)}[t,\dots,n]$.
  - If $d_1 = 0$ then compute the determinant $d_2 = \det \widetilde{A}^{(t)}[n-1,n|t,t+1]$.
    - If $d_2 > 0$ then $A^{(t)} := \widetilde{A}^{(t)}$.
    - If $d_2 < 0$ then $A^{(t)}[t,\dots,n] := P_{n-t+1}\widetilde{A}^{(t)}[t,\dots,n]$.

 ISBN: 978-84-617-8694-7

In Section 3 of [7] it is shown that this pivoting strategy is well defined for nonsingular SR matrices. The computational cost of the NE without row exchanges for an $n \times n$ matrix coincide with the cost of GE without row exchanges. So it has a cost of $\frac{4n^3+3n^2-7n}{6} \simeq \frac{2n^3}{3}$ flops (floating-point operations). Using the two-determinant pivoting strategy, this cost is increased with at most $2n-2$ subtractions and $4n-4$ multiplications. Besides, by Theorem 4.1 of [7], for a nonsingular SR matrix, the two-determinant pivoting strategy for NE is a scaled partial pivoting strategy for any monotone vector norm.

Other pivoting strategies used in both GE and NE are called pairwise pivoting (see [18, 19]). These are suitable for implementations on parallel computers and reduce the communication cost considerably .

In contrast to row pivoting strategies described above (associated with (1)) pairwise pivoting strategies interchange consecutive rows in each step and then produce a zero. In fact *pairwise pivoting for NE* is defined as follows: to produce a zero at position $(n,1)$ in $\widetilde{A}^{(1)}$, one compares the element $\widetilde{a}_{n1}^{(1)}$ with $\widetilde{a}_{n-1,1}^{(1)}$. If $|\widetilde{a}_{n1}^{(1)}| > |\widetilde{a}_{n-1,1}^{(1)}|$ the corresponding rows are exchanged, in order that $|\widetilde{a}_{n1}^{(1)}/\widetilde{a}_{n-1,1}^{(1)}| \leq 1$. Then the elements of row n are updated producing a zero in the $(n,1)$ entry. We continue with the first column until producing a zero in the $(2,1)$ entry, and then we would continue with the second column and later columns, analogously to NE, until obtaining an upper triangular matrix U. For a nonsingular matrix A, NE with pairwise pivoting consists of al most $n(n-1)/2$ successive step, resulting in a sequence of matrices as follows:

$$A = \widetilde{A}^{(1)} \to A^{(1)} \to \cdots \to \widetilde{A}^{(\frac{n(n-1)}{2})} = A^{(\frac{n(n-1)}{2})} = U \tag{9}$$

where U is an upper triangular matrix.

3 Comparison of the pivoting strategies

In this section, some aspects regarding the application of pivoting strategies defined in the previous section to ASSR matrices are studied. We compare those pivoting strategies under different points of view.

Let A be an $n \times n$ matrix. The Wilkinson-type growth factor associated to NE with a certain pivoting strategy is given by

$$\rho(A) = \frac{\max_{i,j,t} \left|\widetilde{a}_{ij}^{(t)}\right|}{\max_{i,j} |a_{ij}|} \tag{10}$$

where $\widetilde{A}^{(t)} = \left(\widetilde{a}_{ij}^{(t)}\right)_{1\leq i,j\leq n}$ are the intermediate matrices of the elimination process. A similar Wilkinson-type growth factor for GE with partial pivoting can be defined (see Section 9.3 of [13]).

 ISBN: 978-84-617-8694-7

We shall define another growth factor, which is a normwise growth factor, in contrast to the componentwise growth factor defined in (10). We announce that the two-determinant pivoting strategy is optimal for both growth factors. It also has other important advantages over the other pivoting strategies defined in Section 2. In fact, two-determinant pivoting is zero-increasing and preserves the almost strictly sign regularity.

Given an ASSR matrix A we can observe that, NE with partial pivoting, GE with partial pivoting and pairwise pivoting for NE do not preserve the structure of this matrix. The following example illustrates this situation.

Let A be an ASSR matrix with signature $\varepsilon = (-1, 1, -1, 1, -1, -1)$

$$A = \widetilde{A}^{(1)} = \begin{pmatrix} -1 & -4 & 0 & 0 & 0 & 0 \\ -2 & -10 & -10 & -16 & -2 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}.$$

Taking into account that $|a_{21}| = 2 > |a_{11}| = 1$, the application of NE with partial pivoting (which coincides with GE with partial pivoting in the first step) implies that the rows 1 and 2 must be exchanged, so

$$A^{(1)} = \begin{pmatrix} -2 & -10 & -10 & -16 & -2 & 0 \\ -1 & -4 & 0 & 0 & 0 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}, \ \widetilde{A}^{(2)} = \begin{pmatrix} -2 & -10 & -10 & -16 & -2 & 0 \\ 0 & 1 & 5 & 8 & 1 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}$$

and $\widetilde{A}^{(2)}[2, \ldots, 6]$ matrix is not an ASSR matrix. Note that $\widetilde{A}^{(2)}$ has less zeros than A.

If pairwise pivoting with NE is considered, then

$$A = \widetilde{A}^{(1)} = A^{(1)} = \widetilde{A}^{(2)} = A^{(2)} = \widetilde{A}^{(3)} = A^{(3)} = \widetilde{A}^{(4)}$$

and the matrices

$$A^{(4)} = \begin{pmatrix} -2 & -10 & -10 & -16 & -2 & 0 \\ -1 & -4 & 0 & 0 & 0 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}, \ \widetilde{A}^{(5)} = \begin{pmatrix} -2 & -10 & -10 & -16 & -2 & 0 \\ 0 & 1 & 5 & 8 & 1 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}.$$

Observe that the property of almost strict sign regularity is not inherited by $\widetilde{A}^{(5)}[2, \ldots, 6]$. Note also that $\widetilde{A}^{(5)}$ has less zeros than A.

 ISBN: 978-84-617-8694-7

As for two-determinant pivoting strategy, we get the following matrices $A = \widetilde{A}^{(1)} = A^{(1)}$ and

$$\widetilde{A}^{(2)} = \begin{pmatrix} -1 & -4 & 0 & 0 & 0 & 0 \\ 0 & -2 & -10 & -16 & -2 & 0 \\ 0 & -6 & -33 & -60 & -21 & 0 \\ 0 & -8 & -46 & -92 & -70 & -36 \\ 0 & 0 & -9 & -60 & -242 & -316 \\ 0 & 0 & -6 & -60 & -443 & -2823 \end{pmatrix}.$$

In this case $\widetilde{A}^{(2)}[2, \ldots, 6]$ is ASSR and $\widetilde{A}^{(2)}$ has more zeros than A. These properties also hold by matrices $\widetilde{A}^{(t)}[t, \ldots, 6]$, for all $t = 3, \ldots, 6$, when we apply NE with two-determinant pivoting. Besides, $\rho(A) = 1$ and in this case the stability of the strategy is assured.

Abstract

In this paper, we offer a comparison in terms of computational efficiency between two techniques to avoid order reduction when using Strang method to integrate nonlinear initial boundary value problems with time-dependent boundary conditions. Considering different implementations for each of the techniques, we show that the technique suggested by Alonso et al. is more efficient than the one suggested by Einkemmer et al.

Key words: Strang splitting, avoiding order reduction, computational comparison,
MSC 2000: 65M12 65M20

1 Introduction

There are several papers in the literature concerning the important fact of avoiding the order reduction in time which turns up when integrating with splitting methods nonlinear problems of the form

$$\begin{aligned} u'(t) &= Au(t) + f(t, u(t)), \quad 0 \le t \le T, \\ \partial u(t) &= g(t), \\ u(0) &= u_0, \end{aligned} \tag{1}$$

where A is an elliptic differential operator, f is a smooth real function which acts as a reaction term, ∂ is a boundary operator, g is the boundary condition which in principle does not vanish and is time-dependent and u_0 is a smooth initial condition which makes that the solution of (1) is regular enough.

 ISBN: 978-84-617-8694-7

More particularly, in [6, 7] a technique is suggested to do it, in which each part of the splitting is assumed to be solved in an exact way for the analysis and, in the numerical experiments, standard subroutines are used to integrate each part in space and time. Although, from the point of view of the analysis, the technique in both papers is equivalent, the difference is that, in [6], the solution of this elliptic problem is required at each time $t \in [0, T]$,

$$Az(t) = 0, \quad \partial z(t) = g(t),$$

and a suggestion for $z_t(t)$ must be given. This is very simple analytically in one dimension but much more complicated and expensive in several dimensions. Nevertheless, that is avoided in [7] by considering just a function q which coincides with $f(g)$ at the boundary. That can also be done analytically in one dimension and simple domains in two dimensions, and numerically in more complicated domains, according to a remark made in [7] although it is not in fact applied to such a problem there. In this paper, we will concentrate on the technique in [7] for 1-dimensional and 2-dimensional simple domains.

On the other hand, in [3], another different technique is suggested in which appropriate boundary conditions are suggested for each part of the splitting. The analysis there considers both the space and time discretization. The linear and stiff part is integrated 'exactly' in time through exponential-type functions while the nonlinear but smooth part is assumed to be numerically integrated by a classical integrator just with the order of accuracy that the user wants to achieve with the whole method. Although the latter seems to be the more natural, in order to be more similar in the comparison with the technique in [7], we will use standard subroutines which use variable stepsizes with given small tolerances for the nonlinear and smooth problems of both techniques.

We will concentrate on the extensively used second-order Strang splitting and the aim of the paper is to compare both techniques in terms of computational efficiency, considering different space discretizations, different tolerances for the standard subroutines which integrate in time some of the split problems, and different (although standard) ways to tackle the calculation of terms which contain exponential-type functions of matrices. For that, both one-dimensional and bidimensional problems will be considered. There is already another comparison in the literature between both techniques [8] but there they just compare in terms of error against the time stepsize without entering into the details of implementation and its computational cost, which we believe that is the interesting comparison. Moreover, they just consider time-independent boundary conditions and 1-dimensional problems, for which many simplifications can be made.

The paper is structured as follows. Section 2 gives some preliminaries on the description of the different techniques and suggest different implementations for each of them. Section 3 presents results for all the methods suggested in terms of error against cpu time when using accurate spectral collocation methods in space and very small tolerances for the standard subroutines in time. Section 4 offers also a numerical comparison, but now using less

 ISBN: 978-84-617-8694-7

accurate finite differences in space and less small tolerances for the standard subroutines in time. Moreover, numerical differentiation is also considered in order to achieve local order 3 instead of just 2, and again the computational comparison is performed.

2 Preliminaries and suggestion of different implementations

The technique suggested in [7] consists of the following: A function $q(t)$ is constructed which satisfies $\partial q(t) = \partial f(t, u(t))$. Then, given the numerical approximation at the previous step u_n, the numerical approximation at the next step u_{n+1} is given by the following procedure:

$$\begin{aligned}
&\left\{\begin{array}{rcl} v'_{n,1}(t) &=& Av_{n,1}(t) + q(t), \\ v_{n,1}(t_n) &=& u_n, \\ \partial v_{n,1}(t) &=& g(t), \end{array}\right. \\
&\left\{\begin{array}{rcl} w'_n(t) &=& f(t, w_n(t)) - q(t), \\ w_n(t_n) &=& v_{n,1}(t_n + \frac{k}{2}), \end{array}\right. \\
&\left\{\begin{array}{rcl} v'_{n,2}(t) &=& Av_{n,2}(t) + q(t), \\ v_{n,2}(t_n + \frac{k}{2}) &=& w_n(t_n + k), \\ \partial v_{n,2}(t) &=& g(t), \end{array}\right. \\
&u_{n+1} = v_{n,2}(t_n + k).
\end{aligned} \tag{2}$$

However, we notice that two of three problems which turn up here are stiff and therefore solving them will be more expensive than solving the unique nonlinear but smooth problem. In order to reverse that, the decomposition of the splitting method can be done in another order and then the following procedure would turn up, for which with similar arguments, no order reduction would either turn up:

$$\begin{aligned}
&\left\{\begin{array}{rcl} w'_{n,1}(t) &=& f(t, w_{n,1}(t)) - q(t), \\ w_{n,1}(t_n) &=& u_n, \end{array}\right. \\
&\left\{\begin{array}{rcl} v'_n(t) &=& Av_n(t) + q(t), \\ v_n(t_n) &=& w_{n,1}(t_n + \frac{k}{2}), \\ \partial v_n(t) &=& g(t) \end{array}\right. \\
&\left\{\begin{array}{rcl} w'_{n,2}(t) &=& f(t, w_{n,2}(t)) - q(t), \\ w_{n,2}(t_n + \frac{k}{2}) &=& v_n(k), \end{array}\right. \\
&u_{n+1} = w_{n,2}(t_n + k).
\end{aligned} \tag{3}$$

Then, two of the problems are cheap and just one is more expensive.

On the other hand, in [3], the main idea is to consider, from u_n,

$$\left\{\begin{array}{rcl} w'_n(s) &=& Aw_n(s), \\ w_n(0) &=& \Psi^{f,t_n}_{\frac{k}{2}}(u_n), \\ \partial w_n(s) &=& \partial[u(t_n) + \frac{k}{2} f(t_n, u(t_n)) + sAu(t_n)], \end{array}\right.$$

 ISBN: 978-84-617-8694-7

$$u_{n+1} = \Psi_{\frac{k}{2}}^{f,t_n+\frac{k}{2}}(w_n(k)).$$

where $\Psi_{\frac{k}{2}}^{f,t_n}$ and $\Psi_{\frac{k}{2}}^{f,t_n+\frac{k}{2}}$ integrate respectively with order 2 the following problems from $s = 0$ to $s = k/2$:

$$v_n'(s) = f(t_n + s, v_n(s)), \quad z_n'(s) = f(t_n + \frac{k}{2} + s, z_n(s)).$$

Moreover, the procedure to integrate this is more explicitly stated. Firstly, in [3] (see also [1, 2, 5]), a general space discretization is introduced which discretizes the elliptic problem

$$Au = F, \quad \partial u = g,$$

through the 'elliptic projection' $R_h u$ which satisfies

$$A_{h,0}R_h u + C_h g = P_h F,$$

for a certain matrix $A_{h,0}$, an associated boundary operator C_h and a projection operator P_h. Then, given the numerical approximation at the previous step U_h^n, the procedure in [3] to obtain U_h^{n+1} reads as follows:

$$\begin{aligned} V_h^n &= \Psi_{\frac{k}{2}}^{f,t_n}(U_h^n), \\ W_{h,n}(k) &= e^{kA_{h,0}}V_h^n + k\varphi_1(kA_{h,0})C_h[g(t_n) + \frac{k}{2}\partial f(t_n, u(t_n))] \\ &\quad + k^2\varphi_2(kA_{h,0})C_h[g'(t_n) - \partial f(t_n, u(t_n)] \\ U_h^{n+1} &= \Psi_{\frac{k}{2}}^{f,t_n+\frac{k}{2}}(W_{h,n}(k)), \end{aligned} \tag{4}$$

where φ_1 and φ_2 are the standard functions which are used in exponential methods [3]. The original suggestion used this order for the decomposition thinking that Ψ_k is just an explicit method which is applied with a single stepsize k, and therefore it would be cheaper than the equation in $W_{h,n}(k)$. We still believe that would be the best. However, as in this paper, in order to do it more similarly to [7], we will solve that part with a standard variable stepsize subroutine for non-stiff problems until a given small tolerance, the first and last problem may be more expensive than the middle one. Therefore, we will also consider this other implementation which comes from reversing the order of the problems in the decomposition:

$$\begin{aligned} W_{h,n}(\frac{k}{2}) &= e^{\frac{k}{2}A_{h,0}}U_h^n + \frac{k}{2}\varphi_1(\frac{k}{2}A_{h,0})C_h g(t_n) + \frac{k^2}{4}\varphi_2(\frac{k}{2}A_{h,0})C_h\partial Au(t_n) \\ V_h^n &= \Psi_k^{f,t_n}(W_{h,n}(\frac{k}{2})), \\ U_h^{n+1} &= e^{\frac{k}{2}A_{h,0}}V_h^n + \frac{k}{2}\varphi_1(\frac{k}{2}A_{h,0})C_h\partial[u(t_n) + \frac{k}{2}Au(t_n) + kf(t_n, u(t_n)] \\ &\quad + \frac{k^2}{4}\varphi_2(\frac{k}{2}A_{h,0})C_h\partial Au(t_n). \end{aligned} \tag{5}$$

 ISBN: 978-84-617-8694-7

In the following, we will denote by **EO1** to (3), by **EO2** to (2), by **ACR1** to (4) and by **ACR2** to (5).

3 Numerical comparison with spectral collocation methods in space and high accuracy in time

In this section a comparison in terms of computational efficiency among the different techniques is given when solving all the problems at hand with high accuracy. In such a way, we will be seeing the error which comes from the splitting itself for a large range of values of the timestepsize k. More precisely, spectral collocation methods [4] are used for the space discretization with the two implementations of both techniques. Moreover, the nonlinear and non-stiff problems of both techniques are integrated with MATLAB subroutine ode45 with relative tolerance 10^{-12} and absolute tolerance 10^{-15}. As for the linear and stiff part of **EO1** and **EO2** ((3) and (2) respectively), we have considered subroutine ode15s with the same tolerances. On the other hand, in this section, for the implementation of the equation on $W_{h,n}$ in **ACR1** and the first and last equation in **ACR2** ((4) and (5) respectively), as $A_{h,0}$ is a full but small matrix and we consider k as fixed during the whole integration, we have calculated once and for all the matrices $e^{kA_{h,0}}$, $\varphi_1(kA_{h,0})C_h$ and $\varphi_2(kA_{h,0})C_h$. The calculation of these matrices is not included in the measured computational time since this initial cost is negligible when integrating till large times but may be very big when T is small. (For another implementation of those terms with no initial cost, look at Section 4.)

In a first place, we have considered the following one-dimensional Dirichlet boundary value problem whose exact solution is $u(x,t) = e^{t+x^3}$:

$$\begin{aligned} &u_t(x,t) = u_{xx}(x,t) + u^2 - e^{t+x^3}(9x^4 + 6x + e^{t+x^3} - 1), \quad 0 \le x \le 1, \quad t \in [0, 0.2], \\ &u(x,0) = e^{x^3}, \\ &u(0,t) = e^t, \quad u(1,t) = e^{t+1}. \end{aligned} \tag{6}$$

For the spectral space discretization, 16 Gauss-Lobatto interior nodes have been used so that the error in space is negligible. We also notice that the matrix $e^{kA_{h,0}}$ has dimension 16×16 while $\varphi_1(kA_{h,0})C_h$ and $\varphi_2(kA_{h,0})C_h$ have dimension 16×2 since they are just multiplied by the values at the boundary. Therefore, the calculation of the terms in $e^{kA_{h,0}}$ is more expensive than the calculation of those in $\varphi_i(kA_{h,0})C_h$ $(i = 1, 2)$. On the other hand, as it is a one-dimensional problem, the function q in **EO1** and **EO2** is calculated directly for every value of t as the straight line which joins the corresponding values $f(t, 0, e^t)$ and $f(t, 1, e^{t+1})$ at $x = 0$ and $x = 1$ respectively. The values of the time stepsize which have been displayed have been $k = 10^{-3}, 5 \times 10^{-4}, 2.5 \times 10^{-4}, 1.25 \times 10^{-4}, 6.25 \times 10^{-5}$ for **EO** and $k = 10^{-3}, 5 \times 10^{-4}, 2.5 \times 10^{-4}, 1.25 \times 10^{-4}, 6.25 \times 10^{-5}, 3.125 \times 10^{-5}$ for **ACR**. The results in terms of maximum error against computational cost are in Figure 1 and we can

 ISBN: 978-84-617-8694-7

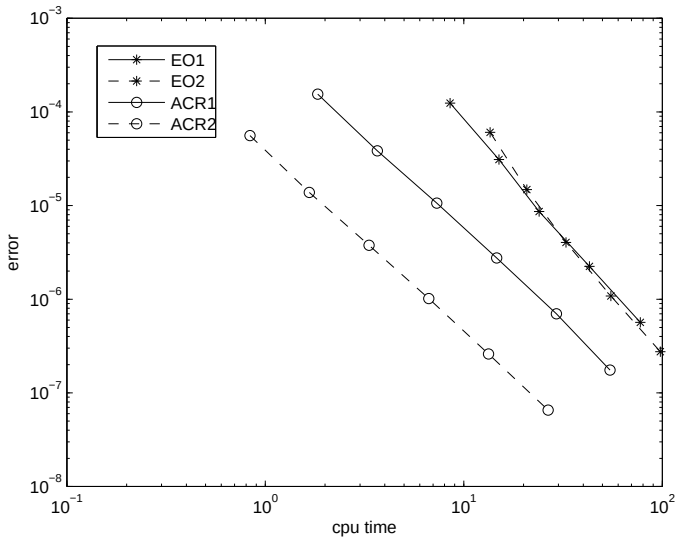

Figure 1: Numerical comparison with spectral collocation methods in space and high accuracy in time for the 1-dimensional problem (6)

see that techniques **ACR1 and ACR2 are more efficient than EO1 and EO2**, that **ACR2** is three times more efficient than **ACR1** and that **EO1** and **EO2** are very similar in efficiency. In any case, we can check that, as already remarked in the previous section, for a fixed value of k, **ACR2** is cheaper than **ACR1** and **EO1** cheaper than **EO2**. Moreover we can observe that, at least for this particular problem, for fixed k, the error is smaller with the second implementation of both techniques than with the first.

In a second place, we have considered the two-dimensional problem

$$\begin{aligned}
&u_t(x,y,t) = u_{xx}(x,y,t) + u_{yy}(x,y,t) + f(t,x,y,u(x,y,t)), \quad 0 \le x,y \le 1, \quad t \in [0,0.2],\\
&u(x,y,0) = e^{x^3+y^3},\\
&u(0,y,t) = e^{t+y^3}, \quad u(1,y,t) = e^{t+1+y^3}, \quad u(x,0,t) = e^{t+x^3}, \quad u(x,1,t) = e^{t+1+x^3}. \qquad (7)
\end{aligned}$$

where $f(t,x,y,u) = u^2 - e^{t+x^3+y^3}(9(x^4+y^4)+6(x+y)+e^{t+x^3+y^3}-1)$, so that the exact solution is $u(x,y,t) = e^{t+x^3+y^3}$. Now, 16 interior Gauss-Lobatto nodes have been taken in each direction of the square for the space discretization and the implementation has been performed with similar remarks to those of the one-dimensional case. The only remarkable difference is that the function $q(t,x,y)$ in **EO1** and **EO2** must be chosen in a different way. We consider a function of the form $q(t,x,y) = r(t,x)f(t,1,y,e^{t+1+y^3}) + s(t,x)f(t,0,y,e^{t+y^3})$ which satisfies the corresponding conditions at the boundary and that is achieved if $r(t,x)$

 ISBN: 978-84-617-8694-7

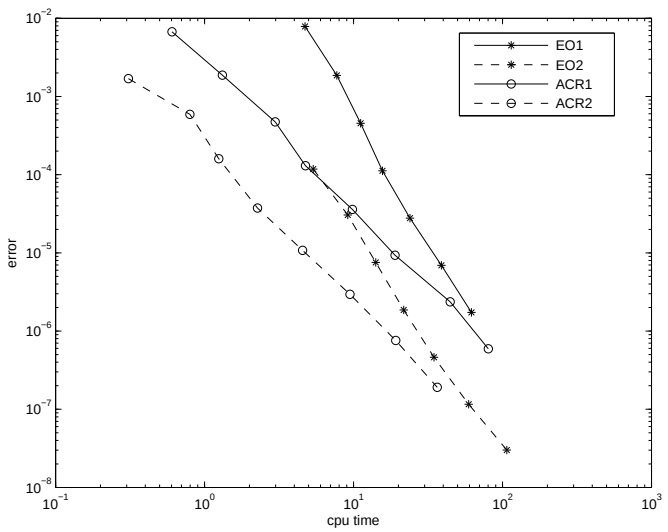

Figure 2: Numerical comparison with spectral collocation methods in space and high accuracy in time for the 2-dimensional problem (7)

and $s(t,x)$ satisfy

$$\begin{pmatrix} f(t,1,0,e^{t+1}) & f(t,0,0,e^{t}) \\ f(t,1,1,e^{t+2}) & f(t,0,1,e^{t+1}) \end{pmatrix} \begin{pmatrix} r(t,x) \\ s(t,x) \end{pmatrix} = \begin{pmatrix} f(t,x,0,e^{t+x^3}) \\ f(t,x,1,e^{t+1+x^3}) \end{pmatrix}.$$

(Notice that this technique to calculate q analytically can be applied in a rectangular domain but not in more complicated domains in two dimensions.) In Figure 2, which corresponds to the following values of the timestepsize $k = 2\times10^{-2}, 10^{-2}, 5\times10^{-3}, 2.5\times10^{-3}, 1.25\times10^{-3}, 6.25\times10^{-4}, 3.125\times10^{-4}$ for **EO** and $k = 2.5\times10^{-3}, 1.25\times10^{-3}, 6.25\times10^{-4}, 3.125\times10^{-4}, 1.5625\times10^{-4}, 7.8125\times10^{-5}, 3.9063\times10^{-5}, 1.9531\times10^{-5}$ for **ACR**, we can see that the second implementation of both techniques is cheaper than the first and that **the best of all implementations is ACR2**, at least for a range of errors $\geq 10^{-7}$.

4 Numerical comparison with finite difference methods in space and middle accuracy in time

In this section we have been a bit less demanding when solving each part of the splitting. We have just considered 10^{-7} and 10^{-8} as relative and absolute tolerances respectively

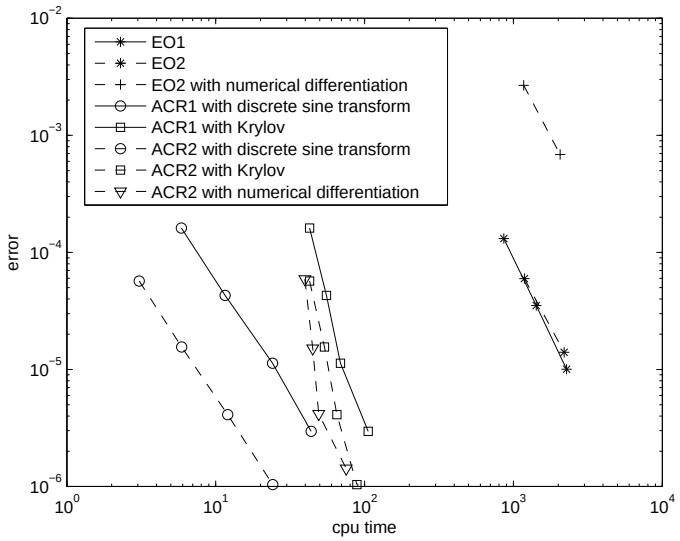

Figure 3: Numerical comparison with finite difference methods in space and middle accuracy in time for the 1-dimensional problem (6)

for the standard subroutines ode45 and ode15s. As Strang method just has second-order accuracy, it is usually used for problems in which a very high precision is not required. Moreover, in space we have considered finite differences of just second order accuracy in the space grid. More particularly, as in the problems above the operator A is the Laplacian, we have taken the standard symmetric second-order difference scheme in 1 dimension and the five-point formula in 2 dimensions [11]. We have considered as space grid $h = 5 \times 10^{-4}$ for the 1-dimensional case and $h = 2 \times 10^{-2}$ for the 2-dimensional case. With this type of implementation, the matrix $A_{h,0}$ is sparse and, in this particular case, their eigenvalues and eigenvectors are well-known [9]. Because of the former, it is natural to use standard Krylov subroutines [10] in **ACR1** and **ACR2** to calculate the application of exponential-type functions over vectors. Due to the latter, which is more specific of this particular example and space discretization, in order to calculate the same terms, it seems advantageous to use the discrete sine transform in the same way that FFT is used in Poisson solvers [9]. When using Krylov subroutines [10], we have considered the default tolerance 10^{-7}. The comparison is performed in Figure 3 for the 1-dimensional problem (6) with $k = 10^{-3}, 5 \times 10^{-4}, 2.5 \times 10^{-4}$ for **EO1**, $k = 10^{-3}, 5 \times 10^{-4}$ for **EO2** and $k = 10^{-3}, 5 \times 10^{-4}, 2.5 \times 10^{-4}, 1.25 \times 10^{-4}$ for **ACR**. **We again see that ACR1 and ACR2 are more competitive than EO1 and EO2**. Although, for a fixed value of k, **EO2** takes more computational time than

 ISBN: 978-84-617-8694-7

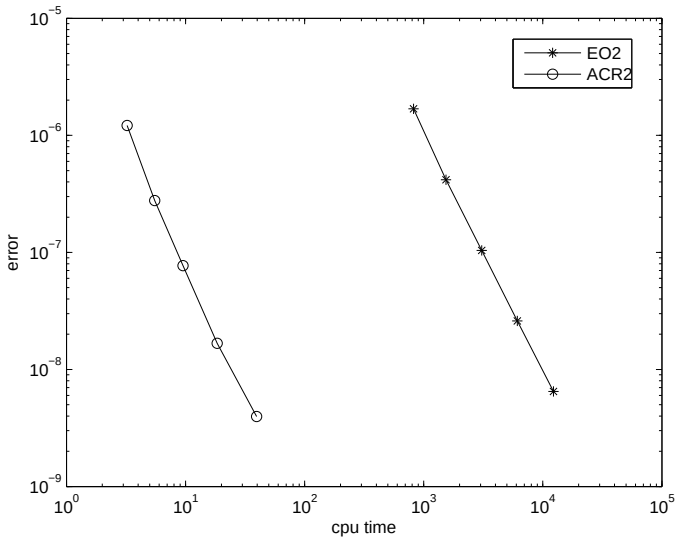

Figure 4: Numerical comparison with finite difference methods in space and middle accuracy in time for the 2-dimensional problem (8)

EO1, in the end they are very similar in efficiency since, at least in this case, the error is also quite smaller. As for **ACR1** and **ACR2**, **ACR2** is more competitive since not only the computational time is smaller for a fixed value of k but also the error is smaller. In this particular case, considering discrete sine transforms is much cheaper than using Krylov techniques. However, for a general operator A, that may not be possible and that is why it is also interesting to see the comparison when using these techniques. In any case, **the worst of ACR implementations is about 20 times cheaper than the best of EO**.

Moreover, following [8], we have also considered numerical differentiation in order to get local order 3 with **EO1** and **EO2** in (6). More precisely, a function q has been taken for which $\partial q(t) = \partial f(t, u(t))$ and $\partial Aq(t) = \partial Af(t, u(t))$. Although the order for the global error does not improve, it is interesting to see whether the fact that the local errors maybe smaller implies a better overall behaviour. Notice that, in (6),

$$\frac{d}{dx^2} f = f_{xx} + 2f_{x,u}u_x + f_{uu}u_x^2 + f_u u_{xx}.$$

As $\partial u_{xx} = g'(t) - \partial f(t, u)$, numerical differentiation is just required to calculate ∂u_x. For that, we have considered the second-order scheme

$$u_x(0,t) \approx \frac{-\frac{3}{2}u(0,t) + 2u(h,t) - \frac{1}{2}u(2h,t)}{h}, u_x(1,t) \approx \frac{\frac{3}{2}u(1,t) - 2u(1-h,t) + \frac{1}{2}u(1-2h,t)}{h}.$$

 ISBN: 978-84-617-8694-7

Although numerical differentiation is a badly-posed problem, its effect is still not visible with the considered value of h for the first derivative and the range of errors which we are considering. What is true is that the error constants may grow significantly because the size of q may be very big, as it happens in this problem and Figure 3 shows. The latter is the explanation that **numerical differentiation is not worth when using EO2**, as it was already remarked in [8] for some other particular problems and fixed k.

As for **ACR2**, considering also terms of second order in s for the boundaries of the problems in which the operator A appears, the following full scheme turns up:

$$\begin{aligned}
W_{h,n}(\frac{k}{2}) &= e^{\frac{k}{2}A_{h,0}}U_h^n + \frac{k}{2}\varphi_1(\frac{k}{2}A_{h,0})C_h g(t_n) + \frac{k^2}{4}\varphi_2(\frac{k}{2}A_{h,0})C_h\partial A u(t_n) \\
&\quad + \frac{k^3}{8}\varphi_3(\frac{k}{2}A_{h,0})C_h\partial A^2 u(t_n) \\
V_h^n &= \Psi_k^{f,t_n}(W_{h,n}(\frac{k}{2})), \\
U_h^{n+1} &= e^{\frac{k}{2}A_{h,0}}V_h^n \\
&\quad + \frac{k}{2}\varphi_1(\frac{k}{2}A_{h,0})C_h\partial[u(t_n) + k(\frac{1}{2}Au(t_n) + f(t_n,u(t_n)) \\
&\qquad + k^2(\frac{1}{8}A^2u(t_n) + \frac{1}{2}f_u(t_n,u(t_n))Au(t_n) + \frac{1}{2}(f_t(t_n,u(t_n)) + f_u(t_n,u(t_n))f(t_n,u(t_n)))] \\
&\quad + \frac{k^2}{4}\varphi_2(\frac{k}{2}A_{h,0})C_h\partial[Au(t_n) + \frac{k}{2}A^2u(t_n) + kAf(t_n,u(t_n))] \\
&\quad + \frac{k^3}{8}\varphi_3(\frac{k}{2}A_{h,0})C_h\partial A^2 u(t_n).
\end{aligned}$$

As $\partial A^2 u = \partial A\dot{u} - \partial Af = \ddot{g} - \partial(f_t + f_u\dot{u}) - \partial Af$, what is again necessary is to approximate u_x with numerical differentiation and we have done it in the same way as before. As it is observed, **there is a small ganancy in efficiency when using numerical differentiation with ACR2 although it is not extremely significant**.

Notice that, surprisingly, for both **EO2** and **ACR2**, for a fixed value of k, the computational cost does not increase but is slightly smaller when using numerical differentiation. This must be due to the fact that the standard subroutines which are used converge more quickly when numerical differentiation is applied. A full explanation for that is out of the scope of this paper although it might be a subject of future research.

In this section, in order to assure that the errors in space are negligible without having to decrease too much the space grid, we have considered as bidimensional problem

$$\begin{aligned}
&u_t(x,y,t) = u_{xx}(x,y,t) + u_{yy}(x,y,t) + f(t,x,y,u(x,y,t)), \quad 0 \le x,y \le 1, \quad t \in [0,0.2], \\
&u(x,y,0) = x^2 + y^2, \\
&u(0,y,t) = e^t y^2, \quad u(1,y,t) = e^t(1+y^2), \quad u(x,0,t) = e^t x^2, \quad u(x,1,t) = e^t(1+x^2). \qquad (8)
\end{aligned}$$

 ISBN: 978-84-617-8694-7

where $f(t,x,y,u) = u^2 - e^{2t}(x^2+y^2)^2 + e^t(x^2+y^2-4)$, so that the exact solution is $u(x,y,t) = e^t(x^2+y^2)$. For the sake of brevity, we have concentrated on **ACR2** and **EO2** because they were the best implementations in previous problems. We have implemented **EO2** calculating q in a similar way as in the bidimensional problem of the previous section and **ACR2** again with Krylov subroutines [10]. In Figure 4 we can see that **ACR2 is 500 times more efficient than EO2** where $k = 10^{-2}, 5\times10^{-3}, 2.5\times10^{-3}, 1.25\times10^{-3}, 6.25\times10^{-4}$ has been displayed for **EO2** and $k = 1.25\times10^{-3}, 6.25\times10^{-4}, 3.125\times10^{-4}, 1.5625\times10^{-4}, 7.8125\times10^{-5}$ for **ACR2**.

Abstract

The processing of some digital sound signals can involve the QR factorization of a rectangular system matrix. But, sometimes, only a given (and probably small) part of the system matrix varies from the current sample to the next one. We exploit this fact to reuse some computations of the former samples processing to save execution time in the processing of the actual sample. This saving in execution time can be critical for real time application addressed to low power consumption devices with high mobility.

Key words: QR factorization, QR Updating, real-time, block QR.

1 Introduction

The QR factorization of a matrix is a very known method to solve systems of linear equations or to approximate the solution to an overdetermined system (more equations than unknowns). Let $A \in R^{m \times n}$, with $m \geq n$, be a matrix that represents the linear system, its QR factorization is $A = QR$, being $Q \in \Re^{m \times m}$ orthogonal and $R \in \Re^{m \times n}$ upper triangular.

This factorization can be computed in $O(mn^2)$ flops either through Householder reflections or through Givens rotations [3]. Also, there exist block algorithms that improve performance on processors with a hierarchical set of cache memories [4, 2]. In this work we start form a sequential block algorithm that performs this factorization [5], and that we modify to incorporate our proposal. We use OpenBLAS [1] in the basis of our algorithm.

We use the QR factorization with the aim of extracting the most approximate solution of a least squares problem. The least squares problem arises as the main computational kernel

 ISBN: 978-84-617-8694-7

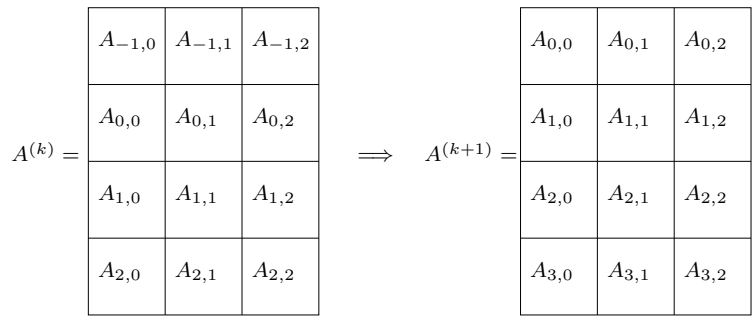

Figure 1: Updating of system matrix A from iteration k to $k+1$.

of a more complex process used to evaluate a sound signal sample. The digital sound signal is sampled real time, what means that there exists a very short slot of time to perform all the computations associated to the sample processing. Furthermore, the problem is critical since we are interested in the use of devices with low computational capabilities (mobile phones, tablets, etc.). Hence, what we propose is to speed up the process of performing the QR factorization of each matrix at each sample by reusing some computations performed in the processing of the former sample since there exist some common data to matrices consecutive samples that can be reused.

2 The QR updating

The process we tackle here is iterative (a new sample is processed at each iteration). At iteration k, $k = 0, \ldots$, a QR factorization is carried on the system matrix $A^{(k)}$. Matrix $A^{(k)}$ is "updated" with new data to form the system matrix of the following iteration $A^{(k+1)}$. This "update" consist of 1) deleting the most ancient rows, which are the first t_s rows; and 2) appending a new set of t_s rows to the bottom of the system matrix, which are coming from the sampled signal. The updating carried out between iterations k and $k+1$ can be observed in Figure 1, represented by matrices $A^{(k)}$ and $A^{(k+1)}$. The figure represents the matrix partitioned in tiles of size $t_s \times t_s$.

As stated before, the most time consuming process at iteration k consists of the QR factorization, i.e. $A^{(k)} = Q_k R_k$. In order to save flops in each factorization we propose to work on matrices that we denote as *jagged*, and that are represented by J in Figure 2. Each block row of J^k is the "R" factor of each corresponding row in $A^{(k)}$. Hence, to form J^{k+1} there exists an intermediate step that consists of performing the QR factorization of the new t_s rows $\begin{pmatrix} A_{3,0} & A_{3,1} & A_{3,2} \end{pmatrix}$, and append the "R" factor i.e. $\begin{pmatrix} J_{3,0} & J_{3,1} & J_{3,2} \end{pmatrix}$ to the bottom of the matrix. The "Q" is not explicitly formed since it is not needed. It is

 ISBN: 978-84-617-8694-7

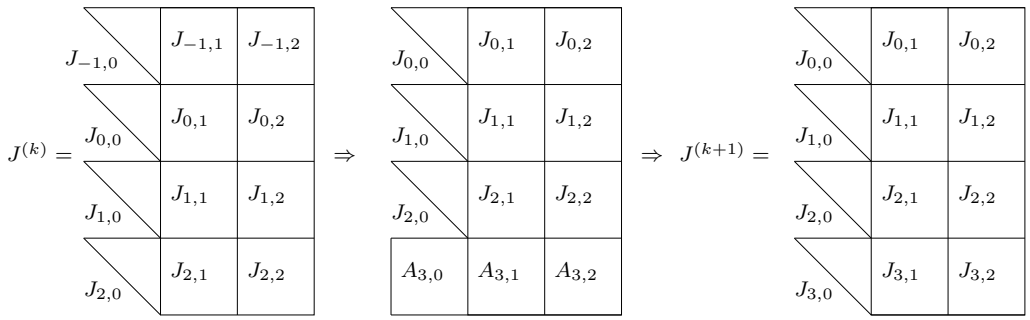

Figure 2: Updating of system matrix J from iteration k to $k+1$ with a *jagged* matrix.

clear that computing the QR factorization of the *jagged* matrix is cheaper than to compute the QR of the original one.

3 Experimental Results

The experimental results have been obtained in a single ARM® Cortex-A15 core of a NVIDIA Jetson TK1 development kit. Table 1 shows the time in seconds to perform the QR factorization of each matrix $A^{(k)}$ (column QR($A^{(k)}$)), and the factorization of the *jagged* matrix $J^{(k)}$ (column QR($J^{(k)}$)). We show two problem sizes and two different tile sizes for each problem. Also, we vary the block size b_s, which is a parameter that must be tuned to exploit the cache memory when working on a tile. Both sizes influence the performance of the algorithm, but while the tile size t_s is problem dependent (number of rows to be updated on the system matrix) there exist freedom to select the block size (b_s).

The best performance of the QR factorization of the two matrices, i.e. QR($A^{(k)}$) and QR($J^{(k)}$), is obtained always for the same (t_s, b_s) combination. In these cases, the speed up in percentage of QR($J^{(k)}$) with regard to QR($A^{(k)}$) is in the range $\approx [41, 45]$.

4 Conclusion

Real time applications are characterized by performing the same computation repeatedly over new coming data. Sometimes, data, which frequently is represented as a system matrix, changes from one iteration to the next one only in a small part. If the computation on this matrix is expensive, as it is the QR factorization, we can use this fact to save processing time. We propose to work on a modified matrix, called *jagged*, instead of on the original system matrix. With this simple idea, it is possible to increase performance by a factor close to 1.45 in the particular case we tackled in this paper, i.e. when data is represented

Abstract

This document tries to give an overview of some applications related to ship analysis using subdivision schemes. It presents a little introduction of some subdivision schemes and its properties. It reviews the modeling, simulation and design of the ship structures.

Key Words. Computer-Aided Ship Analysis, simulation, modeling, structural analysis, design.

1 Introduction

The importance of subdivision to applications in computer-aided geometric design is clear. The surfaces generated by their subdivision schemes can generate bivariate functions, but also they can easily represent surfaces of arbitrary topology (Doo and Sabin (1978) and by Catmull and Clark (1978)).

The first work on a subdivision scheme was by de Rahm (1956), but in the pioneering work of Chaikin (1974) was introduced the first subdivision as a practical algorithm for curve design.

Subdivision algorithms are well suited to computer applications: they are simple to compute, highly flexible, and well adapted for dynamical problems.

The subdivision tools have been applied in several design applications, such as in the 3D animation industry, but is not the case in other more demanding application related to geometric modelling in the industry.

 ISBN: 978-84-617-8694-7

For overviews and tutorials on subdivision schemes and their applications, the reader may turn to Cavaretta, Dahmen and Micchelli (1991), Schröder (2001), Zorin and Schröder (2000) and Warren (1995) or Dyn and Levin (2002).

In this paper, we are interesting in the use of subdivision schemes in the analysis and desing of ship applications. After a little review of some mathematical tools for Ship applications, we mention the advantages of the use of subdivision schemes.

2 Ship design and analysis: A brief introduction

We start with a brief review of some mathematical tools used in the Ship design and analysis.

2.1 Ship design

The modern engineering designs are becoming increasingly more complex because of the pressing demands of economies of scale, higher speed, lower motions, operational ability in adverse weather conditions, energy efficiency, clean environment, and advancements in material science and technologies. Today, modern engineering design and analysis around the world can no longer be imagined without intensive use of computers and computational methods.

The discipline of Computer-Aided Ship Design (CASD) was certainly well established by 1960, although it has several roots and historical precursors we can recognize three main roots:

- The need for digital media in the numerical control of manufacturing automata.
- The desire for digital representation of the ship geometric product model replacing the tedious and error prone graphical process of ship lines definition.
- The application of computers for computationally intensive, time-consuming tasks of ship design calculations as in ship stability, hydrodynamic and structural analysis.

The digital modeling of ship hull geometries was a primary prerequisite in capturing the complex, curved, free form shape of ship lines and surfaces for all purposes of hull form analysis.

Ship design is a decision-making process that leads from given requirements to a product definition with all relevant information for the performance assessment and production of the ship.

The definition of the ship hull form is one of the earliest steps in ship design because initially many necessary assessments depend on at least a provisional description of hull shape. Later this tentative description is refined into a definitive and fair ship hull form definition for production purposes.

 ISBN: 978-84-617-8694-7

The predominant curve representations in hull form definition as in other branches of CAD (Computer Aided Design) applications soon became parametric polynomial forms, in particular:

- Bézier curves [5, 12, 1].
- B-splines [5, 12, 13].
- Non-uniform rational B-Splines [5, 12, 11].

These representations have the advantage of being manipulable interactively by control points, hence also on computer monitors. They offer any desired orders of piecewise continuity and can be elevated to high polynomial degrees. The rational variant of Bézier and B-spline curves also includes conic sections, sometimes used for special features of hull form. For an overview of these geometric modeling capabilities see [5, 12]. For a nice history introduction see [9].

A frequent approach is the generation of hull surfaces from given curves. Initially a set of piecewise continuous characteristic curves is generated from provided offset data and end constraints. As an example of offset data in Maxsurf. They may come from another ship with features similar to the one which is modeled. Together they form a regular or irregular mesh, not unlike a lines plan, connected at the mesh knots.

There exist several software, some of them that can be use for the ship design and that they use Bézier and/or NURBS curves and/or surfaces: Autoship (Autoship Systems Corporation), DefCar (DefCar Engineering), Fastship (Proteus Engineering), HullCAO (HullCAO), Hull Form (Blue Peter Marine Systems), Maxsurf (Formation Design Systems), MultiSurf (Aerohydro), Prolines (Vacanti Yacht Design), ProSurf (New Wave Systems), Rhino (Robert McNeel and Assoc.), Naval Designer (US Sales by Forum Marine), SeaSolution (SeaSolution), TouchCAD (Lundström Design).

2.2 Ship structural analysis

The application of ship structural analysis is a key element in ensuring the safety and economy of the ship. The ship must meet unique safety standards to operate safely in the hostile maritime scenario without jeopardizing human lives, cargo and hull, or the marine environment. The design solutions must realize low light ship weights and production costs in order to be economically competitive. These basic objectives are not new, but the approach to achieving viable and attractive solutions has changed significantly during the recent decades of Computer-Aided Ship Design.

Traditionally before the computer era the structural design of merchant ships was generally based on classification rules and international ship safety conventions which were derived in part on analytical grounds, but in large measure also on empirical observations

 ISBN: 978-84-617-8694-7

and accident statistics. Load assumptions and operating risk scenarios were often hidden behind declarative statements in the rules. Most of the design was founded on deterministic load cases combined with protective safety factors to cope with uncertainties. This methodology was applied responsibly and without undue risks to conventional designs.

The picture has grossly changed during the following decades driven by advances in structural analysis, load assumptions, probabilistic modeling, reliability analysis, nonlinear optimization, and many innovative ideas in design solutions. Ship structural analysis has benefited from general progress in this field, such as by Finite Element Method, Finite Volume Method, and Boundary Element Method developments. But much of the innovation was also due to the maritime field with its unique requirements. The common denominator of many small steps of innovation seems to be a long-term trend toward more rational design assumptions, based on probabilistic models of many actual load cases and operating scenarios, treated by systematic optimization strategies.

Aside of many advances in computational capabilities, mainly by discrete element methods, which were also shared with many other engineering branches, I want to single out the important influence of probabilistic models in ship structural design. Ships operate in uncertain conditions, mainly because of their environment in irregular seaways of varying character and because of their vulnerability to random accidents such as collisions, groundings etc. A safe design must take these risk factors into account. The response of the ship to such random influences could be modeled probabilistically as soon as analytical methods for describing random processes had become available. This entry into the area of ship theory is marked by two milestone papers:

Ship structural design today has become a rationally based, optimization oriented, mature discipline of ship design. It uses accurate, statistically described load assumptions, multiple load cases and failure modes, reliability-based constraints, and modern analysis and optimization techniques. A modern approach based on these principles is well described by Hughes [8].

2.3 Isogeometric analysis

The finite element method is an useful technique in solving partial differential equations, which has been widely applied to the solve problems in engineering. Starting from the variational model, piecewise low order polynomials on the subdivision meshes of the domain are computed to approximate the solution of the differential model.

The main motivation in isogeometric analysis is to reduce the gap between the the finite element community and the computer-aided design community (Hughes et al., 2005). This gap has become increasingly with the past of the years. It is not only a shortcoming of the current technology but of the entire engineering process. The idea in isogeometric analysis has been to connect in a natural way the design and analysis camps. In particular, isogeometric analysis seeks to unify the fields of CAD and FEA.

 ISBN: 978-84-617-8694-7

There are many computational geometry technologies that could serve as a basis for isogeometric analysis. Maybe, the most studied is Non-Uniform Rational B-Spline (NURBS) basis functions. There are several reasons for selecting NURBS as the initial basis, but the most important is that these basis are widely used computational geometry technology in engineering design.

3 Why Subdivision schemes?

There are a main problem with NURBS is that they are not good adapted for dynamics applications. Some artifacts appear on the generated surfaces that can be corrected by hand. For these reason, subdivision schemes have been considered as an alternative in the animation industry.

Subdivision schemes are a tool that has become widely used in the computer aided geometric design (CAGD) community in the past years. They are usually used to generate smooth curves and surfaces. If the subdivision scheme is convergent, a discrete set of data points can be used for generating a smooth limit curve or surface using low complexity algorithms. In general, the limit function is obtained applying recursively the subdivision scheme.

In the CAGD field, the criteria used to decide the quality of the algorithms are not only based on complexity, convergence or regularity of the schemes. It is also important to have into account the order of approximation, in order to determine the precision of the scheme. Numerical artifacts introduced by the scheme are also another point to have into account: Gibbs oscillations usually occur in the proximity of data with strong gradients, possibly obtained from the sampling of discontinuous data. These oscillations that appear in the limit function are undesirable.

In the past years, several attempts have been done in order to improve the results of linear subdivision algorithms. Some of the mentioned attempts are related to the modification of linear schemes in order to introduce data dependent non linearities. In these cases, the subdivision rule also becomes data dependent and the stability is not anymore a consequence of the convergence of the scheme. Thus, it is a must to introduce a stability property in order to assure that the nonlinear scheme is linearly affected by perturbations of the data.

On the other hand, mixed finite element methods based on surface subdivision technology have been used to construct high-order smooth surfaces with specified boundary conditions [4, 7, 10, 11, 12]. Moreover, subdivision surfaces are compatible with NURBS. The geometry models can be refined to arrive at a satisfactory accuracy of the numerical simulation where the subdivision schemes are simple, efficient and can be applied to meshes with arbitrary topology.

Isogeometric analysis based on Catmull-Clark solids was first investigated in [5]. In

 ISBN: 978-84-617-8694-7

[10], the authors present a make-up approach for isogeometric analysis where they utilize the finite element function space induced from the limit form of the Catmull-Clark surface subdivision to uniformly describe the geometric domain and perform numerical simulation on it. It is compatible with NURBS as the standard in CAD system where the boundary of geometry is modelled as piecewise cubic B-spline curves. The advantage of this strategy admits quadrilateral meshes of arbitrary topology and any-shaped boundary. The computational domains considered in this paper are planar geometries. They develop the approximation character of Catmull-Clark surface subdivision function, which provides the mathematical support for the isogeometric analysis based on Extended Catmull-Clark surface subdivision.

Abstract

The solution of chemical kinetics is one of the most computationally intensive tasks in atmospheric chemical transport simulations. Due to the stiff nature of the system, implicit time stepping algorithms which repeatedly solve linear systems of equations are necessary. In some recent works, we have proposed a variational approximation of stiff systems of differential equations based on an analysis of a certain error functional associated. By using standard descent schemes, the procedure can never get stuck in local minima, but will always and steadily decrease the error until getting to the original solution. We show the efficiency of this approach in some standard chemical kinetics problems found in the literature.

Key words: Variational methods, stiff problems, chemical kinetics, implicit Runge-Kutta, variable step implementation.

1 Introduction

A typical property of chemical calculations is that different reactions occur at dramatically different time scales, with some species achieving quasi-steady-state solutions rather quickly, while others can evolve very slowly. For this reason, the solution of chemical kinetics is one of the most computationally intensive tasks in atmospheric chemical transport simulations. Due to the stiff nature of the system, implicit time stepping algorithms which repeatedly solve linear systems of equations are necessary.

 ISBN: 978-84-617-8694-7

Implicit Runge-Kutta schemes are widely used in mathematics and engineering to numerically solve stiff differential equations. These methods require the solution to a (possibly large) nonlinear system of equations at every time step, which in the past was deemed prohibitively costly. The increasing ability for scientists to solve large-scale nonlinear systems with relative efficiency, thanks to advances in numerical methods and the growth in computing power, has increased the use of these methods.

Every integration method is associated with a step-size h for the integration. If h is too large or too small, the efficiency of the scheme is relatively low. For this reason, variable step implementations are usually considered.

On the other hand, in some previous works [1, 2, 3, 4, 5], we have proposed a new variational approach for the approximation of different types of differential equations. The approach is based on an analysis of a certain error functional associated, in a natural way, with the original problem. The performance is very good due to the fact that we only need to approximate linear problems for which one can use very robust methods. In particular, the problem of having good initial guesses in the application of Newton-type methods, in order to approximate the associated nonlinear Runge-Kutta equations, is avoided.

In this paper, we show the efficiency of this approach in some standard chemical kinetics problems found in the literature.

2 Our basic variational approach: an overview

Our variational approach for the treatment of ODEs is based on the analysis of a certain error functional of the form

$$E(\mathbf{x}) = \frac{1}{2}\int_0^T |\mathbf{x}'(t) - \mathbf{f}(\mathbf{x}(t))|^2\, dt,$$

to be minimized among the absolutely continuous paths $\mathbf{x} : (0,T) \to \mathbf{R}^N$ with $\mathbf{x}(0) = \mathbf{x}_0$. This error functional is associated, in a natural way, with the Cauchy problem

$$\mathbf{x}'(t) = \mathbf{f}(\mathbf{x}(t)) \text{ in } (0,T), \quad \mathbf{x}(0) = \mathbf{x}_0. \tag{1}$$

The following claim is easy to check. It is one of the most appealing features of our viewpoint.

Proposition 1 ([2]) *Let $\overline{\mathbf{x}}$ be a critical point for the error E. Then $\overline{\mathbf{x}}$ is the solution of the Cauchy problem (1).*

On the other hand, suppose we start with an initial crude approximation $\mathbf{x}_{(0)}(\equiv \mathbf{x})$ to the solution of our basic problem (1). We would like to improve this approximation in such a way that the error is significantly decreased.

 ISBN: 978-84-617-8694-7

It is straightforward to find the Gâteaux derivative of E at a given feasible $\mathbf{x}$ in the direction $\mathbf{y}$ with $\mathbf{y}(0) = \mathbf{0}$. Namely

$$\langle E'(\mathbf{x}), \mathbf{y} \rangle = \int_0^T (\mathbf{x}'(t) - \mathbf{f}(\mathbf{x}(t))) \cdot (\mathbf{y}'(t) - \nabla \mathbf{f}(\mathbf{x}(t))\mathbf{y}(t))\, dt.$$

This expression suggests to select $\mathbf{y}$ as a solution of the linear problem

$$\mathbf{y}'(t) - \nabla \mathbf{f}(\mathbf{x}(t))\mathbf{y}(t) = \mathbf{f}(\mathbf{x}(t)) - \mathbf{x}'(t) \text{ in } (0,T), \quad \mathbf{y}(0) = \mathbf{0}.$$

In this way, it is easy to calculate that $\langle E'(\mathbf{x}), \mathbf{y} \rangle = -2E(\mathbf{x})$, and so the (local) decrease of the error is of the size $E(\mathbf{x})$. Finding $\mathbf{y}$ requires solving the above linear problem iteratively.

Theorem 1 *If the mapping* $\mathbf{f}$ *is smooth enough, and the horizon* T *is sufficiently small, the iterative procedure* $\mathbf{x}^{(j)}(t) = \mathbf{x}^{(j-1)}(t) + \mathbf{y}^{(j)}(t)$ *where*

$$(\mathbf{y}^{(j)})'(t) - \nabla \mathbf{f}(\mathbf{x}^{(j)}(t))\mathbf{y}^{(j)}(t) = \mathbf{f}(\mathbf{x}^{(j)}(t)) - (\mathbf{x}^{(j)})'(t) \text{ in } (0,T), \quad \mathbf{y}(0) = \mathbf{0},$$

converges strongly in $H^1(0,T;\mathbf{R}^N)$*, and in* $L^\infty(0,T;\mathbf{R}^N)$ *to the unique solution of problem (1).*

Note that this result can be used successively in an arbitrary time interval $[0,T]$ by dividing it in a sufficient big number of subintervals.

This strategy can be used, and extended for more general situations: differential-algebraic equations, delay differential-equations or Hamiltonian systems [1, 2, 3, 4, 5].

An implicit fixed-step solver computes the state at the next time step as an implicit function of the state at the current time step, and the state derivative at the next time step. The variable-step solvers dynamically vary the step size during the simulation. These solvers increase or reduce the step size using its local error control to achieve the tolerances that you specify. Computing the step size at each time step adds to the computational overhead, but can reduce the total number of steps, and the simulation time required to maintain a specified level of accuracy.

For a stiff problem, solutions can change on a time scale that is very small as compared to the interval of integration, while the solution of interest changes on a much longer time scale. Methods that are not designed for stiff problems are ineffective on intervals where the solution changes slowly because these methods use time steps small enough to resolve the fastest possible change.

If we denote by $\mathbf{y}(t_n, t_{n-1}, \mathbf{y}_{n-1})$ the solution of a given differential equation (system) $\mathbf{F}(t, \mathbf{y}, \mathbf{y}') = 0$, then a method of order p will verify that locally its error has the form

$$||e_n|| = ||\mathbf{y}(t_n, t_{n-1}, \mathbf{y}_{n-1}) - \mathbf{y}_n|| = C\ h^{p+1} + O(h^{p+2}).$$

 ISBN: 978-84-617-8694-7

In order to estimate C, we can use extrapolation techniques. Another possibility is to consider another scheme $\tilde{\mathbf{y}}_n$ with bigger order q starting from $\mathbf{y}_{n-1}$. In this case we have

$$||\tilde{e}_n|| = ||\mathbf{y}(t_n, t_{n-1}, \mathbf{y}_{n-1}) - \tilde{\mathbf{y}}_n|| = \tilde{C}\ h^{q+1} + O(h^{q+2}),$$

then

$$||e_n|| = ||\mathbf{y}_n - \tilde{\mathbf{y}}_n|| + O(h^{p+2}).$$

With an estimation of the error, the variable step codes select the new step such that the error is smaller than a prescribed tolerance TOL.

The desired error associated to a h_* will be

$$||e_n(h^{'})|| = Ch_*^{p+1} = TOL$$

and the real error

$$||e_n(h)|| = Ch^{p+1} = ||\mathbf{y}_n - \tilde{\mathbf{y}}_n||,$$

dividing both equations we obtain

$$h_* = h\ \sqrt[p+1]{\frac{TOL}{||\mathbf{y}_n - \tilde{\mathbf{y}}_n||}}.$$

Remark 1 *As every implicit integration scheme has a global error inherent to the scheme, in [6] the authors choose the total number of computations (in order to solve the inner nonlinear Runge-Kutta equations by Newton-type methods) in order to achieve a prescribed global error as a measure of efficiency of the integration scheme. This efficiency function is the critical component in making these methods variable step-size methods. This approach does not sense in our case since we use Runge-Kutta methods only in linear problems. In any case, we recommended to see [6] and its references.*

In our case, we can use the norm of the direction $\mathbf{y}^{(j)}$. These numbers are related to the local error (see the following corollaries). That is, without any extra computation (in fact this norm is used in the stop criterion, we stop in $j_{\max}$ when $|\mathbf{y}^{(j_{\max})}| \leq TOL$), we will be able to implement a variable step strategy.

The estimation of the error and the new h_* has been introduced from a mathematical point of view. However, in order to be effective in practice we need some control strategies.

Let $h_{n+1} = t_{n+1} - t_n$ be the discretization parameters. We introduce the following equation

$$h_{n+1} = \sigma h_n\ \sqrt[p+1]{\frac{TOL}{|\mathbf{y}^{(j_{\max})}(t_n)|}},$$

where σ is a security factor smaller than 1.

 ISBN: 978-84-617-8694-7

If in a step $|\mathbf{y}^{(j_{\max})}(t_n)| > TOL$ we reject $\mathbf{y}_n$, and compute a new iteration with

$$h_n = \sigma h_n \sqrt[p+1]{\frac{TOL}{|\mathbf{y}^{(j_{\max})}(t_n)|}}.$$

Finally, it is important to add some computational restrictions. Namely

$$h_{\min} \leq h_n \leq h_{\max}$$

and

$$\omega \leq \frac{h_{n+1}}{h_n} \leq \Omega$$

for some given positive constants $h_{\min}$, $h_{\max}$, ω and Ω.

Some classical examples are:

$$\begin{aligned} h_{\min} &= 10^{-6}, \\ h_{\max} &= 1, \\ \omega &= \frac{1}{5}, \\ \Omega &= 5. \end{aligned}$$

3 A stiff problem: Chapman atmosphere

This model represents the Chapman mechanism for the generation of the ozone and the oxygen singlet. In this example, the concentration of the oxygen $y_3 = [O_2]$ will be held constant. It is a severe test for a stiff ODE package governed by the following equations:

$$\begin{aligned} y_1'(t) &= 2k_3(t)y_3 + k_4(t)y_2(t) - (k_1 y_3 + k_2 y_2(t))y_1(t), \\ y_2'(t) &= k_1 y_1(t) y_3 - (k_2 y_1(t) + k_4(t))y_2(t), \end{aligned}$$

with $y_3 = 3.7 \times 10^{16}$, $k_1 = 1.63 \times 10^{-16}$, $k_2 = 4.66 \times 10^{-16}$,

$$k_i(t) = \begin{cases} \exp(\frac{a_i}{\sin(\omega t)}), & \text{if } \sin(\omega t) > 0 \\ 0, & \text{otherwise} \end{cases}$$

for $i = 3, 4$, with $a_3 = 22.62$, $a_4 = 7.601$ and $\omega = \frac{\pi}{43200}$. The constant 43200 is 12 h measured in seconds. The initial conditions are $y_1(0) = 10^6$ and $y_2(0) = 10^{12}$.

This problem has important features like:

- The Jacobian matrix is not a constant.

 ISBN: 978-84-617-8694-7

- The diurnal effect is present.
- The oscillations are fast.
- The time interval used is fairly long, $0 \leq t \leq 8.64\ 10^5$, or 10 days.

We obtain a good approximation, see Figure 1. Note that $y_2 = [0_3]$ looks like a staircase with a rise at midday every day and $y_1 = [O]$ looks like a spike with its amplitude increases each day.

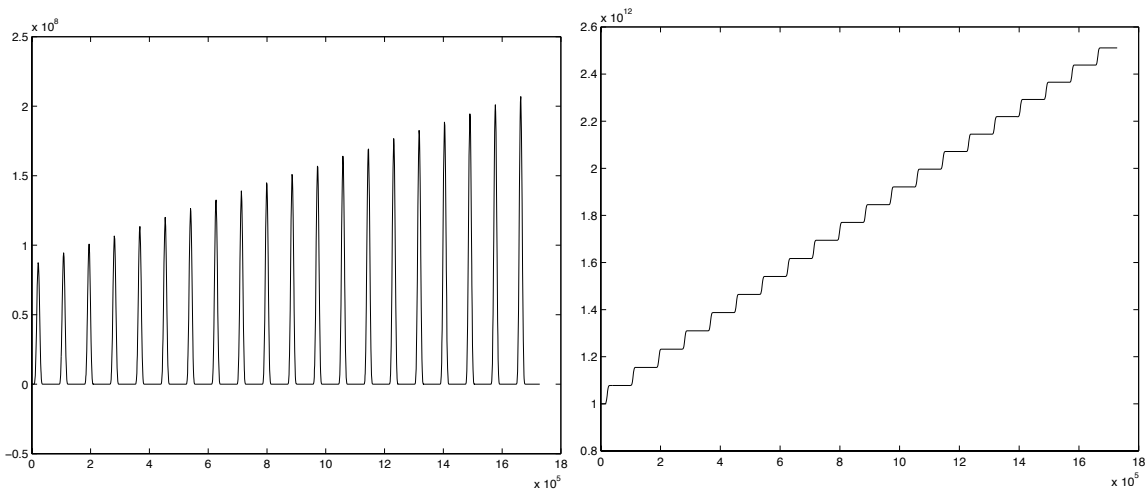

Figure 1: Chapman atmosphere approximated via our variational approximation. Left: first component. Right: second component.

Abstract

Hamiltonian systems appear in numerous areas and have many applications. Many interesting Hamiltonian systems arising from different fields of study are defined by polynomial Hamiltonian functions. Methods preserving the qualitative properties of the exact solution are essential. In general, the integration of these systems requires the use of geometric integrators. In this paper, we propose the use of a variational approach for models which are formulated naturally as Hamiltonian systems. Our variational method for polynomial Hamiltonian systems does not require the use of any integrator and moreover it penalize the not preservation of the energy. We indicate its most basic properties, and test its numerical performance in some examples.

Key words: Polynomial Hamiltonian systems, symplecticity, energy preserving, variational approach.

1 Introduction

It is well-known that numerical methods, such as the ordinary Runge-Kutta schemes, are not particularly efficient in integrating Hamiltonian systems, because Hamiltonian systems are not generic in the set of all dynamic systems. They are not structurally stable against non-Hamiltonian perturbations. Numerical solution of Hamiltonian systems is frequently carried out by symplectic integrators due to their good performance in moderate and long-time integration, see [10, 12, 14, 15, 19]. Symplectic numerical methods belong to the family

 ISBN: 978-84-617-8694-7

of Geometric Numerical Integrators, which preserve important qualitative and geometric properties of the underlying differential system, and are arguably the most popular methods in this class. Certain qualitative properties of the evolution, like symplecticity, are preserved and, in general they exhibit smaller error growth along the numerical trajectory.

Some pioneering works on symplectic integrations are due to Vogelaere [21], Ruth [17], and Feng Kang [9]. The derivation of higher-order methods is covered by several approaches such as composition methods, classical Runge-Kutta methods (RK) as well as partitioned Runge-Kutta (PRK) methods, and methods based on generating functions. The systematic study of symplectic Runge-Kutta methods started around 1988, and a complete characterization has been found independently by Lasagni [13] (using the approach of generating functions), and by Sanz-Serna [18] and Suris[20] (using the ideas of the classical papers of Burrage and Butcher [7] and Crouzeix [8] on algebraic stability).

Nowadays, it is well-known that certain implicit RK methods of Radau type (generalizing the implicit Euler method) are useful in the context of systems with strong dissipation, like electronic circuits or chemical reaction dynamics. Partitioned Runge- Kutta (PRK) methods are another way to approximating the solution trajectory which it is based on using different approximation formulas for different components of the solution. (use different sets of quadrature rules for each subset of the variables). The starting point of generating function (GF) theory was the discovery of Hamilton that the motion of the system is completely described by a characteristic function S, and that S is the solution of a partial differential equation, now called the Hamilton-Jacobi differential equation. It was noticed later, especially by Siegel (Siegel and Moser 1971), that such a function S is directly connected to any symplectic map. It was called generating function. See [10, 14].

Another important point should be taken into account regarding Hamiltonian systems, even with symplectic maps, and that is the lack of energy conservation in the map. It would seem to be an obvious goal for Hamiltonian integration methods both to preserve the symplectic structure and to conserve the energy, but it was shown that this was in general impossible. Thus a symplectic map which only approximates a Hamiltonian cannot conserve energy [22]. Recently, some research has been carried out about energy-preserving symplectic methods based on the key tool line integral associated with conservative vector fields, as well as its discrete version. See,[5, 6].

Polynomial Hamiltonian systems appear frequently in physics and it is important to build good integrators for numerical simulations. In general, it is not possible to find analytical expressions for, so numerical methods are required. Of course, methods preserving the qualitative properties of the exact solution are essential in order to have a good picture of the stability regions. Basically, we have to consider symplectic integrators.

In [1], we introduce a new variational approach for models which are formulated naturally as conservative systems of ODEs, most importantly Hamiltonian systems. The variational method for Hamiltonian systems, which is proposed here, is in some sense symplectic

 ISBN: 978-84-617-8694-7

and energy preserving, and is based on a natural modification of the schemes introduced in [2, 3, 4].

We would like to highlight the advantages of our approach.

- A symplectic map which only approximates a Hamiltonian cannot conserve energy [22]. In our case, by definition the functional penalizes the nonpreservation of the energy, and our linearization can be approximated by well known sympletic quadrature rules. Moreover, for polynomial systems, the formula for the direction $\mathbf{Y}$ can be obtained exactly.
- In the non-stiff situation, the long-time behaviour of symplectic methods is well understood, and can be explained with the help of a backward error analysis (modified equations). In the highly oscillatory (stiff) case, this theory breaks down. However, our linearization is well understood in both cases.

2 A variational approach for Hamiltonian systems

Consider the hamiltonian dynamical system

$$\mathbf{x}'(t) = \frac{\partial \mathbf{H}}{\partial \mathbf{p}}(\mathbf{x}(t), \mathbf{p}(t)), \quad \mathbf{p}'(t) = -\frac{\partial \mathbf{H}}{\partial \mathbf{x}}(\mathbf{x}(t), \mathbf{p}(t)), \tag{1}$$

to hold in a certain time interval $(0, T)$, subject to initial boundary conditions $(\mathbf{x}(0), \mathbf{p}(0)) = (\mathbf{x}_0, \mathbf{p}_0)$. Both $\mathbf{x}$ and $\mathbf{p}$ take on values in $\mathbf{R}^N$. We are interested in setting up a method to understand, and approximate, the trajectories of such a system. In particular, we would like to focus on how the a priori knowledge of conserved quantities may help in improving our ability to approximate such system. It is well-known that the hamiltonian itself $\mathbf{H}(\mathbf{x}, \mathbf{p}) : \mathbf{R}^N \times \mathbf{R}^N \to \mathbf{R}$ is one such conserved quantity so that $\mathbf{H}(\mathbf{x}(t), \mathbf{p}(t)) = \mathbf{H}(\mathbf{x}_0, \mathbf{p}_0) \equiv \mathbf{H}_0$ for all times t in $(0, T)$.

Recently, an alternative to the analysis and numerical approximation of dynamical systems has been introduced ([2, 3, 4]), based on the minimization of the error functional

$$E(\mathbf{X}) = \int_0^T \frac{1}{2} |\mathbf{X}'(t) - \mathbf{F}(\mathbf{X}(t))|^2 \, dt$$

regarded as a measure of how far a given absolutely-continuous path $\mathbf{X}$ complying with $\mathbf{X}(0) = \mathbf{X}_0$ is from being a solution of the underlying dynamical system

$$\mathbf{X}'(t) = \mathbf{F}(\mathbf{X}(t)) \text{ in } (0, T), \quad \mathbf{X}(0) = \mathbf{X}_0. \tag{2}$$

It is elementary to realize that solutions of the system are precisely those $\mathbf{X}$ for which $E(\mathbf{X}) = 0$, and preserve the initial condition. We would like to explore one possibility of

 ISBN: 978-84-617-8694-7

taking advantage of the hamiltonian structure of the system for this variational approach. Namely, if the dimension is even $2N$, and (1) holds for some hamiltonian $\mathbf{H}$, then, as remarked above, $\mathbf{H}$ must be constant on integral curves, and so we could modify the error functional to take into account this extra information to write

$$E(\mathbf{x},\mathbf{p}) = \int_0^T \left[\frac{1}{2}|\mathbf{x}' - \frac{\partial \mathbf{H}}{\partial \mathbf{p}}(\mathbf{x},\mathbf{p})|^2 + \frac{1}{2}|\mathbf{p}' + \frac{\partial \mathbf{H}}{\partial \mathbf{x}}(\mathbf{x},\mathbf{p})|^2 + \frac{1}{2}|\mathbf{H}(\mathbf{x},\mathbf{p}) - \mathbf{H}_0|^2\right] dt. \tag{3}$$

The basis for our proposal is the following.

Proposition 2.1 *Suppose the path* $\mathbf{x}$ *is a critical point for the functional in (3), under the initial condition* $(\mathbf{x}(0),\mathbf{p}(0)) = (\mathbf{x}_0,\mathbf{p}_0)$*. Then* $\mathbf{x}$ *is the unique solution of (1).*

What Proposition 2.1 ensures is that the only critical points of the error functional (3) are the solutions of the hamiltonian system (1) itself, and so an approximation procedure based on minimizing the error functional can never get stuck in local minima, but proceed to steadily approximate the true solution of the dynamical system. Moreover, by construction, the functional penalizes the non conservation of the energy.

We focus on finding the steepest descent direction with respect to the norm

$$\int_0^T |\mathbf{Y}'(t)|^2 dt,$$

in this case, the steepest descent direction can be found as the solution of a variational problem of the following form.

Minimize $\mathbf{Y}$:

$$\frac{1}{2}\int_0^T [|\mathbf{Y}'|^2 + (\mathbf{X}' - \Omega\nabla\mathbf{H}(\mathbf{X})(\mathbf{Y}' + \Omega^T\nabla^2\mathbf{H}(\mathbf{X})\mathbf{Y}) + (\mathbf{H}(\mathbf{X}) - \mathbf{H}(\mathbf{X}(0)))\nabla\mathbf{H}(\mathbf{X})\mathbf{Y}]\, dt,$$

under $\mathbf{Y}(0) = 0$, where

$$\Omega = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{4}$$

This is a standard quadratic variational problem whose optimal solution can be found through the system

$$-\frac{d}{dt}\left[\mathbf{Y}' + \mathbf{X}' + \Omega^T\nabla\mathbf{H}(\mathbf{X})\right] + \nabla^2\mathbf{H}(\mathbf{X})\Omega\left(\mathbf{X}' + \Omega^T\nabla\mathbf{H}(\mathbf{X})\right) + \left(\mathbf{H}(\mathbf{X}) - \mathbf{H}(\mathbf{X}_0)\right)\nabla\mathbf{H}(\mathbf{X}) = 0$$

 ISBN: 978-84-617-8694-7

in $(0,T)$, together with the end-point conditions

$$\mathbf{Y}(0) = 0, \mathbf{Y}'(T) + \mathbf{X}'(T) + \Omega^T \nabla \mathbf{H}(\mathbf{X}(T)) = 0.$$

It is remarkable that the solution of this system can be given in an fully explicit form as

$$\mathbf{Y}(t) = -\int_0^t [s\mathbf{G}(s) + \mathbf{F}(s)]\, ds - t\int_t^T \mathbf{G}(s)\, ds, \tag{5}$$

where

$$\begin{aligned} \mathbf{F} &= \mathbf{X}' + \Omega^T \nabla \mathbf{H}(\mathbf{X}) \\ \mathbf{G} &= \nabla^2 \mathbf{H}(\mathbf{X})\Omega(\mathbf{X}' + \Omega^T \nabla \mathbf{H}(\mathbf{X})) + (\mathbf{H}(\mathbf{X}) - \mathbf{H}(\mathbf{X}(0)))\nabla \mathbf{H}(\mathbf{X}). \end{aligned}$$

We can therefore establish a steepest descent strategy to decrease the error in each iteration. Note that the derivative of the error at $\mathbf{X}$ in the direction $\mathbf{Y}$ is

$$-\int_0^T |\mathbf{Y}'(t)|^2 dt$$

Then we can choose $\eta \in (0,1)$ such that

$$E(\mathbf{X} + \eta \mathbf{Y}) \leq E(\mathbf{X}) - \frac{1}{2}\int_0^T |\mathbf{Y}'(t)|^2 dt.$$

Moreover, it is possible to check uniform convergence of this procedure for smooth Hamiltonian systems (see [16]). The following statement is a direct adaptation of similar results in [16].

Theorem 2.2 *The iterative procedure $\mathbf{X}^{(j)} = \mathbf{X}^{(j-1)} + \eta_j \mathbf{Y}^{(j)}$, starting from arbitrary feasible $\mathbf{X}^{(0)}$, converges strongly in $H^1(0,T)$ to the unique solution of any sufficiently smooth Hamiltonian system.*

3 Numerical results

The iterative numerical procedure is easily implementable.

1. Start with an initial approximation $\mathbf{X}^0(t)$ compatible with the initial conditions, for instance $\mathbf{X}^{(0)}(t) = \mathbf{X}_0$.
2. Assume we have approximation $(\mathbf{X}^{(j)})(t)$ in $[0,T]$.
3. Compute its derivative $(\mathbf{X}^{(j)})'(t)$.
4. Define $\mathbf{F}$ and $\mathbf{G}$ through the formulas

$$\begin{aligned} \mathbf{F}^{(j)} &= (\mathbf{X}^{(j)})' + \Omega^T \nabla \mathbf{H}(\mathbf{X}^{(j)}), \\ \mathbf{G}^{(j)} &= \nabla^2 \mathbf{H}(\mathbf{X}^{(j)})\Omega((\mathbf{X}^{(j)})' + \Omega^T \nabla \mathbf{H}(\mathbf{X}^{(j)})) \\ &\quad + (\mathbf{H}(\mathbf{X}^{(j)}) - \mathbf{H}(\mathbf{X}(0)))\nabla \mathbf{H}(\mathbf{X}^{(j)}). \end{aligned}$$

 ISBN: 978-84-617-8694-7

5. Approximate the mapping

$$\mathbf{Y}^{(j)}(t) = -\int_0^t \left[s\mathbf{G}^{(j)}(s) + \mathbf{F}^{(j)}(s)\right] ds - t\int_t^T \mathbf{G}^{(j)}(s)\, ds, \tag{6}$$

using (symplectic) quadrature formulas. In the case of polynomial Hamiltonians perform an exact integration-

6. Update $\mathbf{X}^{(j)}$ to $\mathbf{X}^{(j+1)}$ by using the formula

$$\mathbf{X}^{(j+1)}(t) = \mathbf{X}^{(j)}(t) + \eta_j \mathbf{Y}^{(j)}(t).$$

7. Iterate (3), (4), (5) and (6) until numerical convergence.

Many interesting Hamiltonian systems arising from different fields of study are defined by polynomial Hamiltonian functions. For example the Fermi-Pasta-Ulam problem and the polynomial pendulum oscillator of degree k, obtained from the Hamiltonian function of the nonlinear pendulum equation $H(p,q) = 1/2p^2 + 1 - cosq$, by retaining a finite number of terms in the Taylor expansion of the cosine.

It is well known that symplectic RK-methods only conserve quadratic Hamiltonian functions but, in general, they fail to yield conservation for higher degree, and so do symmetric methods.

We consider the polynomial problem:

$$H(p,q) = \frac{1}{3}p^3 - \frac{1}{2}p - \frac{1}{3}q^3 + \frac{1}{2}q^2 + \frac{1}{6} \tag{7}$$

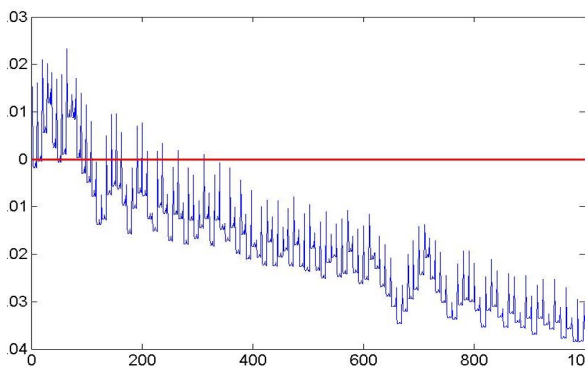

Figure 1: Energy function associated to the integration by Lobatto IIIB.

 ISBN: 978-84-617-8694-7

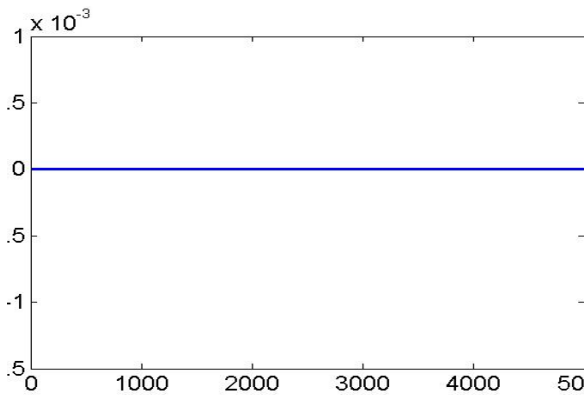

Figure 2: Energy function associated to the integration by our variational approach.

Energy function H evaluated over the numerical solution obtained by the Lobatto IIIB method is given in Figure 1 and by our variational approach in Figure 2 applied to problem (7).

It is possible to modified the original RK method in order to preserve energy but in a most sophisticated way [11]. Moreover, as we said before, in the highly oscillatory (stiff) case, the classical theory for RK breaks down. However, our linearization is well understood in all the cases.

Abstract

In this paper, a parametric family of seventh-order of iterative method to solve systems of nonlinear equations is presented. Its local convergence is studied and quadratic polynomials are used to investigate its dynamical behavior. The study the fixed and critical points of the rational function associated to this class allows us to obtain regions of the complex plane where the method is stable. By depicting parameter planes and dynamical planes we obtain complementary information of the analytical results.

Key words: Nonlinear system of equations, iterative method, basin of attraction, dynamical plane, stability

1 Introduction

The problem of finding roots of nonlinear system $F(x) = 0$, where $F : D \subseteq \mathbb{R}^n \longrightarrow \mathbb{R}^n$ arises in different areas of scientific computing and engineering. The solution of this problem is usually obtained by a fixed point function $\overline{G} : D \subseteq \mathbb{R}^n \longrightarrow \mathbb{R}^n$ associated to a fixed point iteration scheme. There are many iterative schemes to solve this problem. The most common root-finding method for solving systems of nonlinear equations is the second order Newton's scheme. But in recent years, some researchers have used new iterative methods as an alternative to classical one that have higher order and better efficiency (see, for example [5, 8]). However, the analysis of the stability of these iterative methods when $n > 1$ is so complicated and most of the times is impossible, but the study of the behavior of the

 ISBN: 978-84-617-8694-7

iterative method in scalar case that is, for $n = 1$, in the complex plane is an interesting field of study(see, for instance [1, 7]). Specially the advent of computers in last decades, made it practically possible to study the structure of the dynamical and parameter planes of iterative methods closely, since large amount of computational power is need to obtain their precise shape, that can be easily performed in computers.

The main aim of this analysis is finding the regions in the complex plane where our function shows better stability behavior when converges to the zeros of the function. But even in the scalar case, finding stable regions for a high order iterative method is not easy. High order iterative methods, even for simple scalar nonlinear function $f(z)$, usually results in a high degree fixed point operator, since the key of stability analysis is the study of the fixed point operator.

In this paper we propose the following family of seventh-order iterative methods to solve systems of nonlinear equations, whose iterative expression is

$$\begin{aligned} y^{(k)} &= x^{(k)} - \left[F'(x^{(k)})\right]^{-1} F(x^{(k)}), \\ z^{(k)} &= y^{(k)} - \frac{1}{\beta}\left[F'(x^{(k)})\right]^{-1} F(y^{(k)}), \\ w^{(k)} &= z^{(k)} - \left[F'(x^{(k)})\right]^{-1} \left((2 - 1/\beta - \beta)F(y^{(k)}) + \beta F(z^k)\right), \\ x^{(k+1)} &= w^{(k)} - G(t^{(k)}) \left[F'(x^{(k)})\right]^{-1} F(w^{(k)}), \end{aligned} \tag{1}$$

where $t^{(k)} = I - \frac{1}{\beta}\left[F'(x^{(k)})\right]^{-1}[y^{(k)}, z^{(k)}; F]$ and $G : \mathbb{R}^{n\times n} \longrightarrow \mathbb{R}^{n\times n}$ is a matrix weight function that is chosen in order to obtain the seventh-order of convergence. Let us remark that the first three steps of 1 correspond to family M4 of parametric methods. It was shown in [3] to have fourth-order of convergence for all non-zero values of β.

In this paper, we are going to analyze the dynamical behavior of class (1) on scalar functions. This analysis will be made on quadratic polynomials, as they are the simplest nonlinear functions. This analysis will give us important information about the stability of the family in terms of the value of the parameter.

The rational function associated with a subclass of (1) on the quadratic polynomial $p(z) = (z - a)(z - b)$ is used in the following and denoted by $O_p(z)$. The obtained results can be extrapolated to more complicated nonlinear function.

The rest of paper is organized as follows: in Section 2 the local convergence of the iterative class (1) is presented. In Section 3, we obtain the operator $O_p(z)$ of a particular subfamily of (1) on $p(z)$ and then the stability of fixed points of the operator is studied. Critical points of $O_p(z)$ are investigated in Section 4. Finally, Section 5 is devoted to study the parameter and dynamic planes for some members of the subclass.

2 Convergence analysis

In this section, we present a local convergence theorem for family (1). In order to get this result, we introduce the following notation.

Let us denote by $X = \mathbb{R}^{n\times n}$ the space of all $n \times n$ real matrices; the weight function in this context is $G : X \to X$ such that

(i) $G'(u)(v) = G_1uv$, being G' the first derivative of G, $G' : X \to \mathcal{L}(X)$, $G_1 \in \mathbb{R}$ and $\mathcal{L}(X)$ denotes the space of linear mappings from X to itself.

(ii) $G''(u, v)(w) = G_2uvw$, being G'' the second derivative of G, $G'' : X \times X \to \mathcal{L}(X)$ and $G_2 \in \mathbb{R}$.

Then, the Taylor expansion of G around the identity matrix gives

$$G(\eta^{(k)}) \approx G\left(\frac{\beta-1}{\beta}I\right) + \left(t^{(k)} - \frac{\beta-1}{\beta}I\right)G_1 + \frac{1}{2}\left(t^{(k)} - \frac{\beta-1}{\beta}I\right)^2 G_2.$$

The following result establishes that this class have order of convergence at least seven.

Theorem 1 *Let $F : D \subseteq \mathbb{R}^n \longrightarrow \mathbb{R}^n$ be a sufficiently differentiable function in an open convex set D and let $\overline{x} \in D$ be a solution of the system of nonlinear equations $F(x) = 0$. We suppose that $F'(x)$ is continuous and nonsingular at $\overline{x}$. Then, the sequence $\{x^{(k)}\}_{k\geq 0}$, obtained by expression (1), converges to $\overline{x}$ with order of convergence at least seven when $G_0 = G\left(\frac{\beta-1}{\beta}I\right) = I$, $G_1 = \beta$ and $G_2 = \frac{1}{2}(-\beta + 6\beta^2)$. Moreover, the special case of $\beta = \frac{1}{5}$ has order of convergence eight.*

One could use different weight functions $G(t)$, satisfying the conditions of previous result, for designing specific families of iterative schemes. For example,

$$G(t^{(k)}) = I + \beta\left(t^{(k)} - \frac{\beta-1}{\beta}I\right) + \frac{1}{4}(-\beta + 6\beta^2)\left(t^{(k)} - \frac{\beta-1}{\beta}I\right)^2 \tag{2}$$

or the rational function,

$$G(t^{(k)}) = I + \frac{10\beta-1}{(1-6\beta)\beta}[t^{(k)}]^{-1}\left[\frac{1-6\beta}{10\beta-1}I - \frac{(1-2\beta)\beta}{10\beta-1}t^{(k)}\right]$$

The subclass corresponding to the first function $G(t^{(k)})$ is denoted by M7.

3 Fixed points of operator $O_p(z)$

In this section, we study the fixed points of operator $O_p(z)$ as a function of β and in the next section, we investigate its critical points. To get this aim, we are going to recall some dynamical concepts of complex dynamics (see [2]) that we use in this work.

Given a rational function $R : \hat{\mathbb{C}} \to \hat{\mathbb{C}}$, where $\hat{\mathbb{C}}$ is the Riemann sphere, the *orbit of a point* $z_0 \in \hat{\mathbb{C}}$ is defined as:

$$\{z_0,\, R(z_0),\, R^2(z_0), ..., R^n(z_0), ...\}.$$

We analyze the phase plane of the map R by classifying the starting points from the asymptotic behavior of their orbits. A $z_0 \in \hat{\mathbb{C}}$ is called a *fixed point* if $R(z_0) = z_0$. A *periodic point* z_0 of period $p > 1$ is a point such that $R^p(z_0) = z_0$ and $R^k(z_0) \neq z_0$, for $k < p$. A *pre-periodic point* is a point z_0 that is not periodic but there exists a $k > 0$ such that $R^k(z_0)$ is periodic. A *critical point* z_0 is a point where the derivative of the rational function vanishes, $R'(z_0) = 0$. Moreover, a fixed point z_0 is called *attractor* if $|R'(z_0)| < 1$, *superattractor* if $|R'(z_0)| = 0$, *repulsor* if $|R'(z_0)| > 1$ and *parabolic* if $|R'(z_0)| = 1$. The fixed points that do not correspond to the roots of the polynomial $p(z)$ are called *strange fixed points*.

The basin of attraction of an attractor α is defined as:

$$\mathcal{A}(\alpha) = \{z_0 \in \hat{\mathbb{C}} \ :\ R^n(z_0) \to \alpha,\ n \to \infty\}.$$

The *Fatou set* of the rational function R, $\mathcal{F}(R)$, is the set of points $z \in \hat{\mathbb{C}}$ whose orbits tend to an attractor (fixed point, periodic orbit or infinity). Its complement in $\hat{\mathbb{C}}$ is the *Julia set,* $\mathcal{J}(R)$. That means that the basin of attraction of any fixed point belongs to the Fatou set and the boundaries of these basins of attraction belong to the Julia set.

The fixed and critical points as well as their asymptotic behavior depend on the values of parameter β. Since even for quadratic polynomials, $O_p(z)$ is so complicated and difficult to work with, instead we use conjugacy maps to get a simpler operator. By using the following conjugacy map

$$M(z) = \frac{z-a}{z-b}, \qquad M^{-1} = \frac{zb-a}{z-1},$$

with the properties:

$$M(\infty) = 1, \qquad M(a) = 0, \qquad M(b) = \infty,$$

P. Blanchard in [2] proved that, for quadratic polynomials, Newton's operator is conjugated to rational function z^2,

In a similar way, it is easy to show that operator $O_p(z)$ is conjugated to the rational function

$$M_p(z,\beta) = z^7 \frac{(-1+5\beta+14\beta z+14\beta z^2+6\beta z^3+\beta z^4)r(z)}{(\beta+6\beta z+14\beta z^2+14\beta z^3-z^4+5\beta z^4)s(z)},$$

 ISBN: 978-84-617-8694-7

where $r(z) = 4\beta^2 - 24\beta^3 + 80\beta^4 + (\beta + 26\beta^2 - 188\beta^3 + 900\beta^4)z + (6\beta + 72\beta^2 - 608\beta^3 + 4592\beta^4)z^2 + (14\beta + 108\beta^2 - 968\beta^3 + 13952\beta^4)z^3 + (10\beta + 128\beta^2 - 688\beta^3 + 28080\beta^4)z^4 + (-1 + 3\beta + 114\beta^2 + 8\beta^3 + 39580\beta^4)z^5 + (-4\beta + 44\beta^2 + 320\beta^3 + 40400\beta^4)z^6 + (184\beta^3 + 30496\beta^4)z^7 + (40\beta^3 + 17216\beta^4)z^8 + (4\beta^3 + 7260\beta^4)z^9 + 2240\beta^4 z^{10} + 480\beta^4 z^{11} + 64\beta^4 z^{12} + 4\beta^4 z^{13}$ and $s(z) = 4\beta^4 + 64\beta^4 z + 480\beta^4 z^2 + 2240\beta^4 z^3 + (4\beta^3 + 7260\beta^4)z^4 + (40\beta^3 + 17216\beta^4)z^5 + (184\beta^3 + 30496\beta^4)z^6 + (-4\beta + 44\beta^2 + 320\beta^3 + 40400\beta^4)z^7 + (-1 + 3\beta + 114\beta^2 + 8\beta^3 + 39580\beta^4)z^8 + (10\beta + 128\beta^2 - 688\beta^3 + 28080\beta^4)z^9 + (14\beta + 108\beta^2 - 968\beta^3 + 13952\beta^4)z^{10} + (6\beta + 72\beta^2 - 608\beta^3 + 4592\beta^4)z^{11} + (\beta + 26\beta^2 - 88\beta^3 + 900\beta^4)z^{12} + (4\beta^2 - 24\beta^3 + 80\beta^4)z^{13}$.

The fixed points are the roots of equation $M_p(z, \beta) = z$, or $z(z-1)q(z) = 0$. In this case, $q(z)$ is a polynomial of degree 22, whose roots are different from $z = 0$ and $z = 1$. That is, fixed points of operator $M_p(z, \beta)$ are, $z = 0$, $z = 1$, $z = \infty$ and the 22 roots of $q(z)$, denoted by $s_i(\beta)$, $i = 1, 2, \cdots, 22$.

In order to study the stability of the fixed points, we calculate the first derivative of $M_p(z, \beta)$ and evaluate it at every fixed point. The resulting absolute value gives us information about the asymptotic behavior of the point. We conclude that $z = 0$ and $z = \infty$ are always superattracting fixed points, but the stability of other fixed points depend on the value of the parameter β.

On the other hand, changes in the multiplicity of the fixed points imply also alterations in their dynamical behavior. For different values of β we have:

- If $\beta = 0$, we have only one simple fixed point.
- There are many different values of β in the complex plane that for these values, strange fixed points $s_i(\beta)$, $i = 1, 2, \cdots, 22$ are equal to 1, so strange fixed point 1 can have different multiplicities.
- However, the behavior of the strange fixed points are different in the complex plane especially around 0, as in a small region near 0 some of them satisfy $|M_p'(s_i(\beta), \beta)| < 1$. Figure 1, depicts $|M_p'(s_i(\beta), \beta)| < 1$, for $i = 18, 19, \cdots, 22$ and strange fixed point 1 simultaneously near 0. These six strange fixed points among all strange fixed points have the bigger regions in which $|M_p'(s_i(\beta), \beta)| < 1$, in this figure S_{one} denoted strange fixed point $z = 1$. One can see more details of these stability functions in Figure 2, where boundaries of regions around the basin of attraction of strange fixed point $z = 1$ are shown. These four regions are denoted by $B1$, $B2$, $B3$ and $B4$.

4 Critical points of operator $M_p(z, \beta)$

Let us recall that critical points of $M_p(z, \beta)$ are the roots of $M_p'(z, \beta) = 0$, since we have

$$M_p'(z, \beta) = (z + 1)^{12} z^6 u(z),$$

 ISBN: 978-84-617-8694-7

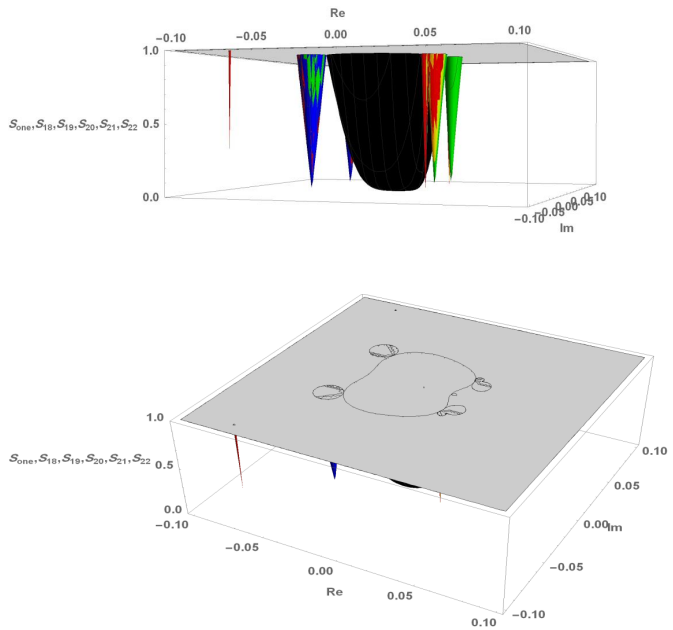

Figure 1: Stability functions of strange fixed points S_{one} and $S_{18}, S_{19}, \cdots, S_{22}$.

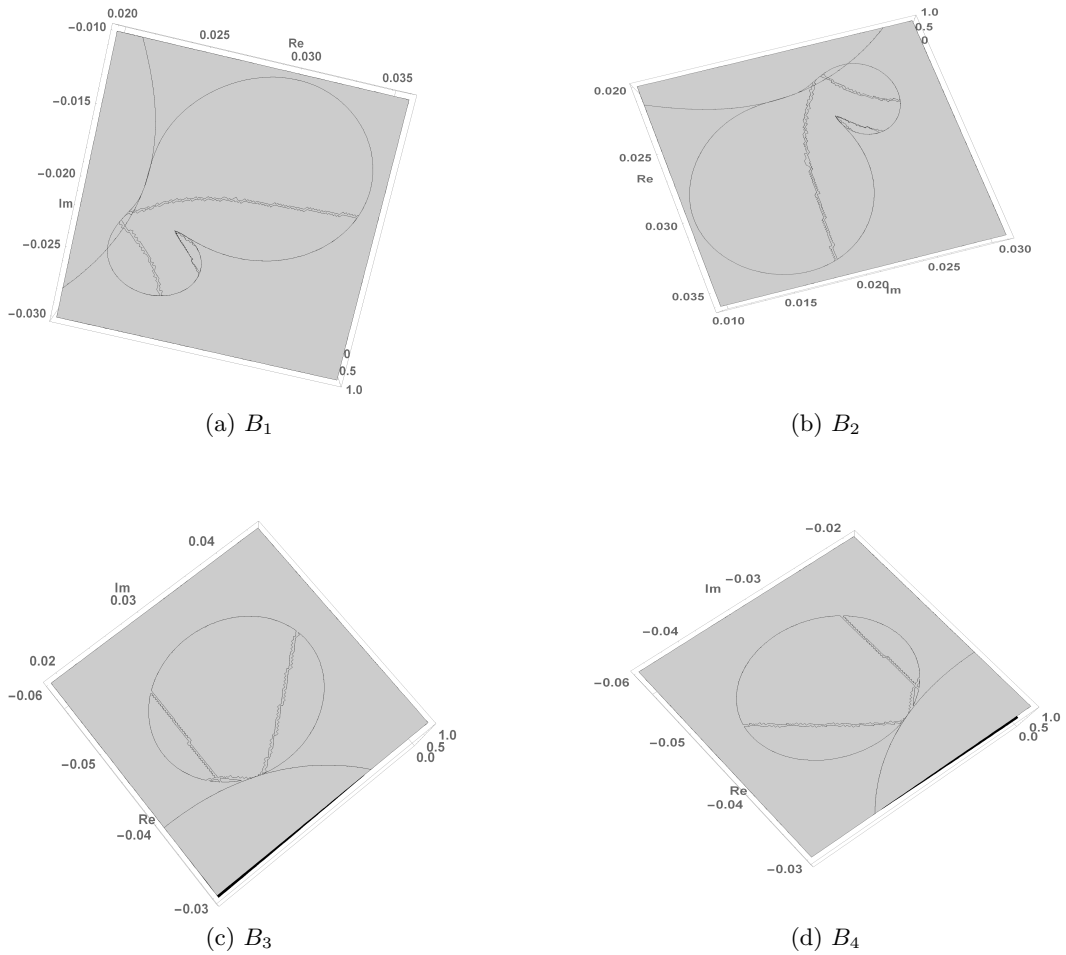
where $u(z) = 1400\beta^5 + (-4\beta - 40\beta^2 + 1012\beta^3 - 6504\beta^4 + 18080\beta^5)z + (-16\beta + 71\beta^2 + 2506\beta^3 - 25464\beta^4 + 106640\beta^5)z^2 + (-12\beta + 440\beta^2 + 2244\beta^3 - 51208\beta^4 + 377120\beta^5)z^3 + (54\beta + 274\beta^2 + 510\beta^3 - 49668\beta^4 + 886920\beta^5)z^4 + (6 - 36\beta - 224\beta^2 + 2184\beta^3 - 7824\beta^4 + 1458240\beta^5)z^5 + (-11 - 42\beta - 310\beta^2 + 4540\beta^3 + 20592\beta^4 + 1716960\beta^5)z^6 + (6 - 36\beta - 224\beta^2 + 2184\beta^3 - 7824\beta^4 + 1458240\beta^5)z^7 + (54\beta + 274\beta^2 + 510\beta^3 - 49668\beta^4 + 886920\beta^5)z^8 + (-12\beta + 440\beta^2 + 2244\beta^3 - 51208\beta^4 + 377120\beta^5)z^9 + (-16\beta + 71\beta^2 + 2506\beta^3 - 25464\beta^4 + 106640\beta^5)z^{10} + (-4\beta - 40\beta^2 + 1012\beta^3 - 6504\beta^4 + 18080\beta^5)z^{11} + (-14\beta^2 + 154\beta^3 - 700\beta^4 + 1400\beta^5)z^{12}$.

So the critical points of $M_p(z, \beta)$ are $z = 0$, $z = \infty$ and $z = -1$ and the 12 roots of polynomial $u(z)$. We denote these 12 roots of $p(z)$ as $c_i(\beta)$, $i = 1, 2, \cdots 12$. To obtain some properties of $c_i(\beta)$ we discretize the square of $[-2, 2] \times [-2, 2]$ in the complex plane with 400×400 mesh points. We denote this mesh points by (i, j), where $i, j = 1, 2, \cdots, 400$, then

 ISBN: 978-84-617-8694-7



(a) B_1 (b) B_2

(c) B_3 (d) B_4

Figure 2: Details of the stability functions of strange fixed points S_{one} and $S_{18}, S_{19}, \cdots, S_{22}$.

 ISBN: 978-84-617-8694-7

by obtaining the roots of $p(z)$ for each $\beta = (i, j)$, a numerical value of critical points c_i in the square $[-2, 2] \times [-2, 2]$, for $i = 1, 2, \cdots, 12$ is obtained.

A classical result establishes that there is at least one critical point associated with each invariant Fatou component. Points $z = \infty$ and $z = 0$ are both superattractive fixed points of $M_p(z, \beta)$, so they also are critical points and give rise to their respective Fatou components. So, the way to calculate the parameter planes associate to $M_p(z, \beta)$ is to study the orbits of each free independent critical point for all the complex value of the parameter β in the defined mesh. In the next section we investigate parameter planes of $M_p(z, \beta)$.

5 The parameter space

As mentioned in the previous sections, the dynamical behavior of operator $M_p(z, \beta)$ depends on the values of the parameter β. In order to get the parameter plane we study the orbits of the free critical points for each β in the complex square $[-2, 2] \times [-2, 2]$. Strange fixed points are attracting near zero, so we only focus our attention in this region. To find the most stable members of the family M7, we are looking for regions in which the orbits of free critical points converge to zero or infinity. Since 12 critical points of $M_p(z, \beta)$ are two-

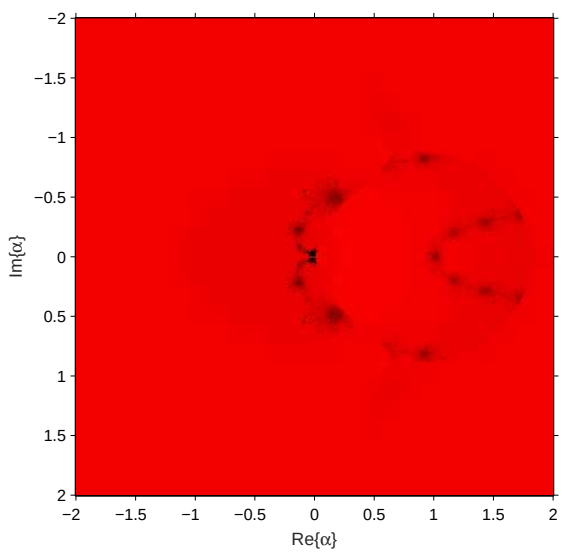


Figure 3: Parameter plane for critical point c_1

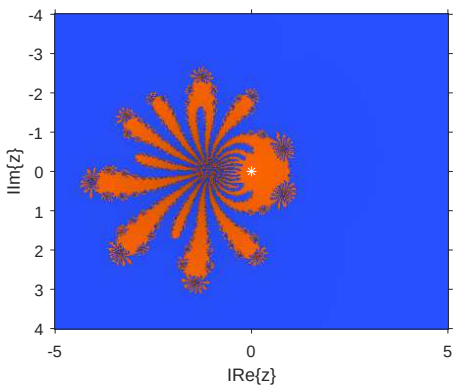
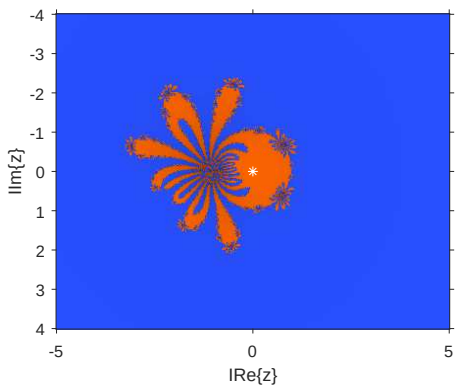
by-two dependent and we here study the parameter plane of one of these 6 critical points, shown in Figure 3, calculated by using the routines presented in [4]. We have painted in red the values of the parameter that makes the critical point converge to $z =$ or $z = \infty$

 ISBN: 978-84-617-8694-7

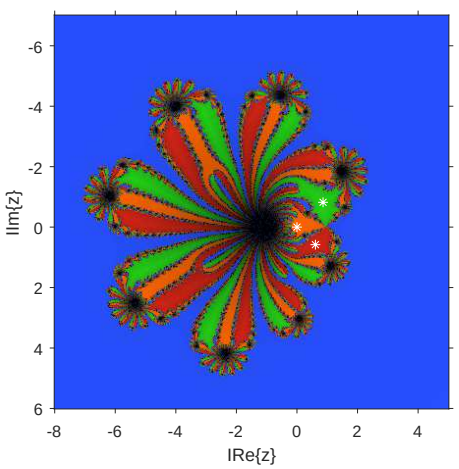
(brighter as lower is the number of iterations needed), and in black if the critical point has not converged after 600 iterations, or has converged to another element (attracting strange fixed point or periodic orbit).



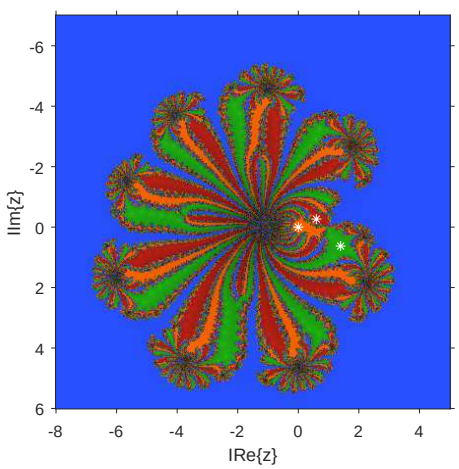
(a) $\beta = 0.1 - 0.1i$



(b) $\beta = 0.5 + 0.5i$



(c) $\beta = -0.05 + 0.03i$



(d) $\beta = 0.032 - 0.021i$

Figure 4: Some dynamical planes of family M7

By analyzing the conclusions obtained from the parameter planes of the family M7, we select some elements of this family to depict their dynamical planes. These planes show different behaviors of the members of the family (see Figure 4). These dynamical planes have generated by iterating an element of the family M7 that is, for a constant β and using

each point of the complex plane as an initial estimation the dynamical plane associated to each member obtained. These dynamical planes are built (again with the routines appearing in [4]) by using an a mesh of 400×400 points, a maximum number of 100 iterations and a tolerance of 10^{-3}. Figures 4a and 4b show the dynamical planes of members of $\beta = 0.1-0.1i$ and $0.5 + 0.5i$, respectively, corresponding to the red area of the parameter plane. In both figures there are only two basins of attraction that correspond to superattracting $z = 0$ and $z = \infty$, respectively shown in orange and blue colors. On the other hand, Figure 4c and 4d show the members $\beta = -0.05+0.03i$ and $\beta = 0.032-0.021i$, corresponding to values of β in the stability regions appearing in Figure (2a) and (2c) of some strange fixed points. For both of them there exists four basins of attraction. Value $\beta = -0.05 + 0.03i$ results in a member of the family whose dynamical plane shows the basins of attraction of $z = 0$, $z = \infty$ and, in red and green colors, the basins of attraction of two strange fixed points which numerical values for $\beta = -0.05 + 0.03i$ are equal to $0.608121 + 0.58028i$ and $0.860704 - 0.821302i$. Also $\beta = 0.032-0.021i$ results in a member of the family that has four basins of attractions corresponding to $z = 0$, $z = \infty$ and two strange fixed points $z = 1.39925 + 0.626732i$ and $z = 0.59525 - 0.266617i$ whose basins of attraction are represented in the dynamical planes in green and red color, respectively.

Abstract

In the present paper it is presented the flow around a 2D square cylinder which is located downstream of a splitter plate and at a certain distance of it. The fluid velocity below and above the splitter plate is different, several velocity ratios are considered, it is interesting to see that the downstream vortex shedding frequency and amplitude highly depends on the velocity ratio defined upstream. So far, the Reynolds numbers evaluated fall into the laminar unsteady regime, yet the interaction between the upstream mixing layer and the wake generate fully different downstream vortex shedding for different upstream velocity ratios, lift, drag and Strouhal numbers are as well highly dependent on the velocity ratios. In the present paper, the comparison between the resuls obtained via CFD finite volumes and Lattice Boltzmann Method are being presented. For these initial cases studied the agreement is very good.

Key words: Laminar flow, CFD, Finite volumes, Lattice Boltzmann Methods, Passive flow control.

1 Introduction

It has been shown by past investigations on circular cylinders, e.g., [1–6], that the flow approaching with linear shear greatly altered the vortex dynamics in the wake when compared to the uniform flow case. They attributed this phenomena to the constant vorticity embedded in the free-stream. For square-sectional cylindrical bodies, shear effects have been reported by, e.g., [7–14]. Saha et al. [9] studied numerically the same problem for a wide range of Reynolds numbers. They showed that due to influence of shear, Karman Vortex Street mainly consisted of clockwise vortices, whose decay was very slow when compared to that of uniform flow. Cheng et al. [12, 13] reported that vortex shedding disappeared

for large shear parameters. The mean lift and drag coefficients tended to decrease with increasing the shear parameter. They also observed that the vortex shedding frequency tended to decrease with the increase of the shear parameter, although they highlighted that this observation was opposite to the one obtained by Kiya et al. [2] when studding shear flow past circular cylinders.

Lankadasu and Vengadesan [14] also reported a decrease of mean lift and drag coefficients with the increasing shear, for a given Reynolds number. The same phenomenon was observed for a given shear and when Reynolds number was increased. It was also found that the critical Reynolds number at which the flow becomes unsteady periodic, was reduced as shear increased. Bhattacharyya and Maiti [10] studied laminar shear flow past a square cylinder placed nearby a wall, Reynolds up to 1400. For a gap height of 0.25 times the square cylinder height, vortex shedding suppression and steadiness of the wake was observed up to a Reynolds 250. For a Reynolds number equal and above 500, only negative vortices behind the cylinder at closed proximity to the wall were found. Bhattacharyya and Maiti [11] investigated as well laminar flow over a square cylinder placed nearby a wall, Reynolds <1500. They found that the critical gap height for vortex shedding suppression was dependent on the Reynolds number.

There are typical situations, where the non-uniformity of the approaching flow is due to the effect of a body located in front or behind the one to be studied. For example, when a small cylinder is placed in the separated shear layer of a large main cylinder to alter the vortex shedding phenomena behind the main cylinder, the small cylinder is inevitably subjected to the effect of shear induced from the large cylinder. Onset of periodic flow from the small cylinder induces oscillatory forces on the body, which may trigger flow-induced vibrations, and in turn alter the vortex shedding on the main cylinder.

Some of the latest most relevant numerical simulations of flow past a square cylinder with the incorporation of a control plate to alter the wake, which is having similarities to the present study, were carried out among others by, Lesage and Gartshore [15], Sakamoto et al [16, 17], Zhou et al [18], Doolan [19], Ali et al [20, 21], Malekzadeh and Sohankar [22] and Salinas et al [23]. It must be highlithed that none of these previous studies resembles the one presented in this paper, in fact according to the authors knowledge, just a single previous paper undertaken by the authors, see [24] matches with the work presented here.

2 Problem definition

The computational domain under study is defined in figure 1a, notice that it consists of a 2D square cylinder located downstream of a splitter plate, the plate thickness is negligible, being the distance between the splitter plate and the square three times the square cylinder lateral side. This distance, which will remain constant in this research, plays an important role, since it controls the mixing flow upstream. The boundary conditions employed, already

 ISBN: 978-84-617-8694-7

presented in figure 1, consist of, newmann boundary conditions for pressure and Dirichlet boundary conditions for velocity at the inlet, no slip boundary conditions were applied to all solid boundaries, at the upper and lower boundaries Newmann boundary conditions for velocty and pressure vere defined, finally, at the outlet, Newmann boundary conditions for pressure and velocity were considered. A grid of 200x150 was used for all the finite volume simulations carried out in the present study, with 50 cells allocated on the square cylinder side in both x and y directions. The non-dimensional time step employed was of dt=0.001. Three diferent Reynolds numbers Re=100; 150 and 200, defined as a function of the fluid velocity below the plate and the square cylinder side, were evaluated. For each Reynolds six different velocity ratios were considered r= 1.5; 2; 2.5; 3; 3.5 and 4. Via using the conventional LBM, just few cases were considered, the idea behind the employment of this particular method was to compare the results with the previous ones obtained via finite volumes. With LBM, just a single Reynolds number was studied Re=100, two velocity ratios were considered r=1.5 and 2. The advantage of using LBM is that it is computationally less expensive and therefore an extreme fine mesh could be used, the mesh employed was having 6200x3200 cells, 200 cells were used along each square cylinder side. The non-dimensional time step used for the case of LBM was of dt=0.0005.

In the present paper, two different self-made codes for laminar flow were used, the first one is based on finite volumes implementation of the Navier Stokes equations (NS), the second one employs the Lattice Boltzmann Method (LBM) to perform the CFD siulations. The code based on NS equations was already validated in [24], the validation of the LBM code is implementd in the next section. In figure 1b, the mesh used for the finite volumes code is presented, figures 1c and d respectively introduce the mesh used for the LBM code and a zoom view of it.

3 Code validation

The Lattice boltzmann code was validated via comparing the results with the previous researchers ones. It was observed that the flow around a square cylinder, was steady for Reynolds numbers 50 and 52, and unsteady periodical at Re=53. According to Sohankar et al [25], Von Karman vortex street appeared and therefore vortex shedding was happening in the wake of the square cylinder at $Re = 51.2 \pm 1$. Kelkar and Patankar [26] through stability analysis of the flow, found that the critical Reynolds number for the onset of vortex shedding was 54. From the present LBM code, at Reynolds 52, the steady downstream bubble lenght obtained when using LBM differed in 2.9% versus the steady bubble length obtained in [24], based on these results we considered the LBM code presented in this paper, fully validated for the present application at laminar Reynolds numbers.

4 Results

The vast majority of the results presented in this section are the ones obtained with the NS equations finite volumes code, the intention of the authors is comparing these results with the ones obtained using LBM. For the cases studied, this comparisons are presented in figures 2 to 4.

Figure 2 presents the stagnation point location at the square cylinder upstream vertical face. It is important to realize that the stagnation point location fluctuates regardless of the upstream conditions established, the fluctuation amplitude initially decreases and then tends to increase with the velocity ratio increase. What is even more interesting, is that the stagnation point location suffers a drastic jump for velocity ratios bigger than 2, clearly indicating that vortex shedding will suffer a drastic change. The results obained via using LBM are represented by rounded dots, and it is noticed that at small velocity ratios, r=1.5, the stagnation point location fluctuation, is much bigger than the one obtained when using finite volumes. Whenever the velocity ratio was 2, the results were in good agreement with

the ones obtained using finite volumes. At this point, the origin of the disagreement at low velocity ratios is so far unknown, further cases need to be computed to find out which of the two codes produces more accurate results. The wide amplitude associated to the stagnation point location at low velocity ratios is due to the wide fluctuation observed on the upstream mixing layer.

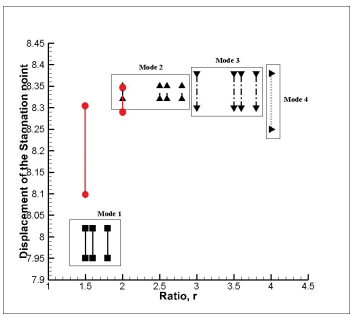

Figure 2: Displacement of the stagnation point vs. the Ratio, r for Reynolds number, Re=100 and upstream length, ul=6a. The rounded dots characterize the results obtained via using LBM.

Figure 3 presents, the average lift and drag coefficients as a fucntion of the velocity ratio and the upstream reynolds number, obtained when employing the velocity below the plate. This figure clearly indicates that the most important parameter is the velocity ratio, Reynolds number plays a secondary role. It also clarifies that four vortex shedding modes are obtained when increassing the velocity ratio from 1.5 to 4. A further explanation of the different modes and its associated downstream vortex shedding is to be found in [24]. When comparing the previous results obtained via finite volumes with the ones obtained using LBM, it can be seen that the agreement is very good. Clearly more results need to be obtained via LBM, but so far the expectatives are promissing.

Figure 4 presents the dowstream vortex sheddding non dimensional frequency as a function of the velocity ratio and the Reynols number, again a very similar trend to the one presented in figure 3 is to be spotted. Yet, although velocity ratio plays a very relevant role, it appears that the vortex shedding frequency is more deeply affected by the Reynolds number than the lift and drag coefficients. The increase in Strouhal number between two consecutive modes is larger for higher velocity ratios and higher Reynolds numbers, because as the velocity ratio increases, it leads to an increase in flow kinetic energy causing higher oscillations in the mixing layer making it unstable and enhancing the vortex shedding frequency downstream. It is observed that in modes 1 and 2 the predominant effect when considering the Strouhal number change is due to velocity ratio r, whereas in modes 3 and 4, the Reynolds number increase generates a higher variation in Strouhal number. This is due to the higher difference in of the kinetic energy, which is 9 and 16 times bigger respec-

 ISBN: 978-84-617-8694-7

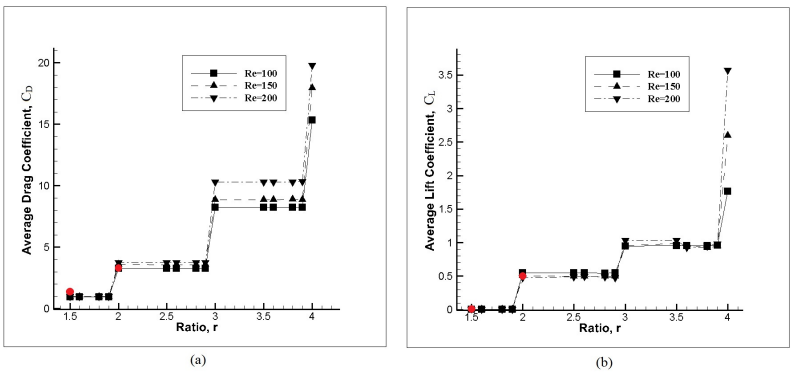

Figure 3: (a) Average drag coefficient, $C_{D_{avg}}$ versus ratio, r. (b) Average Lift coefficient, $C_{L_{avg}}$ versus ratio, r. Upstream length ul = 6a. The rounded dots characterize the results obtained via using LBM.

tively for modes 3 and 4 on the top of the splitter plate when compared to the kinetic energy below the plate, this kinetic energy difference is much higher than the one at lower Reynolds numbers, promoting the vortex dissipation in the wake of the square cylinder. When comparing the results obtained via using LBM with the ones gathered via finite volumes, the agreement is very good, which certifies that at low Reynolds numbers, even when the flow has relatively high shear stresses, the conventional LBM is a reliable and fast methodology to be employed.

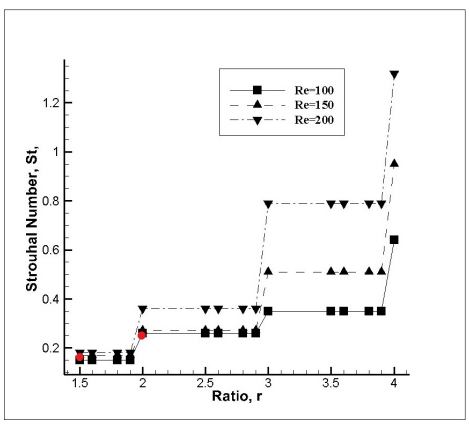

Figure 4: Strouhal Number, St versus Ratio, r for (a) ul=6a. The rounded dots characterize the results obtained via using LBM.

 ISBN: 978-84-617-8694-7

5 Conclusions

This paper is comparing the results obtained when evaluating the flow around a square cylinder with a splitter plate located in front of it, via employing two self made codes, one based on finite volumes and the other based on LBM.

A drastic change in lift and drag coefficients was observed as a function of the upstream velocity ratio. The effect of Reynolds number plays a secondary role, being this role more relevant at high velocity ratios due to the high differences in the splitter plate above/below kinetic energy, which drastically modifies the mixing and shear layers.

For the few cases evaluated using LBM, the results were pretty accurate, althoug the entire set of Reynolds and velocity ratios need to be evaluated using this methodology, the resuls obtained and presented in this paper give confidence to the authors regarding the final outcome of the reserach.

Nondominated solutions in a fully fuzzy linear programming problem

M. Arana-Jiménez[1]

[1] *Department of Statistics and Operations Research, University of Cádiz*

emails: manuel.arana@uca.es

Abstract

In this work, it is presented a new method for solving the fuzzy optimal (nondominated) solutions of a fully fuzzy linear programming problem with inequality constraints and triangular fuzzy numbers, not necessarily symmetric, by the means of solving a multiobjective linear problem. It is proved an equivalence between the set of nondominated solutions of the fully fuzzy linear programming problem and the set of weakly efficient solutions of the considered and related mulitobjective linear problem.

Key words: Fully fuzzy linear programming problem, fuzzy numbers, multiobjective optimization

1 Introduction

Nowadays, the concept of decision making in fuzzy environment introduced by Bellman and Zadeh [1] is well-known and adopted by researchers in fields close to fuzzy linear programming [2, 3, 4, 5, 6]. It was usual that not all parts of the fuzzy linear problem were assumed to be fuzzy. In fact, an interesting problem in the recent literature, at the same time that a challenge, in to solve a fuzzy linear programming problems in which all the parameters as well as the variables are represented by fuzzy. In this regard, Lofti et al. [7] pointed out that there was no method in literature for finding the fuzzy optimal solution of fully fuzzy linear programming (FFLP) problems and proposed a new method to find the fuzzy optimal solution of (FFLP) problems with equality constraints with symmetric fuzzy numbers. Kumar et al. [8] claim that there was no method in the literature to obtain the exact solution of (FFLP) problems with equality constraints, and that in [7] the solutions are approximate not exact and also it is very difficult to apply the existing method. In this regard, they propose a new method for finding the fuzzy optimal solution of (FFLP) problems with equality constraints, with triangular fuzzy numbers involved, although they use ranking function (see [9] and

 ISBN: 978-84-617-8694-7

the bibliography there in) to compare the objective function values. In this way, Khan et al. [10] deal with (FFLP) with inequalities, and they also compare the objective function values via ranking functions (see also [11, 12]).

In this work, it is presented a new method to find the fuzzy optimal (nondominated) solutions of (FFLP) problems with inequality constraints with triangular fuzzy numbers and not necessarily symmetric, via solving a multiobjective linear problem with crips numbers. It is proved that there exists an equivalence between the set of fuzzy optimal (nondominated) solutions of (FFLP) and the set of weakly efficient solutions of its related mulitobjective linear problem. No ranking functions are needed in this method. Due to lenght requirements on this paper, proofs are omited.

2 Notation on fuzzy numbers

We denote by $\mathcal{K}_C$ the family of all bounded closed intervals in $\mathbb{R}$, i.e.,

$$\mathcal{K}_C = \left\{ \left[\underline{a}, \overline{a}\right] \mid \underline{a}, \overline{a} \in \mathbb{R} \text{ and } \underline{a} \leq \overline{a} \right\},$$

A fuzzy set on $\mathbb{R}^n$ is a mapping $u : \mathbb{R}^n \to [0, 1]$. For each fuzzy set u, we denote its α-level set as $[u]^\alpha = \{x \in \mathbb{R}^n \mid u(x) \geq \alpha\}$ for any $\alpha \in (0, 1]$. The support of u we denote by $supp(u)$ where $supp(u) = \{x \in \mathbb{R}^n \mid u(x) > 0\}$. The closure of $supp(u)$ defines the 0-level of u, .i.e. $[u]^0 = cl(supp(u))$ where $cl(M)$ means the closure of the subset $M \subset \mathbb{R}^n$.

Definition 1 *A fuzzy set u on $\mathbb{R}$ is said to be a fuzzy interval if:*

1. *u is normal, i.e. there exists $x_0 \in \mathbb{R}$ such that $u(x_0) = 1$;*
2. *u is an upper semi-continuous function;*
3. *$u(\lambda x + (1 - \lambda)y) \geq min\{u(x), u(y)\}$, $x, y \in \mathbb{R}$, $\lambda \in [0, 1]$;*
4. *$[u]^0$ is compact.*

Let $\mathcal{F}_C$ denote the family of all fuzzy intervals. So, for any $u \in \mathcal{F}_C$ we have that $[u]^\alpha \in \mathcal{K}_C$ for all $\alpha \in [0, 1]$ and thus the α-levels of a fuzzy interval are given by $[u]^\alpha = \left[\underline{u}_\alpha, \overline{u}_\alpha\right]$, $\underline{u}_\alpha, \overline{u}_\alpha \in \mathbb{R}$ for all $\alpha \in [0, 1]$. If $[u]^1$ is a singleton then we say that u is a fuzzy number. In this regard, the representation of fuzzy numbers has been deeply discussed by Stefanini et al. [13]. Triangular fuzzy numbers are a special type of fuzzy numbers, well-known in the literature (see, for instance, [14, 13, 7, 10]) which are well determined by three real numbers $a \leq b \leq c$. Its α-levels are formulated as

$$[u]^\alpha = [a + (b - a)\alpha, c - (c - b)\alpha],$$

 ISBN: 978-84-617-8694-7

for all $\alpha \in [0,1]$. Also we can denote a triangular fuzzy number $u = (a,b,c)$ by $\tilde{b}$. This formulation of α-levels characterizes a unique trianggular fuzzy number, what can be established by the following result, which makes the connection between a fuzzy interval and their endpoint functions (Goestschel and Voxman [15]).

Theorem 1 *Let u be a fuzzy interval. Then the functions* $\underline{u},\ \overline{u} : [0,1] \to \mathbb{R}$*, defining the endpoints of the* α*-level sets of u (*$\underline{u}(\alpha) = \underline{u}_\alpha$ *and* $\overline{u}(\alpha) = \overline{u}_\alpha$*), satisfy the following conditions:*

(i) $\underline{u}$ *is a bounded, non-decreasing, left-continuous function in* $(0,1]$ *and it is right-continuous at* 0*.*

(ii) $\overline{u}$ *is a bounded, non-increasing, left-continuous function in* $(0,1]$ *and it is right-continuous at* 0*.*

(iii) $\underline{u}(1) \leq \overline{u}(1)$*.*

Reciprocally, given two functions that satisfy the above conditions they uniquely determine a fuzzy interval.

The nonnegative conditions in some optimizations problems makes useful the following special consideration of triangular fuzzy numbers.

Definition 2 *Let* $u = (\underline{u}, \overline{u})$ *be a fuzzy interval. We say that u is a nonnegative fuzzy interval (nonpositive fuzzy interval, respectively) if* $\underline{u}(0) \geq 0$ *(*$\overline{u}(0) \leq 0$*, repectively).*

So, from the previus definition, a nonnegative triangular fuzzy number $\tilde{b} = (a,b,c)$ is characterized by $a \geq 0$.

Following, we consider some classical arithmetic operations on interval and fuzzy numbers. Given $A = [\underline{a}, \overline{a}],\ B = [\underline{b}, \overline{b}] \in \mathcal{K}_C$ and $\tau \in \mathbb{R}$:

(i) $A + B = [\underline{a} + \underline{b}, \overline{a} + \overline{b}]$,

(ii) $\tau A = \{\tau a : a \in A\} = \begin{cases} [\tau\underline{a}, \tau\overline{a}], & \text{if } \tau \geq 0, \\ [\tau\overline{a}, \tau\underline{a}], & \text{if } \tau \leq 0 \end{cases}$

We refer to Moore [16, 17] and Alefeld and Herzberger [18] for further details on the topic of interval analysis. As a natural extension of the previous operations, it is well known that if we consider the fuzzy intervals $u, v \in \mathcal{F}_C$ represented by $\left[\underline{u}_\alpha, \overline{u}_\alpha\right]$ and $\left[\underline{v}_\alpha, \overline{v}_\alpha\right]$, respectively, and a real number λ, then the addition $u + v$ and scalar multiplication λu are as follows:

$$(u+v)(x) = \sup_{y+z=x} \min\{u(y), v(z)\}$$

$$(\lambda u)(x) = \begin{cases} u\left(\frac{x}{\lambda}\right), & \text{if } \lambda \neq 0, \\ 0, & \text{if } \lambda = 0. \end{cases}$$

This is equivalent to say that, for every $\alpha \in [0,1]$,

$$[u+v]^\alpha = \left[(\underline{u+v})_\alpha, (\overline{u+v})_\alpha\right] = \left[\underline{u}_\alpha + \underline{v}_\alpha\ ,\ \overline{u}_\alpha + \overline{v}_\alpha\right] \tag{1}$$

 ISBN: 978-84-617-8694-7

and

$$[\lambda u]^{\alpha} = \left[(\underline{\lambda u})_{\alpha}, (\overline{\lambda u})_{\alpha}\right] = \left[\min\{\lambda \underline{u}_{\alpha}, \lambda \overline{u}_{\alpha}\}, \max\{\lambda \underline{u}_{\alpha}, \lambda \overline{u}_{\alpha}\}\right]. \tag{2}$$

Taking into account the previous operations, we have the following arithmetic operations on the set of triangular fuzzy numbers (see, for instance, [14, 8]). Given $\tilde{b} = (a, b, c)$ and $\tilde{e} = (d, e, f)$:

(i) $\tilde{b} + \tilde{e} = (a, b, c) + (d, e, f) = (a + d, b + e, c + f)$.

(ii) $\lambda\tilde{b} = (\lambda a, \lambda b, \lambda c)$, if $\lambda \geq 0$; and, $\lambda\tilde{b} = (\lambda c, \lambda b, \lambda a)$, if $\lambda < 0$.

(iii) If $\tilde{e}$ is a nonnegative triangular fuzzy number, then

$$\tilde{b}\tilde{e} = \begin{cases} (ad, be, cf), & \text{if } a \geq 0, \\ (af, be, cf), & \text{if } a < 0,\ c \geq 0, \\ (af, be, cd), & \text{if } c < 0. \end{cases} \tag{3}$$

With respect to this last multiplication operation (iii), we can find another proposal by Khan et al. [10], as follows: $\tilde{b}\tilde{e} = (ad, be, cf)$. Note that this definition coincides with a particular case in the previous operation (iii). We could think of the multiplication operation given by Khan et al. [10] is applied in the cases when $\tilde{b}$ and $\tilde{e}$ are not nonnegative, since they introduce this operation for two triangular fuzzy numbers. To this respect, if we consider $\tilde{b} = (-5, -3, -1)$ and $\tilde{e} = (-4, -2, 0)$, then $\tilde{b}\tilde{e} = (20, 6, 0)$, which does not represent a triangular fuzzy number. In fact, in the numerical example given by them [10], the variables and objetive coefficients, which appear multiplying, are nonnegative triangular fuzzy numbers. Therefore, we keep (3) as the multiplication operation through out this paper, although coincides with that given in [10] in the case of nonnegative triangular fuzzy numbers.

In order to compare two fuzzy numbers, there exist some definitions as generalization of relationship on intervals (see [19]), in the recent literature. In this regard, given $u, v \in \mathcal{F}_C$, we write their α-levels as $u_{\alpha} = [\underline{u}_{\alpha}, \overline{u}_{\alpha}] \in \mathcal{K}_C$ and $v_{\alpha} = [\underline{v}_{\alpha}, \overline{v}_{\alpha}] \in \mathcal{K}_C$, respectively, for all $\alpha \in [0, 1]$.

Definition 3 *Given $u, v \in \mathcal{F}_C$, we say that*

(i) $u \leqq v$ if and only if $\underline{u}_{\alpha} \leq \underline{v}_{\alpha}$ and $\overline{u}_{\alpha} \leq \overline{v}_{\alpha}$, for all $\alpha \in [0, 1]$,

(ii) $u \prec v$ if and only if $\underline{u}_{\alpha} < \underline{v}_{\alpha}$ and $\overline{u}_{\alpha} < \overline{v}_{\alpha}$, for all $\alpha \in [0, 1]$.

In the previous definition, the relationships given by $\leqq$ and $\prec$ are usually presented under the notation $\leqq_{LU}$ and $\prec_{LU}$ (see [19]). In a similar way, the relations $\succ$ and $\geqq$ are considered. These relationships establish partial orders in $\mathcal{F}_C$.

Remark 1 *Note that, as an inmediate consequence of Theorem 1 and Definition 3, we have that to say $u \leqq v$ and $v \leqq u$ is equivalent to say $u = v$.*

 ISBN: 978-84-617-8694-7

For convenience, we denote $\tilde{0} = (0, 0, 0)$. Observe that a triangular fuzzy number $\tilde{v}$ is nonnegative if and only if $\tilde{v} \geqq \tilde{0}$.

Proposition 1 *Given two triangular fuzzy numbers $\tilde{u} = (u^-, \hat{u}, u^+)$ and $\tilde{v} = (v^-, \hat{v}, v^+)$, it follows that*

(i) $\tilde{u} \prec \tilde{v}$ if and only if $u^- < v^-$, $\hat{u} < \hat{v}$ and $u^+ < v^+$.

(ii) $\tilde{u} \leqq \tilde{v}$ if and only if $u^- \leq v^-$, $\hat{u} \leq \hat{v}$ and $u^+ \leq v^+$.

3 Fully fuzzy linear programming problem

We consider the following formulation of a Fully Fuzzy Linear Programming Problem:

$$\begin{aligned} \text{(FFLP)} \quad \text{Minimize} \quad & \tilde{z} = \sum_{j=1}^{n} \tilde{c}_j \tilde{x}_j \\ \text{subject to} \quad & \sum_{j=1}^{n} \tilde{a}_{ij} \tilde{x}_j \geqq \tilde{b}_i, \quad i = 1, \ldots, m, \\ & \tilde{x}_j \text{ is a nonnegative fuzzy triangular number}, \quad j = 1, \ldots, n, \end{aligned}$$

where $\tilde{z}$ is the fuzzy objective function, $\tilde{c} = (\tilde{c}_1, \ldots, \tilde{c_n})$ is the fuzzy vector with the fuzzy objective function coefficients, $\tilde{x} = (\tilde{x}_1, \ldots, \tilde{x}_n)$ is the vector with the fuzzy decision variables, and $\tilde{a}_{ij}$ and $\tilde{b}_i$ are the thechnical coeficients.

We deal with (FFLP) without any kind of ranking function. And, in this regard, we define the following nondominated solution.

Definition 4 *Let $\tilde{\bar{x}}$ be a feasible solution for (FFLP). $\tilde{\bar{x}}$ is said to be a nondominated solution of (FFLP) if there does not exist a feasible solution $\tilde{x}$ for (FFLP) such that $\sum_{j=1}^{n} \tilde{c}_j \tilde{x}_j \prec \sum_{j=1}^{n} \tilde{c}_j \tilde{\bar{x}}_j$.*

Following the notation for triangular fuzzy number, we have:

$$\tilde{z} = (z^-, \hat{z}, z^+),$$

$$\tilde{x}_j = (x_j^-, \hat{x}_j, x_j^+), \quad j = 1, \ldots, n,$$

$$\tilde{c}_j = (c_j^-, \hat{c}_j, c_j^+), \quad j = 1, \ldots, n,$$

$$\tilde{a}_{ij} = (a_{ij}^-, \hat{a}_{ij}, a_{ij}^+), \quad i = 1, \ldots, m, \; j = 1, \ldots, n,$$

$$\tilde{b}_i = (b_i^-, \hat{b}_i, b_i^+), \quad i = 1, \ldots, m.$$

 ISBN: 978-84-617-8694-7

Since every $\tilde{x}_j$ is a nonnegative triangular fuzzy number, then the the multiplication role given in (3) is considered. We have three possible expressions for $\tilde{c}_j\tilde{x}_j$ depending on $\tilde{c}_j$. So, given $j \in \{1,\dots,n\}$ and $\tilde{c}_j$, then the expression for $\tilde{c}_j\tilde{x}_j$ is unique, and it is the same for all nonnegative fuzzy triangular numbers $\tilde{x}_j$. A similar remark for the multiplication $\tilde{a}_{ij}\tilde{x}_j$, that is, given $i \in \{1,\dots,m\}$, $j \in \{1,\dots,n\}$ and $\tilde{a}_{ij}$, then the expression for $\tilde{a}_{ij}\tilde{x}_j$ is unique, and it is the same for all nonnegative fuzzy triangular numbers $\tilde{x}_j$.

4 An approach as multiobjective linear programming problem

Taking into account the previous arithmetic opertations, the problem (FFLP) can be approach under the following formualation:

$$
\begin{aligned}
\text{(MLP)}\quad \text{Minimize}\quad & f(x) = (f_1(x), f_2(x), f_3(x)) = \Big(\sum_{j=1}^{n}(\tilde{c}_j\tilde{x}_j)^-, \sum_{j=1}^{n}\widehat{(\tilde{c}_j\tilde{x}_j)}, \sum_{j=1}^{n}(\tilde{c}_j\tilde{x}_j)^+\Big)\\
\text{subject to}\quad & \sum_{j=1}^{n}(\tilde{a}_{ij}\tilde{x}_j)^- \leqq b_i^-, \quad i = 1,\dots,m,\\
& \sum_{j=1}^{n}\widehat{(\tilde{a}_{ij}\tilde{x}_j)} \leqq \hat{b}_i, \quad i = 1,\dots,m,\\
& \sum_{j=1}^{n}(\tilde{a}_{ij}\tilde{x}_j)^+ \leqq b_i^+, \quad i = 1,\dots,m,\\
& x_j^- - \hat{x}_j \leqq 0, \quad j = 1,\dots,n,\\
& \hat{x}_j - x_j^+ \leqq 0, \quad j = 1,\dots,n,\\
& x_j^- \geqq 0, \hat{x}_j \geqq 0, x_j^+ \geqq 0, \quad j = 1,\dots,n,
\end{aligned}
$$

$f : \mathbb{R}^{3n} \to \mathbb{R}^3$ is a vector function, with the variable $x = (x_1^-, \hat{x}_1, x_1^+, \dots, x_n^-, \hat{x}_n, x_n^+) \in \mathbb{R}^{3n}$, with f_i linear functions, $i = 1, 2, 3$. All constraints are represented as linear inequalities on the variable x. Then, (MLP) is a multiobjective linear programming problem (for further details, see [20]).

The relationship between (FFLP) and (MLP) is as follows.

Theorem 2 *$\tilde{x} = (\tilde{x}_1,\dots,\tilde{x}_n)$ with $\tilde{x}_j = (x_j^-, \hat{x}_j, x_j^+) \in \mathcal{F}_C$, $j = 1,\dots,n$, is a nondominated solution of (FFLP) if and only if $x = (x_1^-, \hat{x}_1, x_1^+, \dots, x_n^-, \hat{x}_n, x_n^+) \in \mathbb{R}^{3n}$ is a weakly efficient solution of (MLP).*

5 Conclusions

It has been shown that the fully fuzzy linear programming problem (FFLP) can be considered equivalent to the multiobjective lineal programming problem (MLP). In this regard, a fuzzy problem has

been linked to a multiobjetive crisp linear problem without information loss, what is not usually avoided when this transformation is made via ranking functions.

Abstract

The classical Black-Scholes equation for options pricing exhibits several limitations when applied to real markets in certain conditions. In many settings, the consideration of a constant volatility is no more realistic. In the present paper, we consider the case where the volatility is assumed to depend on the product of the asset price and the second derivative of the option with respect to the asset price (an option Greek which is known as Gamma). This hypothesis has been made in models that incorporate transaction costs, market feedback effects related to stocks trading strategies or illiquid markets, risks related to unprotected portfolios, etc. In these settings, the corresponding nonlinear Black-Scholes equation can be transformed into a quasilinear equation (Gamma equation) in a new unknown variable related to the Gamma of the option.

Once this semilinear Gamma equation has been obtained, we propose a duality method, combined with a characteristics scheme and finite elements methods. The duality method is applied to the maximal monotone operator that governs the nonlinear term in the Gamma equation. By a suitable numerical integration technique the value of the European option can be recovered. Finally, we present some examples of European options to show the good performance of the new numerical global strategy.

Key words: option pricing, option gamma, nonlinear Black–Scholes, duality methods, finite elements

1 Introduction

The classical linear Black–Scholes presented in 1973 establishes that the price V of an option can be obtained as the solution of the parabolic equation:

$$\partial_t V + \frac{\sigma^2}{2} S^2 \, \partial_S^2 V + rS\partial_S V - rV = 0\,, \tag{1}$$

 ISBN: 978-84-617-8694-7

where $r > 0$ denotes the risk–free interest rate and σ is the (constant) volatility of the underlying asset, the price of which is assumed to be a stochastic process that follows the stochastic differential equation

$$dS_t = \mu S_t\, dt + \sigma S_t\, dW_t\,,$$

the constant μ being the drift and the process W_t a geometric Brownian motion. Note that the option price, V_t, is a process that is obtained from the solution V of (1), by the expression $V_t = V(t, S_t)$. Equation (1) has been derived under several restrictive assumptions.

However, from the analysis of market data, the need of more realistic models arises. For example, in several setting, different models assume nonconstant volatility expressions that depend on the gamma of the option in the form:

$$\sigma = \hat{\sigma}(S\,\partial_S^2 V)\,,$$

so that the following nonlinear Black–Scholes equation is posed:

$$\partial_t V + \frac{1}{2}\hat{\sigma}(S\partial_S^2 V)^2 S^2\,\partial_S^2 V + rS\partial_S V - rV = 0. \tag{2}$$

For example, this kind of dependency arises in option pricing models that take into account non-trivial variable transaction costs related to assets buying and selling [1, 2, 10], market feedback effects due to large traders choosing given stock–trading strategies [6, 7], risk from volatile and unprotected portfolios [8], or investor preferences [4], among others.

2 Mathematical model

In this section, we just remind a result by Ševčovič and Žitňanská [11] that establishes the equivalence between the nonlinear Black–Scholes equation (2) and a quasilinear parabolic equation. For this purpose, we introduce the function

$$\beta(H) = \frac{\hat{\sigma}(H)^2}{2} H\,.$$

Proposition (Ševčovič–Žitňanská, [11]) *Assume the function $V = V(S,t)$ is a solution to the nonlinear Black–Scholes equation*

$$\partial_t V + S\,\beta(S\partial_S^2 V) + rS\partial_S V - rV = 0\,, \qquad S > 0\,, \quad t \in (0,T)\,. \tag{3}$$

Then the transformed function $H = H(x,\tau) = S\partial_S^2 V(S,t)$, where $x = \ln(S/E)$, $\tau = T - t$, is a solution to the quasilinear parabolic (Gamma) equation:

$$\partial_\tau H = \partial_x^2 \beta(H) + \partial_x \beta(H) + r\partial_x H\,. \tag{4}$$

 ISBN: 978-84-617-8694-7

On the other hand, if H is a solution to (4) such that $H(-\infty,\tau) = \partial_x H(-\infty,\tau) = 0$ and $\beta'(0)$ is finite, then the function

$$V(S,t) = aS + b\, exp(-r(T-t)) + \int_{-\infty}^{+\infty} (S - E\, exp(\xi))^+ H(\xi, T-t)\, d\xi \tag{5}$$

is a solution to the nonlinear Black–Scholes equation (3) for any $a, b \in \mathbb{R}$.

Moreover, if we consider the initial condition

$$H(x,0) = \delta(x)\,, \tag{6}$$

where $\delta(x)$ denotes the Dirac delta function with basis point x, then we can recover the payoffs of the European vanilla options with the choices:

- $a = b = 0$, for the call option (i.e. $V(S,T) = (S-E)^+$),
- $a = -1$, $b = E$, for the put option (i.e. $V(S,T) = (E-S)^+$),

the constant E being the strike price. As the analytical expression for the solution of (4) is not available, in next section we propose a set of numerical techniques for its approximation (see e.g. [8, 9, 11] for other numerical strategies).

3 Numerical solution of the quasilinear parabolic equation

In order to solve numerically the nonlinear equation (4) jointly with the initial condition (6), we note the main difficulties: the possibility of advection term dominating diffusion one, the nonlinear diffusion term, the presence of an unbounded domain and the Dirac delta function in the initial condition. First, as in other problems in which advection can dominate over diffusion, we propose the characteristics method for the time discretization. Secondly, as the nonlinear term can be related to maximal monotone operators [3], we make use of a duality method based on a result in [5]. In order to deal with the unbounded domain, as usually in financial problems, we propose a domain truncation in the asset variable by taking $S_\infty = 4E$, which corresponds to x_∞ as the upper finite boundary of the computational domain in x. Also we consider x_0 as the lower boundary of this domain $\Omega = (x_0, x_\infty)$. Concerning to the Dirac delta function, we approximate it by a Gaussian density. Finally, a finite element method is proposed for the discretization in the spatial-like variable x at each time step.

So, first following [3, 5], we introduce the parameter $\omega > 0$ and a new variable θ given in terms of the function β^ω by:

$$\theta = \beta^\omega(H) = \beta(H) - \omega H\,. \tag{7}$$

 ISBN: 978-84-617-8694-7

As $\beta(H) = \theta + \omega H$, equation (4) can be equivalently written as:

$$H_\tau - (\omega + r)H_x - \omega H_{xx} = \theta_x + \theta_{xx}\,. \tag{8}$$

Next, in order to apply the method of characteristics, we introduce the material derivative of function H:

$$\frac{DH}{D\tau} = H_\tau - (\omega + r)\,H_x\,, \tag{9}$$

which represents the derivative associated to the constant scalar velocity field $-(\omega + r)$, so that (8) turns into:

$$\frac{DH}{D\tau} - \omega H_{xx} = \theta_x + \theta_{xx}\,. \tag{10}$$

Note that (10) is still a nonlinear problem, as θ and H are related by (7).

In order to discretize (10) in time by the characteristics (also known as semilagrangian) method, we introduce the time stepsize $\Delta\tau > 0$ and mesh points in time $\tau^n = n\Delta\tau$ for $n = 0, 1, 2, \ldots$, so that we consider the following final value problem:

$$\begin{cases} \dfrac{d\chi}{d\tau} = -(\omega + r)\,\chi(\tau) \\ \chi(\tau^{n+1}) = x\,, \end{cases}$$

that provides the characteristics curve (associated to the scalar velocity field) passing through the point x at time τ^{n+1}. Its analytical solution provides the position at time τ^n to be used in the characteristics method:

$$\chi^n(x) = \chi(x, \tau^{n+1}; \tau^n) = x\exp((\omega + r)\Delta\tau)\,.$$

We can now approximate the material derivative in (10) by a first order upwinded quotient. If we denote $H^n(\cdot) = H(\cdot, \tau^n)$, then (10) is approximated by:

$$\frac{H^{n+1} - H^n \circ \chi^n}{\Delta\tau} - \omega H_{xx}^{n+1} = \theta_x^{n+1} + \theta_{xx}^{n+1}\,. \tag{11}$$

We will consider homogeneous Dirichlet boundary conditions on $\partial\Omega$, i.e. $H(x_0) = H(x_\infty) = 0$. Thus, the variational formulation of (11) consists in finding $H^{n+1} \in W_0^{1,2}(\Omega)$, such that:

$$\int_\Omega H^{n+1}\varphi - \Delta\tau\omega\int_\Omega H_{xx}^{n+1}\varphi = \int_\Omega (H^n \circ \chi^n)\varphi + \Delta\tau\int_\Omega \theta_x^{n+1}\varphi + \Delta\tau\int_\Omega \theta_{xx}^{n+1}\varphi\,, \quad \forall\varphi \in W_0^{1,2}(\Omega)$$

where $W_0^{1,2}(\Omega)$ stands for the classical notation of Sobolev spaces. Next, using Green's theorem, we get:

$$\begin{aligned}\int_\Omega H^{n+1}\varphi + \Delta\tau\omega\int_\Omega H_x^{n+1}\varphi_x = \int_\Omega (H^n \circ \chi^n)\varphi + \Delta\tau\int_\Omega \theta_x^{n+1}\varphi - \Delta\tau\int_\Omega \theta_x^{n+1}\varphi_x \\ + \Delta\tau\omega\int_{\partial\Omega} H_x^{n+1}\varphi + \Delta\tau\int_{\partial\Omega}\theta_x^{n+1}\varphi\,.\end{aligned}$$

 ISBN: 978-84-617-8694-7

Taking into account the homogeneous boundary conditions, the two integrals on $\partial\Omega$ vanish and we get:

$$\int_\Omega H^{n+1}\varphi + \Delta\tau\omega \int_\Omega H_x^{n+1}\varphi_x = \int_\Omega (H^n \circ \chi^n)\varphi + \Delta\tau \int_\Omega \theta_x^{n+1}\varphi - \Delta\tau \int_\Omega \theta_x^{n+1}\varphi_x \,, \qquad (12)$$

jointly with the relation:

$$\theta^{n+1} = \beta^\omega(H^{n+1}) \,. \qquad (13)$$

We propose the following fixed point algorithm to solve (12)-(13) at each time instant τ^{n+1}. Assume $(H^{n+1,0}, \theta^{n+1,0})$ is given. Then, for $k = 0, 1, \ldots$

- For given $(H^{n+1,k}, \theta^{n+1,k})$, we search $H^{n+1,k+1}$ as the solution of the linear problem

$$\int_\Omega H^{n+1,k+1}\varphi + \Delta\tau\omega \int_\Omega H_x^{n+1,k+1}\varphi_x = \int_\Omega (H^n \circ \chi^n)\varphi + \Delta\tau \int_\Omega \theta_x^{n+1,k}\varphi - \Delta\tau \int_\Omega \theta_x^{n+1,k}\varphi_x \qquad (14)$$

  for all $\varphi \in W_0^{1,2}(\Omega)$.

- We update $\theta^{n+1,k+1}$ by solving the nonlinear equation (13). As the exact solution is not available in most cases, we make use the theory of maximal monotone operators as in [5] and propose the updating:

$$\theta^{n+1,k+1} = \beta_\lambda^\omega(H^{n+1,k+1} + \lambda\theta^{n+1,k}) \,, \qquad (15)$$

  where β_λ^ω denotes the Yosida regularization of function β^ω with parameter λ:

$$\beta_\lambda^\omega(H) = \inf_G \left(\beta^\omega(G) + \frac{(G-H)^2}{2\lambda} \right) .$$

  Moreover, for convergence reasons, we choose $\lambda = 1/(2\omega)$.

We note that Yosida regularization is strongly dependent on the function β and requires the computation of the inverse of an operator. Therefore, it is not always possible to get its analytical expression. This is the reason why we replace (15) by first order Taylor expansion:

$$\begin{aligned}
\theta^{n+1,k+1} &= \beta_\lambda^\omega(H^{n+1,k+1} + \lambda\theta^{n+1,k}) \\
&= \beta^\omega(H^{n+1,k+1} + \lambda\theta^{n+1,k} - \lambda\theta^{n+1,k+1}) \\
&= \beta^\omega\left(H^{n+1,k+1} + \lambda(\theta^{n+1,k} - \theta^{n+1,k+1})\right) \\
&= \beta^\omega\left(H^{n+1,k+1}\right) + (\beta^\omega)'\left(H^{n+1,k+1}\right)\lambda(\theta^{n+1,k} - \theta^{n+1,k+1}) \\
&\quad + o\left(\lambda^2(\theta^{n+1,k} - \theta^{n+1,k+1})^2\right) \,, \qquad (16)
\end{aligned}$$

 ISBN: 978-84-617-8694-7

which does not require the computation of the Yosida regularization and is accurate enough if λ is small. From (16), we deduce:

$$\theta^{n+1,k+1}\left[1+(\beta^\omega)'(H^{n+1,k+1})\lambda\right]=\beta^\omega(H^{n+1,k+1})+(\beta^\omega)'(H^{n+1,k+1})\lambda\theta^{n+1,k}$$

so that:

$$\theta^{n+1,k+1}=\frac{\beta^\omega(H^{n+1,k+1})+(\beta^\omega)'(H^{n+1,k+1})\lambda\theta^{n+1,k}}{1+\lambda(\beta^\omega)'(H^{n+1,k+1})}\,.$$

Finally, taking into account that $\beta^\omega(H)=\beta(H)-\omega H$ we obtain:

$$\begin{aligned}\theta^{n+1,k+1}&=\frac{\beta(H^{n+1,k+1})-\omega H^{n+1,k+1}+\left[\beta'(H^{n+1,k+1})-\omega\right]\lambda\theta^{n+1,k}}{1+\lambda\left[\beta'(H^{n+1,k+1})-\omega\right]}\\&=\frac{\beta(H^{n+1,k+1})+\beta'(H^{n+1,k+1})\lambda\theta^{n+1,k}-\omega\left[H^{n+1,k+1}+\lambda\theta^{n+1,k}\right]}{1-\omega\lambda+\lambda\beta'(H^{n+1,k+1})}\,.\end{aligned}\tag{17}$$

The last expression is used instead of (15) to update θ^{n+1}. Let us remark that the first derivative of β is used in (14). In practice, it is approximated by a second order central differences formula. If the function β is not differentiable, it can be replaced by a regularized function $\hat{\beta}$.

For solving (14), we implement a finite element method. Thus, for a fixed natural number $M>0$, we consider a uniform mesh of the computational domain $\Omega=[x_0,x_\infty]$, the nodes of which are $x_j=x_0+j\Delta x$, $j=0,\ldots,M+1$, where $\Delta x=(x_\infty-x_0)/(M+1)$ denotes the constant mesh step. Associated to this uniform mesh a piecewise linear Lagrange finite elements discretization is considered.

More precisely, we search $H_h^{n+1,k+1}\in W_{0,h}$ such that:

$$\int_\Omega H_h^{n+1,k+1}\varphi+\Delta\tau\omega\int_\Omega H_{h,x}^{n+1,k+1}\varphi_x=\int_\Omega(H_h^n\circ\chi^n)\varphi+\Delta\tau\int_\Omega\theta_x^{n+1,k}\varphi-\Delta\tau\int_\Omega\theta_x^{n+1,k}\varphi_x\,,$$

for all $\varphi\in W_{0,h}$, where the space of finite elements is:

$$W_{0,h}=\left\{v_h:\Omega\to\mathbb{R}\,/\;\;v_h|_{[x_k,x_{k+1}]}\in\mathcal{P}_1\text{ for }k=0,1,\ldots,M,\;\;v_h=0\text{ on }\partial\Omega\right\}\,,$$

$\mathcal{P}_1$ being the space of polynomials of degree less or equal than one. The coefficients of the matrix and right hand side vector defining the linear system associated to the fully discretized problem are approximated by adequate quadrature formulae, when necessary. In particular, a five nodes Gaussian formula has been used. Finally, the system of linear equations is solved by a conjugate gradient method.

Once the function H is approximated at each time instant, we can recover the value of the derivative by means of (5), where $a=b=0$ for a call option and $a=-1, b=E$ for a put option.

 ISBN: 978-84-617-8694-7

4 Numerical results

In this section we present a numerical result concerning Amster *et al* model [1, 2], in which the nonlinear function β is given by

$$\beta(H) = \frac{\sigma^2}{2}(H - \mathrm{Le}|H| + \kappa H^2)\,,$$

with $\sigma = 0.95$, $\kappa = 0.10$ and $\mathrm{Le} = 0.30$. As the function β is not differentiable due to the presence of the absolute value, we introduce the regularized function β_ϵ:

$$\beta_\epsilon(H) = \frac{\sigma^2}{2}(H - \mathrm{Le}\, f_\epsilon(H) + \kappa H^2)\,.$$

The function f_ϵ is a smooth approximation of the absolute value function and its first derivative is given by:

$$f'_\epsilon(H) = \begin{cases} -1\,, & \text{if } H < -\epsilon \\ s(H)\,, & \text{if } -\epsilon \le H \le \epsilon \\ 1\,, & \text{if } H > \epsilon \end{cases}$$

s being a cubic spline and $\epsilon = 10^{-3}$.

We have considered the case of European call and put options, the payoff of which is given in terms of the strike price $E = 100$. Moreover, we have taken the risk-free interest rate $r = 0.05$ and the maturity $T = 4$.

For the numerical solution, the time domain has been discretized in 800 steps, thus $\Delta\tau = 0.005$ and the spatial variable x is in $[-4, 1.4]$, for which we have considered a uniform mesh consisting of 1601 nodes. Figure 1 shows the payoff of the call option as well as the solution at time $t = 0$ (or $\tau = 4$), while Figure 2 shows analogous results for the put option.

5 Conclusions

A nonlinear model for derivatives pricing is solved by a numerical strategy including duality methods based on maximal monotone operators, characteristics methods for time discretization and finite elements. The method is independent of the nonlinear function β.

Abstract

In 1968 Pal, Walker and Kahan presented a stable implementation of the QR algorithm for symmetric tridiagonal matrices that avoided computing square roots. Removing the square roots significantly lowers the computation time making it superior to the traditional QR algorithm when only the eigenvalues are needed. Here we present a square root free version of the QR algorithm for unitary upper-hessenberg matrices. This method is faster than the traditional version and just as stable making it competitive when only the eigenvalues are needed.

1 Introduction

For an $n \times n$ symmetric tridiagonal matrix there exists a number of stable methods for computing all n eigenvalues in $O(n^2)$ flops. An important example is the symmetric tridiagonal QR algorithm. While this algorithm has the same $O(n^2)$ complexity it requires noticeably more arithmetic than competing LR and divide-and-conquer methods. In 1968 Pal, Walker and Kahan [3, p. 178] showed that one can reorder the arithmetic in the symmetric tridiagonal QR algorithm to avoid the most costly arithmetic operation: square roots. Casting out the square roots significantly reduced the total computation time making their algorithm one of the most competitive methods for solving this class of problems.[1] It was also shown that removing the square roots does not affect stability.

[1] This algorithm is implemented as `xSTERF` in LAPACK.

 ISBN: 978-84-617-8694-7

In 1986 Gragg [2] presented a variant of Francis' implicitly-shifted QR algorithm [1] for computing all the eigenvalues of a unitary upper-hessenberg matrix in $O(n^2)$ flops. Just as in the symmetric case, Gragg's method requires the computation of costly square roots. In this paper we illustrate how one can rearrange the arithmetic to completely remove all square roots from the algorithm while preserving the stability.

2 Unitary QR algorithm

Given an $n \times n$ unitary upper-hessenberg matrix U with real subdiagonal entries, Gragg's algorithm begins by factoring U into a product of n essentially 2×2 matrices, $U = U_1 U_2 \cdots U_n$. In the case $n = 3$ we have,

$$\begin{bmatrix} u_1 & -v_1 u_2 & v_1 v_2 u_3 \\ v_1 & \overline{u}_1 u_2 & -\overline{u}_1 v_2 u_3 \\ & v_2 & \overline{u}_2 u_3 \end{bmatrix} = \begin{bmatrix} u_1 & -v_1 & \\ v_1 & \overline{u}_1 & \\ & & 1 \end{bmatrix} \begin{bmatrix} 1 & & \\ & u_2 & -v_2 \\ & v_2 & \overline{u}_2 \end{bmatrix} \begin{bmatrix} 1 & & \\ & 1 & \\ & & u_3 \end{bmatrix},$$

where $|u_1|^2 + v_1^2 = 1$, $|u_2|^2 + v_2^2 = 1$ and $|u_3|^2 = 1$. Such a factorization is always possible.

Given a complex shift ρ, $|\rho| = 1$, a single iteration of Gragg's algorithm begins by constructing a unitary matrix Q_1 such that $Q_1 e_1 = \alpha(U - \rho I)e_1$, where $e_1 = [1, 0, \ldots, 0]^T$ and α is a nonzero complex number, and applying the similarity transformation $U^{(1/2)} = Q_1^* U Q_1$. To construct such a matrix Q_1 when $n = 3$ we set $q_1 = u_1 - \rho$, $p_1 = v_1$, $m_1 = \sqrt{|q_1|^2 + p_1^2}$ and take Q_1 as

$$Q_1 = \begin{bmatrix} q_1/m_1 & -p_1/m_1 & \\ p_1/m_1 & \overline{q}_1/m_1 & \\ & & 1 \end{bmatrix}.$$

From the definitions of q_1 and p_1 we can also express Q_1 as follows,

$$Q_1 = \left(\begin{bmatrix} u_1 & -v_1 & \\ v_1 & \overline{u}_1 & \\ & & 1 \end{bmatrix} + \begin{bmatrix} -\rho & & \\ & -\overline{\rho} & \\ & & 1 \end{bmatrix} + \begin{bmatrix} 0 & & \\ & 0 & \\ & & -1 \end{bmatrix} \right) \begin{bmatrix} m_1^{-1} & & \\ & m_1^{-1} & \\ & & 1 \end{bmatrix}.$$

Taking

$$R_1 = \begin{bmatrix} -\rho & & \\ & -\overline{\rho} & \\ & & 1 \end{bmatrix}, \quad J_1 = \begin{bmatrix} 0 & & \\ & 0 & \\ & & -1 \end{bmatrix} \quad \text{and} \quad M_1 = \begin{bmatrix} m_1^{-1} & & \\ & m_1^{-1} & \\ & & 1 \end{bmatrix}$$

we have that $Q_1 = (U_1 + R_1 + J_1)M_1 = M_1(U_1 + R_1 + J_1)$, where the second equality comes from the fact that M_1 commutes with R_1, J_1 and U_1.

Continuing with our 3×3 example we see that Q_1 commutes with U_3 which gives $U^{(1/2)} = Q_1^* U Q_1 = Q_1^* U_1 U_2 Q_1 U_3$. Using the definition of Q_1 one can show that $Q_1^* U_1 =$

 ISBN: 978-84-617-8694-7

$R_1^*Q_1$. This gives $U^{(1/2)} = R_1^*Q_1U_2Q_1U_3$. To finish the initialization we move R_1^* to the other side by applying the similarity transform $U^{(1)} = R_1U^{(1/2)}R_1^* = Q_1U_2Q_1R_1^*U_3$. The remainder of the iteration involves chasing the matrices Q_1 and R_1^* down the matrix by performing $n-1$ turnovers.

2.1 The turnover

To proceed with Gragg's algorithm we must perform a turnover on the product $Q_1U_2Q_1R_1^*$. A *turnover* is a refactorization of the product $Q_1U_2Q_1R_1^*$. The following lemma shows how this can be done.

Lemma 1. *Let $q_1, \gamma_1, u_2, \rho \in \mathbb{C}$ and $p_1, m_1, v_2 \in \mathbb{R}$ satisfy,*

$$|q_1|^2 + p_1^2 = m_1^2, \quad |\gamma_1| = 1, \quad |u_2|^2 + v_2^2 = 1, \quad |\rho| = 1,$$

and let U_2, Q_1 and R_1 be as above and let $\tilde{Q}_1$ be as follows,

$$\tilde{Q}_1 = \begin{bmatrix} \gamma_1 q_1/m_1 & -p_1/m_1 & \\ p_1/m_1 & \overline{\gamma}_1\overline{q}_1/m_1 & \\ & & 1 \end{bmatrix}.$$

Then the product $\tilde{Q}_1U_2Q_1R_1^*$ can be refactored as the product $Q_2R_2^*U_1\tilde{Q}_2$ where

$$\hat{U}_1 = \begin{bmatrix} \hat{u}_1 & -\hat{v}_1 & \\ \hat{v}_1 & \overline{\hat{u}}_1 & \\ & & 1 \end{bmatrix}, \quad R_2 = \begin{bmatrix} 1 & & \\ & -\rho & \\ & & -\overline{\rho} \end{bmatrix}, \quad Q_2 = \begin{bmatrix} 1 & & \\ & q_2/m_2 & -p_2/m_2 \\ & p_2/m_2 & \overline{q}_2/m_2 \end{bmatrix},$$

and

$$\tilde{Q}_2 = \begin{bmatrix} 1 & & \\ & \gamma_2 q_2/m_2 & -p_2/m_2 \\ & p_2/m_2 & \overline{\gamma}_2\overline{q}_2/m_2 \end{bmatrix},$$

with

$$\begin{aligned} q_2 &= q_1 + u_2\overline{\gamma}_1\overline{q}_1, \\ p_2 &= m_1v_2, \\ m_2 &= \sqrt{|q_2|^2 + p_2^2}, \\ \gamma_2 &= -\rho\gamma_1, \\ \hat{u}_1 &= \overline{\rho}(p_1^2u_2 - \gamma_1q_1^2)/m_1^2, \\ \hat{v}_1 &= m_2v_1/m_1. \end{aligned}$$

Proof. The result follows by direct comparison of the products $\tilde{Q}_1U_2Q_1R_1^*$ and $Q_2R_2^*U_1\tilde{Q}_2$. □

 ISBN: 978-84-617-8694-7

We can compute the turnover for $Q_1U_2Q_1R_1^*$ by setting $\gamma_1 = 1$ and applying the previous lemma. The algorithm continues by applying the similarity transform $Q_2R_2^*$ to $U^{(1)}$ to get $U^{(2)} = \hat{U}_1\tilde{Q}_2U_3Q_2R_2^*$. Since $\tilde{Q}_2U_3Q_2R_2^*$ has the same form as the above lemma, only one row lower and one column to the right, we can perform another turnover. This continues until we reach the last row and column of the matrix.

2.2 Casting out the square roots

To cast out the square roots we simply need to store and update the quantities v_i^2, $\hat{v}_i^2$, p_i^2 and m_i^2 for $i = 1, 2, \ldots, n$. The turnover equations now look as follows

$$\begin{aligned} q_2 &= q_1 + u_2\overline{\gamma}_1\overline{q}_1, \\ p_2^2 &= m_1^2v_2^2, \\ m_2^2 &= |q_2|^2 + p_2^2, \\ \gamma_2 &= -\rho\gamma_1, \\ \hat{u}_1 &= \overline{\rho}(p_1^2u_2 - \gamma_1q_1^2)/m_1^2, \\ \hat{v}_1^2 &= m_2^2v_1^2/m_1^2. \end{aligned}$$

2.3 Stability

With a change variables one can show that the square root free turnover is the exact turnover of a nearby matrix, which means the square root free turnover is normwise backward stable. The stability of the turnover implies that a square root free iteration of Gragg's algorithm is also backward stable and thus the computed eigenvalues are the exact eigenvalues of a nearby matrix.

Abstract

In this paper, we propose a stochastic mathematical model in which the values of the factors involved in the development of a glioma, vary randomly in a biologically congruent range. Stability analysis revealed three fixed points, which allude to a growing glioma, an advanced glioma and a patient without glioma. The graphics of the solutions are presented, we also show the order of influence of the parameters. The results obtained disclose a decay in serum glucose levels when there is glioma, moreover they indicate that glucose consumption by glioma is an important element for its growth.
Key words: Pre-diagnostic glioma, glucose decay, nonlinear differential equations, stochastic noise, dynamical system.

1 Introduction

The most common primary brain tumors are gliomas, believed to originate in glial cells, which are the supporting structure of neurons [1]. The aggressive conduct of these tumors is reflected in their mortality rate of almost 100 % within six to twelve months after being diagnosed [2, 3]. Surgery is the main treatment option and is usually followed by chemotherapy and radiotherapy, but these treatments usually only prolong the patient's life for a short time [4]. Cell culture studies and recent data from glioma patients have revealed that patients with low serum glucose levels have a higher risk of developing gliomas [5]. In this work, a stochastic mathematical model is used to analyze the behavior of glioma and blood

 ISBN: 978-84-617-8694-7

glucose levels when the parameters involved take values with random noise, which shows which parameters have a greater influence on glioma growth and decreased blood glucose levels.

2 The mathematical model

Our start point is the mathematical model proposed in [4] which consider a simplified process of a small glioma growing in the brain which elicits a response from the host immune system. Both the host immune system and the glioma require energy to sustain their functions. Therefore, we also keep track of an energy source, specifically in the form of glucose which can exist in the brain or blood. The model consists of four variables denoted T, σ_{brain}, I, σ_{serum}, which represent the concentration of glioma cells, the concentration of glucose in the brain, the concentration of immune system cells and the concentration of serum glucose levels respectively. We describe this assumptions in the following system of differential equations (the set of values of parameters is presented in table 1 along with descriptions and a reference):

$$\frac{dT}{dt} = \underbrace{\alpha_T \sigma_{brain} T(1 - \frac{T}{K_T})}_{Production} - \underbrace{d_T T}_{Apoptosis} - \underbrace{d_{TI} TI}_{Immune\ response} \tag{1}$$

$$\frac{d\sigma_{brain}}{dt} = \underbrace{\alpha_\sigma(\sigma_{serum} - \sigma_{brain})}_{Glucose\ exchange} - \underbrace{d_{T\sigma} T \sigma_{brain}}_{Glioma\ consumption} - \underbrace{(d_{\sigma 1} + \alpha_s(\nu + I))\sigma_{brain}}_{Natural\ consumption} \tag{2}$$

$$\frac{dI}{dt} = \underbrace{\alpha_s(\nu + I)\sigma_{brain} + \alpha_{TI} TI}_{Production} - \underbrace{d_I I}_{Natural\ decay} - \underbrace{d_{TT} TI}_{Glioma\ response} \tag{3}$$

$$\frac{d\sigma_{serum}}{dt} = \underbrace{\alpha_\sigma(\sigma_{brain} - \sigma_{serum})}_{Glucose\ exchange} + \underbrace{F(t)}_{Glucose\ intake} - \underbrace{d_{\sigma 2}\sigma_{serum}}_{Natural\ consumption} \tag{4}$$

Equation 1 governs the temporal evolution of glioma growth , equation 2 describe the glucose concentration in the brain, equation 3 models immune system activity in the brain and equation 4 explain the behavior of glucose concentration in serum.

Table 1: Model parameter values and description

3 Stability analysis

The stability analysis of the model yielded six fixed points. Three of them were biologically unrealistic due to the negative sign of some of its variables, so they were discarded. The other three were used as initial conditions in the numerical simulations, which refer to a patient with a growing glioma (initial conditions 1), a patient with an advanced stage glioma (initial conditions 2) and a patient without glioma (initial conditions 3). The Lyapunov method is applied to know the stability of each of the biologically real fixed points, resulting in that the fixed points 1 and 2 are unstable states, while the fixed points 3 is a stable state.

4 Numerical simulations

We solved the system of equations for a time corresponding to 9 years, adding stochastic noise according to the following expression:

$$\varepsilon_i + \beta * \varepsilon_i * \Delta B \tag{5}$$

where ε_i corresponds to each parameter presented in table 1, β is the noise intensity, ΔB is an independent random variable with normal distribution of standard deviation 1 and centered in 0. The system of equations (1-4) was solved numerically for each parameter with

noise leaving the rest constant using a noise intensity $\beta = 0.01(1\%)$. The average deviation (S_{ε_i}) between the noisy solutions with respect to the no-noise solution is also calculated. The average deviations obtained for a patient with growing glioma (initial conditions 1) can be seen in Table 2, for a patient with advanced stage glioma (initial conditions 2) in Table 3 and for a patient without glioma (initial conditions 3) in Table 4, where the order of influence of the parameters is observed.

Table 2: Average deviation values (ordered from highest to lowest) obtained for the initial conditions 1 using a noise intensity equal to 1% ($\beta = 0.01$) with respect to each parameter.

The parameters influenced very similarly for a patient with an advanced stage glioma (initial conditions 2) Table 3 and for a patient with a growing glioma (initial conditions 1). In the case of a patient without glioma (initial conditions 3) the parameters related to the tumor have no influence and affect in a different way with respect to the other initial conditions (see Table 4). In accordance with Table 2 one of the parameters that most influences a patient with growing glioma (initial conditions 1) is the baseline immune system cell production rate (ν), the result of which is shown in the Figure 1. It is of interest to observe that the glucose levels and the activity of the immune system diminish as the glioma grows. For the case of a patient with advanced stage glioma (initial conditions 2), Table 3 shows that the glucose consumption rate by glioma ($d_{T\sigma}$) is an influential parameter, the results for noise included in this parameter are shown in Figure 2. In this Figure it can be

 ISBN: 978-84-617-8694-7

seen that the glucose levels and the activity of the immune system are quite decayed because the glioma is already big. Finally in Table 4 it can be observed that the immune system cell recruitment rate (α_s) is an important parameter for the case of a patient without glioma (initial conditions 3) whose results are shown in the Figure 3. It is seen that glucose levels and activity of the immune system remained constant.

5 Conclusion

The model shows that when glioma exists (initial conditions 1 and 2), serum glucose levels fall below healthy levels, which represents a close dependence between tumor growth and available glucose, being consistent with the results obtained in the order of influence of the parameters, given that for the evolution of the glioma one of the parameters that more influences is the glucose consumption rate by glioma ($d_{T\sigma}$) and in general the model is

very sensitive to this parameter. The immune system plays a key role in tumor growth, because the immune system cell recruitment rate (α_s) and the baseline immune system cell production rate (ν) have a considerable influence. Also for the case of the patient without glioma the immune system is highly linked to serum glucose concentration, which suggests that it consumes a considered quantity of glucose for its activity.
The stability analysis shows that the model is stable when there is no glioma and is not stable when there is. In general, it can be concluded that this model serves to determine the level of influence of the parameters in this system. The results obtained can be used to search for blood-biomarkers for early detection of gliomas.

Abstract

In this paper, the MHD flow in a rectangular duct with a slipping wall portion is solved as a Cauchy problem when underspecified boundary conditions are present for the velocity on the slip wall. The aim is to regain the slipping velocity on this part of the duct walls. The dual reciprocity boundary element method (DRBEM) is used to discretize the Cauchy problem which results in an ill-conditioned system of linear algebraic equations, hence a regularization technique is necessary to solve the system. In this study, three regularization techniques, namely Tikhonov regularization, the direct-inverse iteration method, and the well-posed iteration method are used and compared in terms of velocity and induced magnetic field behaviors. Slip velocity behavior of the fluid is investigated for several values of the Hartmann number (Ha) with insulated and conducting vertical duct walls. It is found that all the three methods reconstruct the slip on the wall on which the direct solution has a slip assumption, especially when Ha increases.

Key words: DRBEM, Cauchy problem, MHD duct flow, regularization

1 Introduction

The electrodynamics of magnetic fields in the proximity of electrically conducting fluids, such as liquid metals and blood plasmas is concerned by magnetohydrodynamics (MHD). Conducting fluid movements under the external magnetic field are decribed with the combination of the Navier-Stokes equations with the Maxwell's equations through Ohm's law. The magnetohydrodynamic flow in ducts has many industrial and biological applications as MHD generators and MHD pipes, cooling of nuclear fusion apparatus and measuring the

blood flow pressure [1].

The distance from the fluid to the duct walls within the solid stage where the flow velocity vanishes is defined as the slip length. As current experimental data shows the slip in the MHD flow will likely occur in fusion reactors with liquid metal flows in contact with ceramics. The presence of the Dirichlet or mixed boundary conditions for the velocity on the complete duct walls results in direct problems. These conditions usually refer to no-slip velocity or the slip velocity on the whole duct walls, respectively. The MHD equations have exact solutions only for some special duct geometries used for no-slip velocity or slip velocity and insulated or perfectly conducting duct walls. For the general case of wall conditions, these equations are mostly solved by numerical techniques [2]. In some engineering applications one part of the boundary may allow both the velocity slip and conductivity change depending on the material it is made of. In this case, the boundary conditions are incomplete either in the form of underspecified or overspecified on different parts of the boundary. These are inverse problems and it is well-known that they are generally ill-posed [3]. Thus, a regularization method must be used.

The DRBEM transforms the differential equations defined in the region to integral equations defined on the boundary, approximating also the inhomogeneities of the equations using radial basis functions which are related to differential operator with particular solutions. This way, a system of discretized equations for the boundary nodes and at some selected interior points is solved [4]. There are quite a number of DRBEM solutions of MHD duct flow problems with no-slip velocity condition and various combinations of wall conductivities [5, 6, 7, 8].

In this paper, we present the DRBEM solution of both the direct and inverse MHD flow problems when one part of the duct walls contain the velocity slip. The slip length is not known and thus, both the velocity and its normal derivative are going to be determined which are underspecified boundary conditions. Since the other parts of the boundary have both of these values, they are overspecified which form the Cauchy MHD problem. The Tikhonov regularization method, the direct-inverse iteration method, and the well-posed iteration method are used to regularize the ill-posed discretized problem. The results are obtained for Hartmann number values $\leqslant 50$ and these three methods are compared in terms of the convergence to the direct problem solutions in the sense that direct problem is solved with an approximation added to the underspecified velocity wall conditions. The DRBEM has the advantage of discretizing only the boundary and providing both the velocity and its normal derivative values on the boundary. Thus, it gives the solution of Cauchy MHD flow problem at a small computational expense.

 ISBN: 978-84-617-8694-7

2 Mathematical Formulation of the Problem

The two-dimensional, steady and fully developed MHD flow is considered in a rectangular duct under an external magnetic field applied horizontally. The vertical walls have certain electrical conductivity and the left wall allows also the slip of the fluid. The non-dimensional governing equations in terms of the velocity $V(x,y)$ of the fluid and the induced magnetic field $B(x,y)$ are given as [1]

$$\begin{aligned} &\nabla^2 V + Ha\frac{\partial B}{\partial x} = -1 \\ &\qquad\qquad\qquad\qquad \text{in} \quad -1 \le x, y \le 1 \\ &\nabla^2 B + Ha\frac{\partial V}{\partial x} = 0 \end{aligned} \tag{1}$$

where $Ha = LB_0\sqrt{\sigma/\nu\rho}$ is the Hartmann number resulted from the nondimensionalization of the equations, and L, B_0, σ, ν and ρ are the characteristic length, the external magnetic field intensity, electrical conductivity, kinematic viscosity, and the density of the fluid, respectively.

The physical configuration of the duct walls results in the boundary conditions of the velocity and the induced magnetic field as ($V = 0$, $B = 0$, no-slip and insulated wall)

$$\begin{aligned} &V = 0, && B = 0 && \text{on} \quad y = \mp 1, \quad -1 < x < 1 \\ &V = 0, && B = k && \text{on} \quad x = 1, \quad -1 < y < 1 \\ &V + \alpha\frac{\partial V}{\partial n} = 0, && B = -k && \text{on} \quad x = -1, \quad -1 < y < 1 \end{aligned} \tag{2}$$

where α is the dimensionless slip length and $\mp k$ are the conductivity values of the vertical walls. By taking $U_1 = V + B$ and $U_2 = V - B$ equations (1) are decoupled first as

$$\begin{aligned} &\nabla^2 U_1 = -1 - Ha\frac{\partial U_1}{\partial x} \\ &\qquad\qquad\qquad\qquad \text{in} \quad -1 \le x, y \le 1 \\ &\nabla^2 U_2 = -1 + Ha\frac{\partial U_2}{\partial x} \end{aligned} \tag{3}$$

in which both of the equations are of diffusion-convection type. The aim of the study is to obtain the slip velocity on the left wall $x = -1, -1 \leqslant y \leqslant 1$. Meantime, there will be a conductivity change on this left slipping wall due to the newly computed velocity values. Thus, the MHD problem is reconstructed as a Cauchy problem first in terms of U_1 and U_2 as shown in Figure 1.

 ISBN: 978-84-617-8694-7

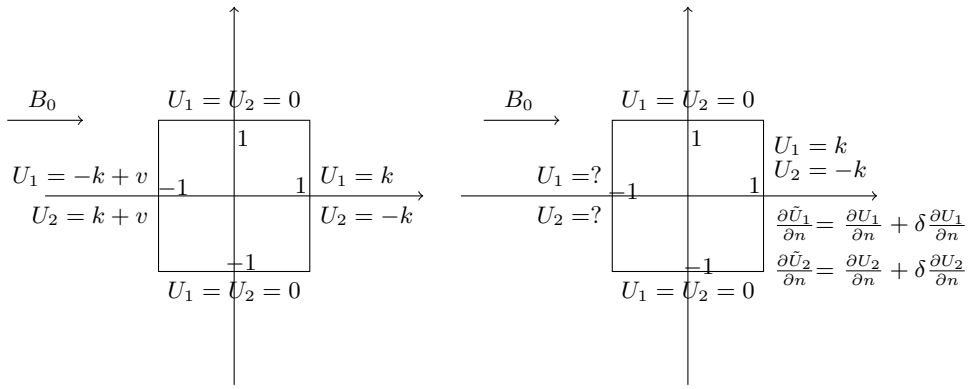

Figure 1: Boundary conditions for the direct (left) and the Cauchy (right) problems.

Here, v is the approximation added to U_1 and U_2 in the direct problem to differ from the no-slip condition $V = 0$ to a slip condition $V + \alpha \dfrac{\partial V}{\partial n}$ on the left wall where both V and $\dfrac{\partial V}{\partial n}$ are not known. Then, the solution of direct problem using DRBEM gives $\dfrac{\partial U_1}{\partial n}$, $\dfrac{\partial U_2}{\partial n}$ everywhere on the boundary. The normal derivative conditions with noisy data on the $x = 1$ wall are obtained as $\frac{\partial \tilde{U}_1}{\partial n} = \frac{\partial U_1}{\partial n} + \delta \frac{\partial U_1}{\partial n}$ and $\frac{\partial \tilde{U}_2}{\partial n} = \frac{\partial U_2}{\partial n} + \delta \frac{\partial U_2}{\partial n}$, where $\delta \frac{\partial U_1}{\partial n}$ and $\delta \frac{\partial U_2}{\partial n}$ are Gaussian random variables with mean zero and standard deviation $\sigma = max_{x=1} |\frac{\partial U_1}{\partial n}, \frac{\partial U_2}{\partial n}| \times (\dfrac{p_u}{100})$ and p_u is the percentage of additive noise for $\frac{\partial U_1}{\partial n}$ and $\frac{\partial U_2}{\partial n}$. Then, the Cauchy problem is solved by DRBEM to determine both U_1, U_2, $\dfrac{\partial U_1}{\partial n}$, $\dfrac{\partial U_2}{\partial n}$ on $x = -1$. Finally, V, B, $\dfrac{\partial V}{\partial n}$, $\dfrac{\partial B}{\partial n}$ are obtained through the relationships $U_1 = V + B$, $U_2 = V - B$.

3 The DRBEM Application

The DRBEM is applied to the decoupled equations (3) of the MHD problem by using the fundamental solution of the Laplace equation which is $u^* = ln(\frac{1}{r})/2\pi$, [4]. Thus, all the terms other than Laplacian are considered as inhomogeneity. That is, by weighting the equations (3) by u^* and applying Green's second identity, we obtain the following equations

$$c_i U_{1i} + \int_\Gamma q^* U_1 d\Gamma - \int_\Gamma u^* \frac{\partial U_1}{\partial n} d\Gamma = - \int_\Omega (-1 - Ha \frac{\partial U_1}{\partial x}) u^* d\Omega \tag{4}$$

$$c_i U_{2i} + \int_\Gamma q^* U_2 d\Gamma - \int_\Gamma u^* \frac{\partial U_2}{\partial n} d\Gamma = - \int_\Omega (-1 + Ha \frac{\partial U_2}{\partial x}) u^* d\Omega \tag{5}$$

 ISBN: 978-84-617-8694-7

where $q^* = \dfrac{\partial u^*}{\partial n}$, Γ is the boundary $x = \mp 1, y = \mp 1$, and the index i denotes the source point. The constant c_i is 1/2 and 1 when the source point is on the boundary and in the interior of the domain, respectively.

The right hand side domain integrals are treated as inhomogeneity and they can be approximated by radial basis functions $f(r) = 1 + r$ which are connected to the particular solutions $\hat{u}_j$'s with the equation $\nabla^2 \hat{u}_j = f_j$. The approximations of the domain integrals are given by $\sum_{j=1}^{N+L} \alpha_j f_j$ and $\sum_{j=1}^{N+L} \beta_j f_j$ for the equations (4) and (5), respectively, where α_j's and β_j's are undetermined coefficients, $f_{ij} = 1 + r_{ij}$, and r_{ij} is the distance between the nodes i and j, N and L denote the number of boundary and interior nodes, respectively, when the bpundary Γ is dicretized using N constant boundary elements.

Then, the right hand sides of the equations (4)-(5) are rewritten as

$$c_i U_{1i} + \int_\Gamma q^* U_1 d\Gamma - \int_\Gamma u^* \frac{\partial U_1}{\partial n} d\Gamma = \sum_{j=1}^{N+L} \alpha_j (c_i \hat{u}_{ij} + \int_\Gamma q^* \hat{u}_j d\Gamma - \int_\Gamma u^* \frac{\partial \hat{u}_j}{\partial n} d\Gamma) \tag{6}$$

$$c_i U_{2i} + \int_\Gamma q^* U_1 d\Gamma - \int_\Gamma u^* \frac{\partial U_2}{\partial n} d\Gamma = \sum_{j=1}^{N+L} \beta_j (c_i \hat{u}_{ij} + \int_\Gamma q^* \hat{u}_j d\Gamma - \int_\Gamma u^* \frac{\partial \hat{u}_j}{\partial n} d\Gamma) \tag{7}$$

by applying the BEM also to the inhomogeneities connected to the same Laplace operator. The discretization of the boundary results in system of matrix vector equations

$$HU_1 - G\frac{\partial U_1}{\partial n} = (H\hat{U} - G\hat{Q})F^{-1}\{-1 - Ha\frac{\partial U_1}{\partial x}\} \tag{8}$$

$$HU_2 - G\frac{\partial U_2}{\partial n} = (H\hat{U} - G\hat{Q})F^{-1}\{-1 + Ha\frac{\partial U_2}{\partial x}\}. \tag{9}$$

The matrices $\hat{U}$, $\hat{Q}$ and F are constructed by taking each of the vectors $\hat{u}_j$, $\hat{q}_j$ and f_{ij} as columns, respectively. The components of the H and G matrices are given as

$$H_{ij} = c_i \delta_{ij} + \frac{1}{2\pi} \int_{\Gamma_j} \frac{\partial}{\partial n}(ln(\frac{1}{r}))d\Gamma_j, \quad H_{ii} = -\sum_{j=1, j\neq i}^{N} H_{ij}$$

$$G_{ij} = \frac{1}{2\pi} \int_{\Gamma_j} ln(\frac{1}{r})d\Gamma_j, \quad G_{ii} = \frac{l}{2\pi}(ln(\frac{2}{l}) + 1)$$

 ISBN: 978-84-617-8694-7

where l is the length of the elements and δ_{ij} is the Kronecker delta function.

The space derivatives for U_1 and U_2 are computed by using the coordinate matrix as

$$\frac{\partial U_1}{\partial x} = \frac{\partial F}{\partial x} F^{-1} U_1 \quad \text{and} \quad \frac{\partial U_2}{\partial x} = \frac{\partial F}{\partial x} F^{-1} U_2.$$

The solution of the system (8)-(9) gives the unknown vectors U_1, U_2, $\frac{\partial U_1}{\partial n}$ and $\frac{\partial U_2}{\partial n}$ which are $(N+L)\times 1$ vectors everywhere on the boundary.

4 Tikhonov Regularization

The unknown vectors U_1, U_2, $\frac{\partial U_1}{\partial n}$ and $\frac{\partial U_2}{\partial n}$ which are $(N+L)\times 1$ vectors everywhere on the boundary are obtained from the system of equations (8)-(9). Since the aim is to find the slip velocity on the left wall ($x=-1$), first the direct problem is solved by adding approximations to U_1 and U_2 on this wall. Then, with the obtained $\frac{\partial U_1}{\partial n}$ and $\frac{\partial U_2}{\partial n}$ values on $x=1$, the Cauchy problem will be solved as an inverse formulation using Tikhonov regularization with the overspecified boundary conditions $(U_1, U_2, \frac{\partial U_1}{\partial n}, \frac{\partial U_2}{\partial n})$ on $x=1$, and underspecified boundary conditions (no boundary condition) on $x=-1$. The resulting ill-conditioned system of equations in the form $Ax=b$ obtained from the DRBEM discretized system for the Cauchy problem configured in Figure 1 is solved by using Tikhonov regularization as defined

$$(A^T A + \lambda^2 I)x = A^T b.$$

λ is the regularization parameter obtained from the L-curve method and reduces the system to least-squares equations for $\lambda = 0$. In the case of λ being large, the residual norm $||Ax-b||_2$ will be large. On the other hand, when λ is small, then the solution will be dominated by the contributions from the data errors and so, $||x||_2$ will be very large. Hence, the choice of the regularization parameter is very crucial. We choose the regularization parameter λ by using the L-curve method. The curve $(||Ax_\lambda - b||_2, ||x_\lambda||_2)$, x_λ is the regularized solution, which is obtained from plotting the norms of the residual and the solution provides controlling these two quantities. The corner of this curve gives the optimal regularization parameter λ, [9].

5 The Direct-Inverse Iterations for the Cauchy Problem

Instead of using one-step Tikhonov regularization, an iterative method including the direct and inverse solutions for the governing equations (3) can be developed. In the inverse

 ISBN: 978-84-617-8694-7

formulations, the Tikhonov regularization is used. In this method, while the direct problem is solved with the Dirichlet type boundary conditions for U_1 and U_2 on each part of the boundary, but containing approximations on $x = -1$, the inverse problem is solved with overspecified boundary conditions $U_1, U_2, \frac{\partial U_1}{\partial n}, \frac{\partial U_2}{\partial n}$ on $x = 1$. The iterations follow as;

1. $U_1 = -k+v$, $U_2 = k+v$ are taken with approximation v to achieve a slip on $x = -1$.

2. Solve the discretized equations (8)-(9) for the direct problem configured in Figure 1.

3. Use $\frac{\partial U_1}{\partial n}, \frac{\partial U_2}{\partial n}$ obtained from step 2 in addition to the Dirichlet boundary conditions for U_1, U_2 on $x = 1$ for solving the inverse problem using Tikhonov regularization with overspecified and underspecified boundary conditions for $x = 1$ and $x = -1$, respectively.

4. Update the values U_1, U_2 with the obtained ones from step 3.

5. Repeat steps 2-4 until the velocity $V = \frac{U_1 + U_2}{2}$ on $x = -1$ converges to the velocity of the direct solution containing the approximation.

6 The Well-posed Iterations for the Cauchy Problem

This method deduces the ill-posed problem to a successive well-posed problems by alternating the given data on the overspecified part of the boundary. This iterative algorithm advanced by Kozlov et. al. [10] for Cauchy problems includes the following steps:

1. $U_1 = -k + v$, $U_2 = k + v$ are taken with an approximation v to achieve slip on $x = -1$ wall.

2. Solve the discretized equations (8)-(9) for the direct problem with the Dirichlet type boundary conditions for U_1 and U_2 given as in Figure 1.

3. Use the normal derivative conditions for U_1 and U_2 on $x = -1$ and $x = 1$ obtained from step 2 for solving the direct problem.

4. Update the values U_1 and U_2 with the values obtained from step 3 on $x = -1$.

5. Repeat steps 2-4 until the velocity $V = \frac{U_1 + U_2}{2}$ on $x = -1$ converges to the perturbed velocity $V = v$.

 ISBN: 978-84-617-8694-7

7 Numerical Results

The MHD duct flow equations (3) are solved numerically in terms of the velocity V of the fluid and the induced magnetic field B with the boundary conditions imposed for the direct and inverse problems as given in Figure 1. The aim is to regain the slipping velocity and compute slip length on the left wall. In the application of DRBEM, $N = 100, 160, 240$ boundary elements and $L = 625, 1600, 3600$ interior nodes are taken for $Ha = 1, 10, 50$, respectively. Both the insulated ($k = 0$) and conducting ($k = 1$) vertical walls are considered.

Figures 2, 3 show the velocity and induced magnetic field profiles for the direct solution with a slipping left wall where the slip length is taken $\alpha = 0.2$, [11], respectively for $k = 0$ (insulated) and $k = \mp 1$ (conducting) vertical walls. This means that the velocity V is perturbed with v corresponding to slip length $\alpha = 0.2$. In Figures 4, 5, we present velocity behaviors obtained from the Tikhonov regularization, the direct-inverse iterations, and the well-posed iterations employed to solve the Cauchy MHD flow problem, respectively for $k = 0$ and $k = 1$. They demonstrate that the slip velocity is reconstructed and converged to the direct solution which is perturbed with a slip length $\alpha = 0.2$. When $Ha = 1$ is taken, all the three methods converge to the direct solution. On the other hand, when Hartmann number increases to $Ha = 10$, the well-posed iterations seem to converge to the direct solution very well while the others show much sharper slip on the left wall. However, all the three methods capture the same velocity behavior of the direct solution. When the Hartmann number is further increased to Ha=50, the velocity slip is detected close to the corners of the left wall and there is no slip on the middle portion of the right wall. In all the methods, an increase in Hartmann number causes boundary layers (Hartmann layers of order $1/Ha$ on the walls perpendicular to the applied magnetic field and side layers of order $1/\sqrt{Ha}$ on the parallel walls [1]). However, Hartmann layers are weakened on the left wall due to the slip effect of the velocity as Ha increases. As Ha increases further to Ha=50, the core region enlarges, and fluid becomes stagnant and the flow is flattened. The slip velocity is regained on the left wall by using DRBEM with all the three methods for the Cauchy MHD duct flow problem.

In Figure 6, we depict also induced magnetic field behaviors obtained from the three methods. The well-posed iterations give exactly the same induced magnetic field of the direct solution since there is no change involved in B. On the other hand, the Tikhonov and direct-inverse methods result in conductivity changes on $x = -1$ due to the perturbations imposed on the direct formulation. However, all the three methods show the same behavior of B especially when Ha increases.

8 Conclusion

The MHD rectangular duct flow is formulated as a direct and a Cauchy problem in terms of the velocity slip on the left wall and is solved by using the DRBEM. The Cauchy problem is solved with the normal derivative conditions obtained from the direct solution to determine the underspecified velocity information on the left wall by using Tikhonov regularization, the direct-inverse iterations, and the well-posed iterations. The Cauchy problem reconstructs the slip velocity on the left wall in accordance with the solution of perturbed direct problem for Ha=1, 10, 50 in all the methods mentioned. The well-posed iterations show very well convergence to the solution of direct problem on the slipping wall while Tikhonov regularization and direct-inverse iterations capture both the slip and conductivity change on this wall. When Hartmann number increases, all the three methods reconstruct the slip velocity on the left wall. The DRBEM is the most suitable numerical method for the Cauchy MHD duct problem since it provides both the velocity and its normal derivative values on the underspecified wall extracting the slip length α between them.

Abstract

When aimed to modify the downstream vortex shedding of a given bluff body, whether any road vehicle or wing profile, the use of Active Flow Control (AFC) appears to be an efficient technology. Among the different (AFC) methodologies the use of periodic forcing is ment to have better efficiency since it requires less energy to activate the shear layer, the reason behind this efficiency lies on the fact that periodic forcing interacts with the shear layer natural instabilites. In the present paper, one of the devices widely emloyed to generate pulsating flow, is carefully studied via 3D-CFD and using OpenFOAM. Initially the base flow is being determined and compared with previous experimental results, in a second step several internal dimensions of the fluidic actuator are being modified to characterize the output frequency and amplitude variations, among the conclusions obtained it is found that a given fluidic actuator is capable of generating several output frequencies and amplitudes when modifiying some internal dimensions while maintaining a constant incoming flow Reynolds number.

Key words: Fluidic actuators, Active flow control, Computational fluid dynamics.

1 Introduction

One of the newest technology to modify the lift and drag of a given body is via injecting or sucking flow to or from the boundary layer nearby the separation point. The technique which seems to be more effective, mostly because it involves the use of the smallest amount of energy, is the use of periodic forcing, the main advantage of using periodic forcing is that

the injected flow interacts with the shear layer natural instabilities, and threrefore deeply activates the flow. To generate pulsating flow, two main types of fluidic oscillators are being used, the Zero Net Mass Flow (ZNMF)fluidic oscillators and the Fluidic actuators (FA). The former consist of a membrane located inside of an open chamber, the membrane moves back and forward and so a pulsating flow is being generated, with positive and negative velocities alternating every half cycle, as a result, the net mass flow at every cycle is null. The later generates a sinusoidal outgoing flow and has the advantage of having no moving parts, this particular advantage is very handy when designing long lasting and reliable systems.

Original (FA) designs goes back to the 60s and 70s, left nearly unchanged for over 45 years. Their possible output frequency ranges from several Hz to KHz and the flow rate is usually of a few dm^3/min. Among their applications in flow control, it is worth to mention their use in combustion control [1, 2, 3], mixing enhancement [4], flow separation in aerofoils [5], boundary layer control on hump diffusers used in turbomachinery [6], flow separation control on stator vanes of compressors [7], drag reduction on trucks [8] and cavity noise reduction [9]. It appears that fluidic actuators have the potential of being much widely used in the near future, and according to the authors there is the need of better understanding their behaviour in order to further improve their performance. Regarding the fluidic actuators design two main groups exist, the one based on Coanda effect [10], and the one based on a jet mixing chamber, also called vortex oscillators [11]. The former group had an early application as pressure, temperature and flow measuring devices [12, 13, 14], the latter group has recently been applied as a flow control device [15]. To push forward (FA) boundaries several new designs have been recently created. Uzol and Camci [16], studied experimentally and via (CFD) a fluidic oscillator based on two elliptical cross-sections placed transversally and an after-body located in front of them. Such configuration was in fact proposed by Bauers patent [17, 18]. The device operates at frequencies of around 30 Hz and under laminar flow. The relation frequency versus Reynolds number was found to be perfectly linear. Huang and Chang [19] performed a deep experimental study on a V-shaped fluidic oscillator. Playing with the dimensions and the internal oscillator circular cavity, they defined the regimes under which oscillation was generated and they proved that frequencies from few Hz to several KHz could be obtained by modifying oscillator parameters. Additionally, an analysis of the streamline patterns behind the oscillator was also presented. Khelfaoui et al [20], presented an experimental and numerical analysis of non-symmetrical mini and micro oscillators. They found a linear relationship between the actuator frequency and the feedback channel volume, and noticed that above a certain input pressure choked flow appeared. Gebhard et al [21] studied a micro-oscillator operated with water, finding a linear relationship between the output frequency and the input volumetric flow. Raman and Raghu [9] evaluated the decrease of a cavity tone by using fluidic oscillators. The main acoustic frequency was reduced by over 10 dB, concluding that fluidic

 ISBN: 978-84-617-8694-7

excitation is a candidate in noise control applications. A numerical simulation of a two dimensional fluidic oscillator by using Navier-Stokes equations in laminar and incompressible flow, was performed by Nakayama et al [22]. They were able to visualize the periodical flow movement and measured the temporal axial and tangential fluid velocities, oscillation frequency being of 40Hz. Gregory and Raghu [23], created a fluidic oscillator based on Coanda effect but driven by piezoelectric devices. One of the main interesting performances of such device is that the oscillating frequency can be decoupled from the input flow and pressure differential. Frequency just depends on input electrical signal, being the oscillator able to work at a range of velocities which goes up to sonic conditions.
The present paper will introduce a numerical evaluation of a fluidic actuator previously studied in [24, 25, 26, 27]. In these previous studies, and extensive CFD model including the analysis of several turbulent models in order to find out which one was the most appropriate, was undertaken. Besides, they performed an experimental study obtaining a good agreement between experimental and CFD results. In the present paper, experimental results obtained in [24, 25], will be compared with the new CFD calculations. A discussion regarding how different fluidic actuators internal parts and dimensions may affect its performance will be carried on. The authors main aim is to give to the reader some hints to be able to modify a given oscillator to fulfil a particular application.

2 Numerical problem definition and boundary conditions

The three dimensional fluidic actuator considered in the present paper is depicted in figure 1, its thickness was of 3.25mm. The incoming flow enters the actuator mixing chamber (2) through the flattered pipe located on the left hand side of the figure (1), on both sides of the mixing chamber there are the feedback channels (3), their function is to allow transporting fluid from the downstream mixing chamber site to the upstream one and vice-versa, the fluid leaves the actuator alternatively through one of the two exit surfaces located on both sides of the external chamber (4). Notice that a second fluidic actuator with a buffer zone (5) is also presented, the idea behind this second configuration is evaluating the efect of the outlet boundary conditions onto the pulsating flow. The mesh employed for the present simulation had a total of 2242000 cells, the grid used was structured and care was taken to obtain a very small y+ in all directions, in fact the maximum y+ respectively obtained in x, y, and z directions was, 1.8, 4.7 and 1.2 for a Reynolds number of 16034. Boundary conditions employed were, fluid velocity at the entrance and absolute pressure $1.01978 * 10^5 Pa$ at the output, Dirichlet boundary conditions were set to all walls. A range of different input velocities from 0.758 to 1.23 m/s were studied, its minimum and maximum Reynolds number associated was 8711 and 16034. The fluid employed was water and it was considered as incompressible. Fluid dynamic viscosity was chosen as 0.001003 $Kg/(m * s)$ and fluid density was 998.2 Kg/m^3. The characteristic length was chosen to be the inlet

 ISBN: 978-84-617-8694-7

width, which value was $2.55 * 10^{-3}m$. The turbulence model used was the SpalartAlmaras DDES, which is a hybrid LES model. OpenFOAM version 3.0, was employed for all 3D simulations, finite volumes approach was employed. Inlet turbulence intensity was set to 0.05% in all cases; PISO was used as a solution method, being the time step of $10^{-6}s$, spatial discretization was set to second order. The CFD model designed had a probe covering one of the two actuator exits, at this section the frequency and amplitude associated to the temporal mass flow were measured. The frequencies obtained were compared with the ones experimentally obtained in [24, 25], table 1 compares both results. Notice that the difference is minimum giving confidence to the CFD simulations undertaken.

Table 1: Comparison experimental and CFD results.

Reynolds number	8711	11152	13593	16034

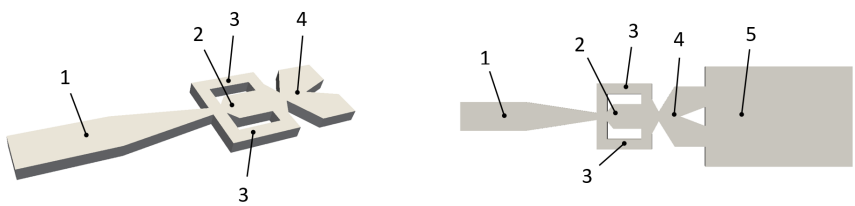
Difference %	0.62%	2.3%	3.7%	4.1%



(a) (b)

Figure 1: Fluid actuator general view and its different parts, (a) original fluidic actuator (b) fluidic actuator with buffer zone.

As previously stated, and in order to characterize the possible effect of the boundary conditions on the flow performance, a fluidic actuator with a buffer zone was generated, for this particular case the outlet boundary conditions were maintained the same as in the original case but the outlet was located at the end of the buffer zone, the total number of cells used in this new model was of 2854500. A single Reynolds number of 16034 was studied, the frequency obtained from this particular buffer zone model increased by 2.6% versus the one obtained with the original case. The authors have considered that the effect of buffer zone is pretty negligible and the rest of the cases will be studied without it. Finally and in order to compare the effect of the mesh on the results obtained, the original fluidic actuator was modelled via using 4.4 million cells, almost twice as much as the ones

employed initially. The simulation was done at the maximum Reynolds number Re=16034. The values of maximum x+, y+ and z+ obtained for this new mesh were of 1.8; 4.7 and 0.6 respectively. The frequency obtained when using this extremely dense mesh was of 22.83Hz which involves an increase of 0.57% versus the original case. Understanding that at lower Reynolds numbers the differences will be even smaller and considering that the time required to simulate the (FA) with 4.4 million cells is 74% higher than the one needed to perform the simulation with 2242000 cells, it can be concluded that using 2.2 million cells is precise enought for the cases under study.

3 Internal dimensions modifications

Figure 2 introduces the three modifications considered in this paper, the mixing chamber inlet width (a), was increased and decreased respectively by 64% and 114%, nine different positions were considered. The outlet width (b), increase and decrease was of 82%, again nine different positions were evaluatd. Regarding the outlet angle reduction (c), it was of 36.5%, the angle increase was of 100%, as in the previous two cases, nine different angles were simulated. In what follows the results obtained when performing these modifications are presented for a single Reynolds number, Re=16034.

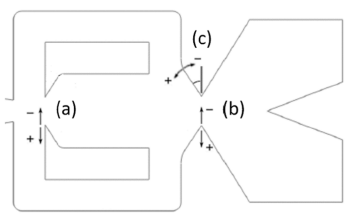


Figure 2: Fluidic actuator mixing chamber internal dimensions modifications.

4 Results

In the present section, the main performance characteristics of a fluidic actuator having some internal dimensions modified will be presented. For all cases, the frequency from the pulsating mass flow measured at one of the two outlets and the amplitude of such pulsating flow will be presented. Some pictures will be introduced for each case to better understand the flow behaviour inside the actuator.

 ISBN: 978-84-617-8694-7

4.1 Outlet width modification

Fiure 3 presents the variation of fluidic actuator non dimensional output frequency and amplitude, whenever the outlet width is being modified. It is interesting to realize that as the width decreases the pulsating frequency increases, increasing as well the output amplitude, and vice-versa. This increase in amplitude is explained when observing that the maximum fluid velocity increases with the width decrease. The temporal mass flow amplitude and the fluid velocity amplitude go hand by hand. Figure 4 shows the velocity magnitudes inside the (FA) for the highest and lowest outlet widths evaluated in this study, notice the difference in velocity at the (FA) output. From figure 3 it must be realized that the change in frequency versus the original actuator one, for the cases evaluated, is about $\pm 10\%$ while the amplitude is suffering an increase of nearly 60% and a decrease of about 40%.

 ISBN: 978-84-617-8694-7

4.2 Outlet angle modification

The variation of non dimensional output frequency and amplitude when the mixing chamber outlet angle is modified, is presented in figure 5. Notice that when the angle decreases, see figures 2, 5 and 6, the output frequency tends to increase, notice as well from figure 6b), that these small angles tend to direct the flow alternatively through the feedback channels, therefore explaining why frequency increases. On the other hand, as the angle increases, the flow is being directed towards the (FA) outlet, jeopardizing the degrees of freedom of the fluid, and so minimizing the output frequency and amplitudes. Notice that the angles variation studied, affected the output frequencies by approximately ±10%, the amplitude was affected by +11% and minus 50%. Clearly, these two modifications already presented, affect much deeply the output amplitudes than the frequencies.

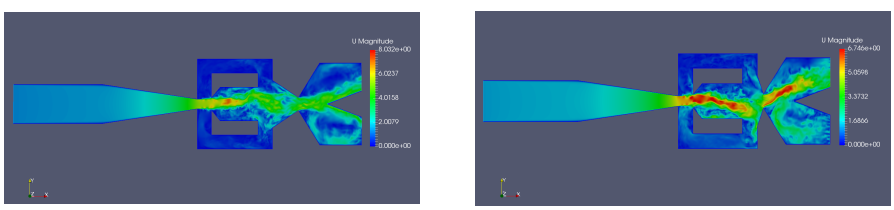
Figure 5: Fluid actuator performance when modifying the mixing chamber outlet angle. (a) Frequency variation (b) Amplitude variation.



(a) (b)

Figure 6: Fluid actuator internal field velocity magnitude, (a) Maximum outlet angle (b) Minimum outlet angle.

4.3 Mixing chamber inlet width variation

The last modification to be introduced consist of changing the mixing chamber inlet width. The first thing to be realized when seeing figures 7 and 8, is that the inlet width modifi-

 ISBN: 978-84-617-8694-7

cation, generates a completely different pattern onto the outgoing flow. If the inlet width overcomes a certain minimum or maximum values, there is no pulsating flow at the outlet, the flow simply goes straight fom inlet to outlet. In fact, for small values of inlet width, the incoming jet borders impinge onto the walls and create a flow stream which goes from left to right,upstream to downstream, along both feedback channels at the same time, preventing any feedback from downstream to upstream. Notice that this feedback is imprescindible to generate pulsating flow inside the mixing chamber. It is interesting to ralize that an increase of the inlet width is capable of producing a frequency increase of about 40%, while making the output amplitude to decrease nearly a 30%. This tendency is completely different than the one obtained with the previous two modifications, and it has mostly do to with the fact that for the present modification, when high widths are considered, the mixing chamber incoming jet, just suffers a slight wavering inside the chamber, causing at the (FA) exit a small variation of amplitude.

 ISBN: 978-84-617-8694-7

5 Conclusions

A given Fluidic actuator has been studied via 3D-CFD and when modifiying its internal parameters, such as mixing chamber inlet and outlet widths, and outlet angle. When outlet width or outlet angle are being decreased, flow output frequency and amplitude increases and vice-versa. The modification of the inlet width produces quite an oposite effect, as inlet width increses the freqeuncy increases generating a decrease of the output amplitude.

Abstract

OpenACC is a parallel programming model for automatic parallelization of sequential code using compiler directives or pragmas. OpenACC is intended to be used with accelerators such as GPUs and Xeon Phi. The different implementations of the standard, although still in early development, are primarily focused on GPU execution. In this study, we analyze how the different OpenACC compilers available under certain premises behave when the clauses affecting the underlying block geometry implementation are modified. These clauses are the Gang number, Worker number, and Vector Size defined by the standard.

Key words: OpenACC, GPU, block geometry, thread geometry

1 Introduction

OpenACC is an open standard intended to automatically parallelize sequential code and manage its execution in accelerators like GPUs or Xeon Phi coprocessors. It defines a number of compiler directives, also called pragmas. The main goal of OpenACC is to reduce both learning and coding time in a portable way [1]. The version of the OpenACC standard at the time of writing is the 2.5 [2].

The OpenACC standard was founded by Nvidia, CRAY, CAPS and PGI. The number of members now is larger, including both academic institutions and companies like the Oak Ridge National Laboratory, the University of Houston, AMD, and the Edinburgh Parallel Computing Centre (EPCC), among others.

There are several compilers that implement the OpenACC standard. The PGI compiler, developed by the Portland Group (subsidiary of Nvidia) is being distributed as part of

 ISBN: 978-84-617-8694-7

the Nvidia OpenACC Toolkit under a free 90-day license. Cray Inc. has its own OpenACC compiler, only available for use with their supercomputers. Pathscale Inc., a software developer for compilers and multicore software, also has an OpenACC implementation, the ENZO compiler.

Among the many academic or open-source alternatives there are the OpenUH compiler [3] by the University of Houston and accULL [4] from Universidad de La Laguna (Spain).

This work presents a study on the impact of different values for the clauses that affect the underlying block geometry of OpenACC-generated code. GPUs are very sensitive to the geometry of the thread-block chosen [5], and OpenACC makes use of the terms "gang", "worker" and "vector" in order to define different levels of parallelism. According to [6], the specification is ambiguous and this functionality depends directly on how each compiler is implemented. In this work, we measure the impact of the choice of an appropriate *thread-block geometry* when running a representative benchmark. By default, the geometry is decided by the compiler unless the specific clause is used inside the OpenACC directive. Our aim is to compare the resulting behaviour among different compilers and options. For thread-block geometry testing, we will modify the most representative of the benchmarks, testing several combinations of values for the clauses to specify gang, workers and vectors, and analyzing the differences in execution time for each compiler. This will offer some insight on the implementation of these clauses on each compiler.

Our contribution shows that the decisions made by each compiler is not always optimal, but manual tuning of the different values is not always possible for every compiler.

The rest of this paper is organized as follows. Section 2 describes the selected compilers. Section 3 shows our selected microbenchmark for testing the behaviour of the generated code when modifying the block geometry. Section 4 contains the result of our analysis about the impact on performance when changing the underlying block geometry. Finally, Section 5 concludes our paper.

2 Available Compilers

We mentioned several compilers in the Introduction. In this section we describe with more detail the compilers we were able to use for this study.

2.1 PGI Compiler

The PGI Compiler [7] is being developed by The Portland Group, being owned by Nvidia. This compiler is frequently presented in webinars, workshops, and conferences.

At the time of writing this paper, the PGI compiler is available for download as part of the OpenACC Toolkit from Nvidia. This toolkit includes a 90-day free trial, the possibility of acquiring an academic license for a whole year, or buying a commercial license.

 ISBN: 978-84-617-8694-7

2.2 accULL

The accULL [4] compiler developed by Universidad of La Laguna (Spain) is an open-source initiative. accULL consists on a structure of two layers containing YaCF [8] (Yet another Compiler Framework) and Frangollo [9], a runtime library. YaCF acts as a source-to-source translatori, while Frangollo works as an interface that provides the most common operations found in accelerators.

2.3 OpenUH

The OpenUH [3] compiler, developed by the University of Houston (USA) is another open-source initiative. It makes use of Open64, a discontinued open-source optimizing compiler.

3 Microbenchmark Description

In OpenACC, block size is defined by gangs, workers and vectors.Their choices affect the performance on memory-bound applications. To study this issue, we are going to use a very simple matrix addition implemented both in CUDA and OpenACC. Our decision is made by the fact that the problem is embarrassingly parallel, memory acceses are perfectly coalesced, and the computational load per global memory access is low (memory-bound application).

The standard only defines the different levels of parallelism, but it is up to each implementation to decide how are these levels exploited in the actual architecture. In order to obtain comparable results, some details should be taken into account. The CUDA version needs to be implemented using elastic kernels, using a fixed number of blocks, which equals the gang number in the OpenACC code. Also, since the OpenACC standard establishes that grid dimensions depend on the use of the collapse clause with nested loops, we have decided to make a one-dimensional grid. We evaluate a number of blocks in the grid ranging from one to 2048 (using only powers of two). The sequential code can be seen in Fig. 1 and the CUDA kernel in Fig. 2.

In OpenACC the X dimension of the CUDA block translates to vector length, whereas the Y dimension equals the worker number. We have also decided to use 512 threads per block, trying each possible combination of X and Y dimension values using powers of two.

4 Evaluation

In this section we analyze the impact of different choices for the geometry of the underlying thread-blocks in the OpenACC generated code.

    int iter;
    for (iter = 0; iter < iterations; ++iter)
    {
        int tx = (blockIdx.x + iter*GANG)*blockDim.x + threadIdx.x;
        int ty = threadIdx.y;
        int i = (tx/SIZE)*blockDim.y + ty;
        int j = (tx%SIZE);
        int offset = i*SIZE + j;
        if (offset < SIZE*SIZE) p_C[offset] = ALPHA*p_A[offset] + p_B[offset];
    }
}
```

Figure 2: CUDA Kernel for the Matrix Addition

 ISBN: 978-84-617-8694-7

4.1 Experimental Setup

We used a Nvidia GTX Titan Black to run the experiments. This GPU contains 2 880 CUDA cores with a clock rate of 980MHz and 15 SMs. It has 6GB of RAM, and Compute Capability 3.5. The host is a Xeon E5-2690v3 with 12 cores at a clock rate of 1.9GHz, and 64GB in four 12GB modules.

The PGI compiler is the one contained in the Nvidia OpenACC Toolkit, version 15.7-0, published in Jul 13, 2015. We used OpenUH version 3.1.0 (published in November 4, 2015), based on Open64 version 5.0 and using GCC 4.2.0, prebuilt, downloaded from the High Performance Computing Tools group website [10]. accULL is version 0.4alpha (published in November 28, 2013), downloaded from Universidad de La Laguna's research group "Computación de Altas Prestaciones" [11].

4.2 Block Geometry Sensibility of Generated Code

Observing the results obtained using the CUDA code in Fig. 3, we can see that the best results are obtained when the block number is high enough to make the GPU reach proper levels of occupation. The X dimension plays a huge role, but we expected to see an improvement in performance when the X dimension was at least 16. We suspect this is due to several factors, being the most important the behaviour of the cache when elastic kernels are used.

The results of the OpenACC code generated by PGI (Fig. 4) show that the only factor affecting the performance is the gangs number, whereas the variation of workers number and vector length does not play a significant role except when a vector length of one is used. In this case, performance is severely affected, which indicates a poor use of the cache. Overall, PGI's behaviour is the closest one to CUDA for this example.

When using OpenUH as the compiler for the OpenACC code (Fig. 5), all three parameters affect the performance of the generated code, which means that the parameters are actually being used to map the computation to the architecture resources. There is an exception when any of the three parameters is set to one. In this case, OpenUH seems to assume direct control and choose what it considers an adequate set of parameters for gangs number, workers number and vector length.

Finally, the results obtained by using accULL (Fig. 6) as our OpenACC compiler show that none of the parameters have any effect on the performance of the generated code, and it is the compiler itself who decides the value to be used.

5 Conclusions

During this work, we have realized that the OpenACC standard is very unspecific about how the different compilers should implement the three levels of parallelism. This allows

 ISBN: 978-84-617-8694-7

very different behaviours while unifying the basic concepts of automatic parallelization for both GPUs and Xeon Phi coprocessors.

Due to the standard leaving freedom for the implementation of the different levels of parallelism to the different compilers, the maturity of the latter directly affects the performance of the OpenACC-generated code. Thus we find that the PGI compiler, being the more mature of the analyzed compilers, generates code that resembles an optimized CUDA implementation. OpenUH shows an implementation that takes the defined levels of parallelism into consideration, but with room for a performance improvement. On the other hand, accULL seems to avoid hand-made changes to the levels of parallelism, choosing always the same configuration.

Although compiler implementations are not very mature yet, the simplicity of our microbenchmark allows us to see the effects of the variations in the different clauses: Gang number, Worker number, Vector length. Our results remark that the performance boost obtained by the tested OpenACC compilers in GPUs is dependant on the implementation of these clauses. However, since the mission of these clauses is to unify different concepts among GPUs and Xeon Phi accelerators, we argue this is complex task for the compiler implementations.

Some statistical approaches to deal with change and confusion matrices obtained from spatial data

Inmaculada Barranco-Chamorro[1]

[1] *Department of Statistics and Operations Research, University of Sevilla*

emails: chamorro@us.es

Abstract

In this paper several statistical methods are considered to deal with change and confusion matrices obtained from spatial data. The proposed methodologies focus on the study of the off-diagonal elements of these matrices. So tests for the marginal homogeneity are considered and correspondence analysis methods tailored for square matrices.

Key words: confusion matrix, correspondence analysis, marginal homogeneity

1 Introduction

Confusion matrices are a quite common tool used to asses the quality of spatial data. Usually, these matrices are obtained as result from classification of images and fotointerpretations. In practice, a variety of situations can be found in which proper statistical techniques are necessary to carry out the statistical inference associated to these matrices. For instance, we can cite: matrix size (it can range from 3×3 to more than 40×40), number of total data (from only a few to thousands), diversity of classes, dates of studies, etc.

To assess the overall accuracy of the classification depicted in a confusion matrix or to compare matrices, the kappa index is commonly used. One of the main drawbacks of this index is that it is an overall measure of agreement in a matrix. The aim of this paper is not to contribute to the debate about the salience of kappa and similar statistics for describing change or accuracy. On the other hand, our aim is to introduce statistical measures that can help us to describe and understand issues of interest in a confusion matrix and/or compare main features in two (or more) confusion matrices. Our results can be applied in two different contexts where these kind of matrices can be obtained related to spatial data:

 ISBN: 978-84-617-8694-7

1. To quantify spatial differences in land cover and land use change over two time periods. In this case, we have a square contingency table, which summarizes the coincident areas or spatial intersection of land classified over the two time periods of time. In this way, the matrix reports us about the change in the area from time 1 to time 2 in which the surveys were carried out. They are usually referred as transition or change matrices.

2. To asses the suitability of a geographical classification method or to compare several ones. In this case, we have a square contingency table showing the agreement between the mapped classes and the reference classes. So the diagonal gives us the number of elements properly classified, and the off-diagonal elements the wrong ones. These tables are usually referred as confusion matrices.

From the statistical point of view, we have, in both cases, a $k \times k$ square asymmetric contingency table where the rows and columns refer to the same set of objects, and their entries are non negative integer numbers. Quite often, standard statistical methods designed for contingency tables are unsuccessful to deal with this kind of matrices because of the strong effect of the diagonal values on the statistical summaries. So, we focus on statistical methods to deal with the off-diagonal elements of these matrices. Two approaches are considered. They are described in the next two sections.

2 Plots and statistical tests to deal with off-diagonal elements in change/confusion matrices

Agreement plots The agreement plots provide a graphical representation for the diagonal and off-diagonal elements in a change/confusion matrix. Large off-diagonal values in the matrix are depicted by the areas around the diagonal. The size, orientation and colour of rectangles indicate the direction of change (gain/loss) in a change matrix, and the existence of possible biases for a classifier in a confusion matrix. These plots are implemented in *vcd* package of R, and they can be the basis to formulate hypothesis tests about the direction of changes and the presence/absence of bias in the previously mentioned matrices.

Marginal homogeneity tests Change/confusion matrices correspond to before/after experiments, so statistical methods for matched-pairs data can be applied. In particular, marginal homogeneity tests are of interest. In these tests, the null hypothesis is the marginal homogeneity, that is, the equality (or lack of significant difference) between the row marginal proportions and the corresponding column proportions, i.e., for a $k \times k$ matrix, it would be

$$H_0 : \pi_{i.} = \pi_{.i}, \quad \text{for} \quad i = 1, \ldots, k-1$$

 ISBN: 978-84-617-8694-7

versus the alternative hypothesis, H_1 : not H_0. In H_0, $\pi_{i.}$ and $\pi_{.i}$ denote the row and the column marginal proportions, respectively.

In the present context, the marginal homogeneity would mean there was no significant change in the change matrix, and there was no significant bias in the confusion matrix. As marginality homogeneity tests, we consider the McNemar test for 2×2 tables, Generalized McNemar / Stuart- Maxwell test and Bhapkar test for $k \times k$ tables, with $k > 2$. The statistical properties of these tests will be studied from a theoretical and computational point of view.

3 Statistical methods based on correspondence analysis

Correspondence analysis (CA) is a multivariate statistical technique designed for visualizing the underlying relationships in a contingency table. There are several ways of defining CA, see for instance Benzécri [2] or Greenacre [4]. We highlight that CA is a least square method of data analysis based on the singular value decomposition (SVD) of certain matrix associated to this technique. For square asymmetric tables, such as those we obtain dealing with spatial data, standard CA usually fails due to the strong effect of the diagonal elements. However, following Greenacre [4], the table can be splitted into symmetric and skew symmetric components. The separate analysis of these parts allows us to gain in interpretability and representation of information. So two separate two-dimensional maps can be obtained which involve one set of points each one. Both maps must be constructed on the same scale in order to show the relative sizes of the variation in each component. In this way, the magnitude of off-diagonal values in change/confusion matrices can be interpreted. The use of these methods is illustrated in change/confusion matrices obtained from real spatial data.

Hermite interpolation by many-knot cubic splines: error analysis

D. Barrera[1]

[1] *Department of Applied Mathematics, University of Granada, 18071-Granada, Spain*

emails: dbarrera@ugr.es

Abstract

The interpolation error is analyzed for three different schemes for Hermite interpolation by many-knot cubic splines. Two of them are local and the third one is global. The first method is of order two, and the two other are of order one. The error estimates are given for C^4 functions.

Key words: Spline functions, B-splines, Hermite interpolation, Bernstein basis
MSC 2000: 41A05, 41A15, 65D07

1 Introduction

Cubic spline interpolation on $\mathbb{R}$ at a strictly increasing sequence $X := (x_i)_{i\in\mathbb{Z}}$ of primary knots can be made more flexible by adding secondary knots, i.e. by using a sequence of knots $T := (t_i)_{i\in\mathbb{Z}}$ containing X.

A very detailed description of different situations in Lagrange interpolation can be found in Dahmen, Goodmand and Micchelli (1988), following a preceding study by Qi (1981), whereas Hermite interpolation is analyzed in Qi and Zhou (1982).

On the other had, a Jackson-type estimate is established for the interpolation error in the completely local Lagrangian scheme in de Villiers (1993).

We analyze the interpolation error associated with three different schemes for Hermite interpolation by cubic splines obtained by adding two knots in each interval $[x_i, x_{i+1}]$ symmetrically distributed around the midpoint. This last restriction is reasonable since the minimization of the uniform error in any scheme designed to recover all functions of a certain smoothness from their values at a fixed finite set of points leads to consider canonical knots of the type indicated above, as shown in Micchelli, Rivlin and Winograd (1976).

The first problem concerns the error analysis of the Hermite interpolation scheme of order two shose data are $(f(x_i), f'(x_i), f''(x_i))_{i\in\mathbb{Z}}$. When the data $f''(x_i)$ are not available, they can be replace by $p''(x_i)$, where p is the cubic polynomial interpolating $f(x_j)$, $j = i-1, j, j+1$, and $f'(x_i)$. The error for the resulting Hermite interpolation scheme of order one is then analyzed. Finally, a third Hermite scheme of order one is proposed and its interpolation error analyzed. The second derivative of the interpolant at the knots is now the solution of a tridiagonal linear system arising from C^3 continuity at x_i.

2 The Hermite interpolation problem of order two

Let $X := (x_i)_{i\in\mathbb{Z}}$ be some arbitrary strictly increasing sequence of real numbers and $Y := (y_{i,j})_{i\in\mathbb{Z},j=1,2}$ be a sequence satisfying the conditions

$$x_i < y_{i,1} < y_{i,2} < x_{i+1},\ i \in \mathbb{Z},$$

where

$$y_{i,1} := x_i + \alpha_i h_i \quad \text{and} \quad y_{i,2} := x_i + (1-\alpha_i) h_i,\ i \in \mathbb{Z},$$

with

$$h_i := x_{i+1} - x_i,\ 0 < \alpha_i < \frac{1}{2}.$$

Define $T := (t_i)_{i\in\mathbb{Z}} = X \cup Y$, where

$$t_{3i} = x_i,\ t_{3i+1} = y_{i,1},\ t_{3i+2} = y_{i,2},\ i \in \mathbb{Z},$$

and consider the space

$$S_4(T) := \left\{ f \in C^2(\mathbb{R}) : f_{|[t_i,t_{i+1}]} \in \mathbb{P}_3 \right\},$$

where $\mathbb{P}_3$ denotes the space of all polynomials of degree at most three.

The Schoenberg-Whitney theorem (see [3]) allows us to state that for any any $i \in \mathbb{Z}$ there exist functions φ_i, ψ_i and χ_i in $S_4(T)$ such that

$$\operatorname{supp}\varphi_i = \operatorname{supp}\psi_i = \operatorname{supp}\chi_i = [x_{i-1}, x_{i+1}]$$

and

$$\begin{aligned}
&\varphi_i(x_j) = \delta_{i,j},\ \varphi_i'(x_j) = 0,\ \varphi_i''(x_j) = 0,\\
&\psi_i'(x_j) = \delta_{i,j},\ \psi_i(x_j) = 0,\ \psi_i''(x_j) = 0,\\
&\chi_i''(x_j) = \delta_{i,j},\ \chi_i(x_j) = 0,\ \chi_i'(x_j) = 0.
\end{aligned}$$

 ISBN: 978-84-617-8694-7

The functions φ_i, ψ_i and χ_i can be expressed in terms of normalized B-splines associated with the knots in T (see [1, 4]) or by means of Bernstein polynomials (see [2]) in each subinterval of their support.

These functions allow us to define an Hermite interpolant. For a C^2 function f, to interpolate $\left(f\left(x_i\right), f'\left(x_i\right), f''\left(x_i\right)\right)_{i\in\mathbb{Z}}$ we define the operator

$$H^{(2)} : C^2\left(\mathbb{R}\right) \longrightarrow S_4\left(T\right)$$

by means of

$$H^{(2)} f := \sum_{i\in\mathbb{Z}} \left(f\left(x_i\right)\varphi_i\left(x\right) + f'\left(x_i\right)\psi_i\left(x\right) + f''\left(x_i\right)\chi_i\left(x\right)\right).$$

This operator is exact on $\mathbb{P}_3$.

The following result holds.

Proposition 1 *For every $i \in \mathbb{Z}$ and any $x \in [x_i, x_{i+1}]$, define, for a function $f \in C^4\left(\mathbb{R}\right)$,*

$$\mathcal{L}f = f\left(x\right) - H^{(2)} f\left(x\right).$$

Then

$$\left|\mathcal{L}f\right| \leq \frac{3 - 15\alpha_i + 16\alpha_i^2 + 48\alpha_i^3 - 96\alpha_i^4 + 32\alpha_i^5}{1152\left(1-\alpha_i\right)} h_i^4 \left\|f^{(4)}\right\|_i,$$

where $\|\cdot\|_i$ denotes the uniform norm in $[x_i, x_{i+1}]$.

3 The Hermite interpolation problem of order one

When the the second derivative is not available at the knots, it is possible to estimate it from the values at some points in a neighbourhood. Let p the cubic polynomial interpolating the data $f\left(x_j\right)$, $j = i-1, j, j+1$, and $f'\left(x_i\right)$. Then $f''\left(x_i\right)$ is estimated from

$$s_i := p''\left(x_i\right) = a_{i-1} f\left(x_{i-1}\right) + b_i f\left(x_i\right) + b_i' f'\left(x_i\right) + c_{i+1} f\left(x_{i+1}\right),$$

where

$$\begin{aligned} a_{i-1} &= \frac{2h_i}{h_{i-1}^2\left(h_{i+1}+h_i\right)}, \\ b_i &= -2\frac{h_{i-1}^3 + h_i^3}{h_{i-1}^2\left(h_{i-1}+h_i\right)h_i^2}, \quad b_i' = 2\frac{h_{i-1}-h_i}{h_{i-1}h_i}, \\ c_{i+1} &= 2\frac{h_{i-1}}{\left(h_{i-1}+h_i\right)h_i^2}. \end{aligned}$$

 ISBN: 978-84-617-8694-7

We define the operator

$$H^{(1)} : C^1(\mathbb{R}) \longrightarrow S_4(T)$$

by means of

$$H^{(1)} f := \sum_{i\in\mathbb{Z}} \left(f(x_i)\,\varphi_i(x) + f'(x_i)\,\psi_i(x) + s_i\chi_i(x) \right).$$

Equivalently,

$$H^{(1)} f = \sum_{i\in\mathbb{Z}} \left(f(x_i)\,\widetilde{\varphi}_i(x) + f'(x_i)\,\widetilde{\psi}_i(x) \right),$$

with

$$\begin{aligned} \widetilde{\varphi}_i &= \varphi_i + c_i\chi_{i-1} + b_i\chi_i + a_i\chi_{i+1}, \\ \widetilde{\psi}_i &= \psi_i + b_i'\chi_i. \end{aligned}$$

We have the following result.

Proposition 2 *Consider $f \in C^4(\mathbb{R})$. For every $i \in Z$ and $x \in [x_i, x_{i+1}]$ the following error estimate holds:*

$$\left| H^{(1)} f(x) - f(x) \right| \le C(\alpha_i)\, h_i^3 \left\| f^{(4)} \right\|_{i-1,3\ j\in\{i-1,i,i+1\}} \max \{h_j\},$$

where

$$\|g\|_{i-1,3} := \max_{x_{i-1}\le x\le x_{i+2}} |g(x)|$$

and

$$C(\alpha_i) := \frac{32\alpha_i^5 - 96\alpha_i^4 + 48\alpha_i^3 - 3\alpha_i + 3}{1152\,(1-\alpha_i)}.$$

4 Another Hermite interpolation scheme of order one

Let $I = [a, b]$ be an interval of $\mathbb{R}$ al let us consider two sets $X_n := (x_i)_{0\le i\le n}$ and $Y_n := (y_{i,j})_{0\le i\le n, j=1,2}$ such that $x_0 = a$, $x_n = b$, and for $0 \le i \le n-1$

$$\begin{aligned} x_i < y_{i,1} < y_{i,2} < x_{i+1}, \\ y_{i,1} = x_i + \alpha_i h_i,\ y_{i,2} = x_i + (1-\alpha_i)\,h_i, \end{aligned}$$

with $h_i := x_{i+1} - x_i$ and $0 < \alpha_i < \frac{1}{2}$.

We define $T_n := X_n \cup Y_n = (t_i)_{0\le i\le 3n}$, where

$$\begin{aligned} t_{3i} &= x_i, \\ t_{3i+1} = y_{i,1}, \quad t_{3i+2} &= y_{i,2}, \quad 0 \le i \le n-1, \\ t_{3n} &= x_n, \end{aligned}$$

 ISBN: 978-84-617-8694-7

and consider the space $S_4(I,T_n)$ of C^2 cubic splines on the partition of I induced by T_n. There exist functions $\varphi_{i,n}$, $\psi_{i,n}$ and $\chi_{i,n}$ in $S_4(I,T_n)$ such that

$$\begin{aligned}\operatorname{supp}\varphi_{0,0}=\operatorname{supp}\psi_{0,0}=\operatorname{supp}\chi_{0,0}&=[x_0,x_1],\\ \operatorname{supp}\varphi_{i,n}=\operatorname{supp}\psi_{i,n}=\operatorname{supp}\chi_{i,n}&=[x_{i-1},x_{i+1}],\ 1\leq i\leq n-1,\\ \operatorname{supp}\varphi_{n,n}=\operatorname{supp}\psi_{n,n}=\operatorname{supp}\chi_{n,n}&=[x_{n-1},x_n],\end{aligned}$$

and

$$\begin{aligned}\varphi_{i,n}(x_j)&=\delta_{i,j}, \quad \varphi'_{i,n}(x_j)=\varphi''_{i,n}(x_j)=0,\\ \psi'_{i,n}(x_j)&=\delta_{i,j}, \quad \psi_{i,n}(x_j)=\psi''_{i,n}(x_j)=0,\\ \chi''_{i,n}(x_j)&=\delta_{i,j}, \quad \chi_{i,n}(x_j)=\chi'_{i,n}(x_j)=0\end{aligned}$$

for $0\leq j\leq n$.

Proposition 3 *We define the operator*

$$H_n^{(2)}:C^2(I)\longrightarrow S_4(I,T_n)$$

by means of

$$H_n^{(2)}f=\sum_{i=0}^{n}\left(f(x_i)\,\varphi_{i,n}(x)+f'(x_i)\,\psi_{i,n}(x)+f''(x_i)\,\chi_{i,n}(x)\right).$$

For each $\lambda=(\lambda_0,\lambda_1,\ldots,\lambda_n)$, define the operator

$$S_{n,\lambda}:C^1(I)\longrightarrow S_4(I,T_n)$$

as follows:

$$S_{n,\lambda}f=\sum_{i=0}^{n}f(x_i)\,\varphi_{i,n}(x)+f'(x_i)\,\psi_{i,n}(x)+\lambda_i\chi_{i,n}(x).$$

Proposition 4 *Consider $f\in C^2(I)$ and define $\lambda_0=f''(x_0)$ and $\lambda_n=f''(x_n)$. Then there exist unique values λ_i, $1\leq i\leq n-1$, such that for $\lambda=(\lambda_0,\lambda_1,\ldots,\lambda_n)$ the function $S_{n,\lambda}f$ is of class C^3 at the knots x_i, $1\leq i\leq n-1$.*

The following result holds.

Proposition 5 *Consider $f\in C^4(I)$. Then, for each $0\leq i\leq n-1$ and $x\in[x_i,x_{i+1}]$ the following inequality is satisfied:*

$$|S_{n,\lambda}f(x)-f(x)|\leq\frac{h_i^2}{1152\,(1-\alpha_i)}D^{(1)}_{\underline{\alpha},\underline{h}}\left\|f^{(4)}\right\|_{\infty,I},$$

 ISBN: 978-84-617-8694-7

where

$$D^{(1)}_{\underline{\alpha},\underline{h}} := 4\alpha_i\,(3-4\alpha_i)\,D^{(2)}_{\underline{\alpha},\underline{h}} + p\,(\alpha_i)\,h_i^2,$$

with

$$\begin{aligned}\underline{\alpha} &:= (\alpha_0,\alpha_1,\ldots,\alpha_{n-1})\,,\\ \underline{h} &:= (h_0,h_1,\ldots,h_{n-1})\,,\\ p\,(\alpha_i) &:= 3-15\alpha_i+16\alpha_i^2+48\alpha_i^3-96\alpha_i^4+32\alpha_i^5\end{aligned}$$

and

$$D^{(2)}_{\underline{\alpha},\underline{h}} := \min_{1\le j\le n-2}\left\{h_j\alpha_j\,(1-\alpha_j)\right\}\max_{0\le j\le j\le n-1}\left\{\frac{1-6\alpha_j+18\alpha_j^2-16\alpha_j^3}{\alpha_j\,(1-\alpha_j)}h_j\right\}.$$

Abstract

In this paper, we use the Nyström method and a quadrature formula based on non-uniform quasi-intepolation for solving nonlinear Fredholm integral equations of the second kind. This method results in a system of nonlinear equations for determining approximate values of the true solution of the integral equations. Numerical examples illustrate the performance of the method.

Key words: Quasi-interpolation, Nonlinear Fredholm integral equations of the second kind, Nyström method Quadrature formula

1 Introduction

We consider the nonlinear Fredholm integral equation

$$u(x) - \int_a^b k(x,t)\, g(u(t))\, dt = f(x), \ x \in I := [a,b], \tag{1}$$

where f is a known continuous function defined on I, and g is a nonlinear function defined on I. The nonlinear integral operator $\mathcal{K}$ is defined as

$$\mathcal{K}u(x) := \int_a^b k(x,t)\, g(u(t))\, dt, \ x \in I.$$

For a continuous kernel, $\mathcal{K}$ is a compact operator on $C(I)$ into $C(I)$.

 ISBN: 978-84-617-8694-7

Many different methods are presented in the literature to solve (1) (see, [4, 5, 6, 7] and references therein). In this work, we construct a quadrature formula based on quadratic spline quasi-interpolation on non-uniform partition, then we approximate the integral operator with this formula, i.e.

$$\mathcal{K}u\left(x\right) \approx \sum_{j} \omega_j k\left(x, \theta_j\right) g\left(u\left(\theta_j\right)\right).$$

where ω_j and θ_j denote the weights and the knots of the formula, respectively. Then we obtain the approximate solution by using the Nyström method.

2 Quadratic spline quasi-interpolation on non-uniform partition

Let $P := \{a = x_0 < x_1 < \cdots < x_{N-1} < x_N = b\}$ be a non-uniform partition of $I = [a, b]$ into N sub-intervals $I_i := [x_{i-1}, x_i]$ of length $h_i := x_i - x_{i-1},\ 1 \leq i \leq N$. The space $S_3(P)$ of splines of order 3 on P admits a basis composed by $N+1$ B-splines $\{B_j,\ 0 \leq j \leq N+1\}$ constructed from an extended partition associated with P. We choose the extended partition with multiple knots at the endpoints, i.e. $x_{-2} = x_{-1} = x_0 = a$ and $x_{N+2} = x_{N+1} = x_N = b$. Then, the support of B_j is the interval $[x_{j-2}, x_{j+1}]$ (see [1]).

We consider the quadratic spline quasi-interpolant to a function f given by

$$\mathcal{Q}f := \sum_{j=0}^{N+1} \mu_j(f) B_j,$$

where the functional coefficients $\mu_j(f)$ are specific linear combinations of the values of f on the set $\Theta := \{\theta_i,\ 0 \leq j \leq (N+1)\}$, where $\theta_0 := a$, $\theta_j := \frac{1}{2}\left(x_{j-1} + x_j\right),\ 1 \leq j \leq N$, and $\theta_{N+1} := b$.

More precisely,

$$\mu_0(f) = f_0,\ \mu_{N+1}(f) = f_{N+1}$$

$$\mu_j(f) = \alpha_j f_{j-1} + \beta_j f_j + \gamma_j f_{j+1},\ 1 \leq j \leq N,$$

where $f_j := f(\theta_j)$, $0 \leq j \leq N+1$,

$$\alpha_j = -\frac{\tau_j^2 \tau'_{j+1}}{\tau_j + \tau'_{j+1}},\ \beta_j = 1 + \tau_j \tau'_{j+1},\ \gamma_j = -\frac{(\tau'_{j+1})^2 \tau_j}{\tau_j + \tau'_{j+1}}$$

and

$$\tau_j = \frac{h_j}{h_{j-1} + h_j},\ \tau'_j = \frac{h_{j-1}}{h_{j-1} + h_j}.$$

 ISBN: 978-84-617-8694-7

We can write the spline quasi-interpolant Q under the following quasi-Lagrange form (see [3])

$$\mathcal{Q}f = \sum_{j=0}^{N+1} f(\theta_j) L_j,$$

with

$$\begin{aligned} L_0 &:= B_0 + \alpha_1 B_1,\ L_1 := \beta_1 B_1 + \alpha_2 B_2, \\ L_j &:= \gamma_{j-1} B_{j-1} + \beta_j B_j + \alpha_{j+1} B_{j+1},\ 2 \le j \le N-1, \\ L_N &:= \gamma_{N-1} B_{N-1} + \beta_N B_N,\ L_{N+1} := \alpha_N B_N + B_{N+1} \end{aligned}$$

Theorem 1 *[3] For f bounded on I and for any partition P of I, the infinity norm of the quadratic quasi-interpolant $\mathcal{Q}_P$ is uniformly bounded by* 2.5.

As a consequence of Theorem 1, the exactness of $\mathcal{Q}_P$ on the space $\mathbb{P}_2$ of quadratic polynomials and a classical result on approximation [1], the following result holds:

Theorem 2 *There exists a constant C independent of h. such that for all $f \in C^3(I)$ and for all partition P of I, with $h := \max h_i$,*

$$\|f - \mathcal{Q}_P f\|_\infty \le C h^3 \left\| f^{(3)} \right\|_\infty .$$

3 Quadrature formula

For any continuous function f, the quadrature formula associated with the quadratic spline quasi-interpolant on a non-uniform partition is obtained by integrating $\mathcal{Q}f$ in the above quasi-Lagrange form:

$$\mathcal{I}_{\mathcal{Q}}(f) = \int_a^b \mathcal{Q}f(t)\, dt = \sum_{j=0}^{N+1} \omega_j f(\theta_j),$$

where $\omega_j := \int_a^b L_j(t)\, dt$.
Explicitly, the weights ω_j are

$$\begin{aligned} \omega_0 &:= \vartheta_0 + \alpha_1 \vartheta_1,\ \omega_1 := \beta_1 \vartheta_1 + \alpha_2 \vartheta_2, \\ \omega_j &:= \gamma_{j-1} \vartheta_{j-1} + \beta_j \vartheta_j + \alpha_{j+1} \vartheta_{j+1},\ 2 \le j \le N-1, \\ \omega_N &:= \gamma_{N-1} \vartheta_{N-1} + \beta_N \vartheta_N,\ \omega_{N+1} := \alpha_N \vartheta_N + \vartheta_{N+1}, \end{aligned}$$

where

$$\vartheta_0 := \frac{1}{3} h_1,\ \vartheta_1 := \frac{1}{3}(h_1 + h_2),\ \vartheta_N := \frac{1}{3}(h_{N-1} + h_N),\ \vartheta_{N+1} := \frac{1}{3} h_N$$
$$\vartheta_j := \frac{1}{3}(h_{j-1} + h_j + h_{j+1}),\ 2 \le j \le N-1.$$

 ISBN: 978-84-617-8694-7

Theorem 3 *Let assume that the points of evaluation* $\Theta := \{\theta_i,\ 0 \leq j \leq (N+1)\}$ *are symmetric with respect to the midpoint of* I*. Then for* $f \in C^4(I)$*, we have*

$$\int_a^b f(t)\,dt - \mathcal{I}_{\mathcal{Q}}(f) = \mathcal{O}\left(h^4\right).$$

4 Nyström method

For $g \in C(I)$, we set

$$\mathcal{K}u(x) \approx \mathcal{K}_N u(x) = \sum_{j=0}^{N+1} \omega_j k(x,\theta_j)\, g(u(\theta_j)).$$

Thus, we approximate the integral equation (1) by

$$u_N(x) - \sum_{j=0}^{N+1} \omega_j k(x,\theta_j)\, g(u_N(\theta_j)) = f(x),\ x \in I. \tag{2}$$

This is equivalent to first solve the system of nonlinear equations

$$u_N(\theta_i) - \sum_{j=0}^{N+1} \omega_j k(\theta_i,\theta_j)\, g(u_N(\theta_j)) = f(\theta_i),\ 0 \leq i \leq N+1$$

where the unknows are $\{u_N(\theta_i),\ 0 \leq i \leq N+1\}$. Then, after using the Nyström method formula and solving the nonlinear system, we obtain the following approximate solution

$$u_N(x) = f(x) + \sum_{j=0}^{N+1} \omega_j k(x,\theta_j)\, g(u_N(\theta_j)),\ x \in I$$

Theorem 4 *Assume* $k \in C^{0,4}\left(I^2\right)$ *and* $g \in C^4(I)$*. Let* u *be the solution of the integral equation (1) and* u_N *be the solution of the approximate integral equation (2). Then, it holds*

$$\|u - u_N\| = \mathcal{O}\left(h^4\right).$$

5 Numerical results and comparisons

In this section, five examples are given to illustrate the results established in the previous sections

$$u_i(x) - \int_0^1 k_i(x,t)\, g_i(u_i(t))\,dt = f_i(x),\ x \in [0,1].$$

Abstract

Resistive RAMs (RRAMs) are the most promising devices for near future in terms of non-volatile applications. The devices present amazing features that make both Academia and Industry deep in the research of these devices. Among the characteristics, we can list the very good endurance, short writing and reading times in comparison to current Flash technology, low voltage operation, CMOS compatibility, etc. This new technology needs advances in all the fronts that need to be addressed prior to industrialization. One of them is connected with compact modeling, i.e, the development of analytical expressions to account for the most important physical effects that are needed to calculate the current, capacitance, transient response, etc. The models are essential for circuit simulation and design. The device models should be accurate and this issue is achieved by implementing the correct physics in a flexible and robust mathematical architecture. We will focus on this latter problem in this work. In particular, we will deal with a good numerical approximation of experimental data based on B-splines construction to perform the integrals of the current and voltage as function of time. We do so to transform the usual modeling domain, consisting of a current-voltage representation, to a charge-flux domain; i.e., the time integral of the current and voltage measured variables. In this new domain an interesting modeling approach can be developed. In particular, once the new representation is obtained, we have introduced a new method to obtain the reset voltage of RRAMs.

The new numerical procedure we have implemented allows a correct integration and help with the treatment of the usual measurement noise that is found in these kind of devices, since their operation is based on the stochastic processes that form and

rupture internal conductive filaments. The main features of the mathematical technique we propose along with a practical example built upon real experimental data will be explained.

1 Introduction

Since the breakthrough that represented the announcement of HP [14] of having successfully implemented the first memristor, these elements have drawn a great deal of interest both in the Academia and in the Industry. Particularly, among the great variety of devices that work as memristors, those based on resistive switching (RS) mechanisms, usually known as Resistive RAMs (RRAMs), can store information without the need of a power source when they are switched off. These RRAMs present interesting features concerning their capability for low power applications, switching speed, endurance, etc., [17, 14]. Thus, RRAMs are a promising emerging new technology for non-volatile memories [9].

Many papers devoted to the fabrication and characterization of RRAMs are being published nowadays [17, 9]; in addition, modeling and simulation tools are being developed to analyze the physics of these devices [15, 7, 3, 6]. The availability of compact models to simulate circuits based on these new devices is essential for the development of this type of technology [9]. Several models have been presented to describe these devices, although new models accounting for the main characteristics of RRAMs are needed because of the variety of physical mechanisms that been detected in these devices [9, 8].

The important issue connected to the intrinsic variability in RRAMs is essential. The cycle to cycle variability is mainly due to the random processes that lead to the formation and destruction of the conductive filaments. In fact, it is so unpredictable that it has even been used to implement random number generators. As an example of this variability, see below, where a set of experimentally measured reset transitions are shown [5]. We would like to highlight that all these curves correspond to different RS cycles of the same device, so the big spread from cycle to cycle is apparent.

The modeling of RRAM can be performed in different domains; i.e., in a I-V domain or in a charge (Q) and flux (ϕ), which in some cases can be simpler as reported by L. Chua [2] and others [13] in the past. This Q-flux domain can be an advantage for modeling since the typical parameters that characterize a technology could be more easily calculated.

The flux ϕ can be calculated as the time integral of the voltage while the charge Q is obtained as the current time integral [2]. Notice that a more formally accurate name for these magnitudes would be voltage momentum and current momentum, as explained in [2]. However for simplicity we will keep the names flux and charge:

 ISBN: 978-84-617-8694-7

$$\phi(t) = \int_{t_0}^{t} V(\tau)\, d\tau \qquad \text{and} \qquad Q(t) = \int_{t_0}^{t} I(\tau)\, d\tau.$$

The calculation of these magnitudes and the determination of parameters such as reset voltage and set voltage need of an accurate representation of the experimental measurements at the mathematical level. We do so in this work, were advanced numerical techniques based on B-Splines are employed to build an approximant that allow the accurate calculation of the integrals to determine the charge and flux previously reported.

In order to apply the new numerical technique to real devices and experimental measurements we have employed structures fabricated at the Institut of Microelectronics of Barcelona IMB-CNM (CSIC), they are based on a Ni/HfO_2/$Si - n^+$ stack (see figure below). The ALD fabricated dielectric layer was 20nm thick; further details of the fabrication process and measurement setup can be found in [5]. The conduction is filamentary in these devices, i.e., it takes place trough conductive filaments (CFs) that are formed and destroyed within the RS device operation [5, 16].

A few experimental current-voltage curves corresponding to several RS (set-reset) cycles are shown below (left). Reset curves for devices based on a Ni/HfO_2/$Si - n^+$ stack are shown in red while set curves are plotted in blue. The curves correspond to different cycles from a set-reset series of almost three thousands cycles. Although the Ni electrode had a negative voltage applied while the substrate was grounded [5], we have considered absolute values for the applied voltage for the sake of simplicity.The V_{Reset} and V_{Set} points are highlighted. The curves are different in all the cases due to the stochastic nature of the processes behind the conductive filament formation that fix the device resistance, i.e., the ratio between the device voltage and the corresponding current [9, 5]. Also the physical estructure of the devices fabricated is shown [5].

2 Mathematical background

Spline quasi-interpolation is an easy method to define approximants to a given function f defined on a interval $I := [a, b]$. The class of the quasi-interpolant can be fixed in advance by using the appropriate spline space. Here we use C^1 quadratic quasi-interpolation from the values of f at the points in $X := \{x_0, x_1, \ldots, x_n\}$.

Let us suppose that $a = x_0 < x_1 < \cdots < x_n = b$. Let $\mathcal{S}_2(X)$ be the space of C^1 quadratic splines on this partition. It is a $n + 2$-dimensional linear space. To compute a good basis $\mathcal{B}_2(X) := \{B_j, 1 \leq j \leq n + 2\}$ for $\mathcal{S}_2(X)$ some auxiliary knots $x_{-2} \leq x_{-1} \leq a$ and $b \leq x_{n+1} \leq x_{n+2}$ are needed. We choose $x_{-2} = x_{-1} = a$ and $x_{n+1} = x_{n+2} = b$. From the extended partition $X_* := \{x_{-2}, x_{-1}, x_0, x_1, \ldots, x_n, x_{n+1}, x_{n+2}\}$, the B-splines B_j can be defined in terms of divided differences as follows:

$$B_j(x) := (x_j - x_{j-3})\,[x_{j-3}, x_{j-2}, x_{j-1}, x_j]\,(\cdot - x)_+^2,$$

where $(\cdot)_+^2$ stands for the quadratic truncated power. The B-spline B_j is supported on the interval $[x_{j-3}, x_j]$ and positive on (x_{j-3}, x_j). It holds (see [12, Theorem 4.21 and Remark 4.1]) that

$$\sum_{j=1}^{n+2} B_j(x) = 1,\ \sum_{j=1}^{n+2} \theta_j^{(1)} B_j(x) = x,\ \ \sum_{j=1}^{n+2} \theta_j^{(2)} B_j(x) = x^2,\ x \in I,$$

where

$$\theta_j^{(1)} := \theta_j := \frac{1}{2}(x_{j-2} + x_{j-1}) \quad \text{and} \quad \theta_j^{(2)} := x_{j-2}x_{j-1}.$$

Taking into account the main goal of this contribution, among all the possibilities at our disposal we associate with f the quasi-interpolant $Q_2 f \in S_2(X)$ defined as

$$Q_2 f := \sum_{j=1}^{n+2} \mu_j(f)\, B_j,$$

where every coefficient $\mu_j(f)$ is a linear combination of values of f at some points lying in a neighbourhood of the support of B_j. More precisely, we impose the following structure for $\mu_j(f)$:

$$\begin{aligned}
\mu_1(f) &:= \alpha_1 f(x_0) + \beta_1 f(x_1) + \gamma_1 f(x_2),\\
\mu_j(f) &:= \alpha_j f(x_{j-2}) + \beta_j f(x_{j-1}) + \gamma_j f(x_j),\ 2 \leq j \leq n+1,\\
\mu_{n+2}(f) &:= \alpha_{n+2} f(x_{n-2}) + \beta_{n+2} f(x_{n-1}) + \gamma_{n+2} f(x_n).
\end{aligned}$$

It can be proved that there are unique coefficients α_j, β_j and γ_j such that the the associated quasi-interpolation operator Q_2 is exact on $\mathbb{P}_2$, i.e. such that $Q_2 p = p$ for all quadratic

 ISBN: 978-84-617-8694-7

polynomial p (see [1]). Since Q is a uniformly bounded operator (see [10, 11]) and exact on $\mathbb{P}_2$, there exists a constant C independent of f and X such that

$$\|f - Q_2 f\|_{\infty,I} \leq Ch^3,$$

where $h := \max_{1\leq i\leq n} h_i$ and $h_i := x_i - x_{i-1}$.

3 Algorithm

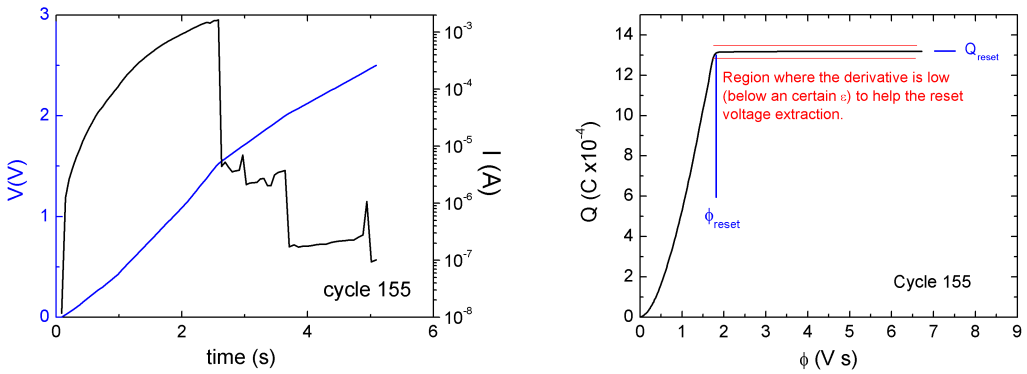
Once we know how to construct a spline quasi-interpolant to a given function, we have to determine approximations to the voltage V and the current I from experimental measurements V_i and I_i made at times x_i.To do so,

1. Define in the space $S_2(X)$ with knots x_i the C^1 quadratic quasi-interpolants V_{app} and I_{app} of V and I, respectively.
2. Define approximations ϕ_{app} and Q_{app} of ϕ and Q, respectively, as follows:
$$\phi_{app}(t) = \int_{x_0}^{t} V_{app}(\tau)\, d\tau \qquad \text{and} \qquad Q_{app}(t) = \int_{x_0}^{t} I_{app}(\tau)\, d\tau.$$
3. Consider a uniform partition of the interval $[x_0, x_n]$ and compute the numerical derivative of Q_{app} with respect to ϕ_{app} at the resulting points, $\overline{x}_i$.
4. Let $J_\epsilon := \min\left\{j : \left|\frac{dQ_{app}}{d\phi_{app}}(\overline{x}_j)\right| < \epsilon\right\}$ for a given threshold ϵ.
5. Let the reset charge Q_{rst} be equal to $Q_{app}(\overline{x}_{J_\epsilon})$.
6. Fit a model $Q = Q(\phi)$ to data $Q_{app}(\overline{x}_i)$, $i = 0, \ldots, k$, for a enough large k.
7. Let the estimated reset flux be the solution of the equation $Q(\phi_{rst}) = Q_{rst}$.

4 An example

The proposed method has been applied to real measurements in order to calculate the charge versus flux relationship. The original data measured are shown in figure bottom left (curve 155 was selected among a long series of resistive switching cycles). The corresponding charge-flux representation employed to estimate the reset flux and finally the reset voltage has been determined using quadratic quasi-interpolation from the values at the knots of V and I.

 ISBN: 978-84-617-8694-7



It shows voltage applied to the device and current versus measurement time (left) and the charge versus flux calculated making use of the data plotted. Some of the parameters employed in the proposed algorithm are plotted for the sake of clarity.

Notice that the region with low derivative (below a certain threshold that can be fitted, corresponding to step 5 in our algorithm) is shown to be contained among the red lines. Once this region is isolated, the reset charge can be estimated, as suggested in the algorithm (Q_{reset}, step 5). Once the determination of Q_{reset} is done, the ϕ_{reset} is obtained as the value needed for the final reset voltage determination. The application of the algorithm to the current curve under study led us to obtain an estimated reset flux equal to 1.72 and an estimated reset voltage of 1.52 V.

Abstract

In most (if not all) textbooks on complex calculus the differentiation and integration of complex functions are presented by employing the algebraic form of complex variables because the respective formulae in terms of polar form are inappropriate. In this paper we demonstrate that by transferring the field structure of the system of complex numbers to the Riemann surface of complex logarithm and changing the sense of derivative and integral, complex calculus can be delivered in terms of polar form of complex variable identically to the presentation in terms of algebraic form.

Key words: complex calculus, complex logarithm, complex exponent, complex differentiation, complex integration, bigeometric calculus
MSC 2000: Primary: 30E20; Secondary: 30E99

1 Introduction

Complex analysis is a continuation of real analysis to complex variables, nicely explicating many eccentric results of the real case. In most (if not all) textbooks on complex calculus [6, 9] the differentiation and integration of complex functions are presented by employing the algebraic form of complex variables. The polar form is used only in a few situations when the capacity of the algebraic form is insufficient.

We investigate the presentation of complex calculus essentially on the basis of the polar form of complex variables and demonstrate that if the field structure of $\mathbb{C}$ is transferred to the Riemann surface of the complex logarithm, which will be denoted by $\mathbb{B}$, and the sense of the complex differentiation and integration is changed to bigeometric, then the polar presentation of complex calculus over $\mathbb{B}$ is identical to its algebraic presentation over $\mathbb{C}$.

2 Elements of bigeometric real calculus

In the 60th decade Michael Grossman and Robert Katz [7] gave an underlying idea for creating different presentations of Newtonian calculus. Bigeometric calculus is one of them. Briefly, on the basis of the exponential function e^x and its inverse the field structure of the real number system $\mathbb{R}$ can be transferred to the interval $(0,\infty)$ by setting exp-operations

(i) $a \oplus_{\exp} b = e^{\ln a + \ln b} = ab$,

(ii) $a \otimes_{\exp} b = e^{\ln a \ln b} = a^{\ln b} = b^{\ln a}$,

(iii) $a \ominus_{\exp} b = e^{\ln a - \ln b} = a/b$,

(iv) $a \oslash_{\exp} b = e^{\ln a / \ln b} = a^{1/\ln b}$.

The neutral elements of exp-addition and exp-multiplication are 1 and e, respectively.

The exp-operations create exp-derivative and exp-integral. Both of them can be expressed in terms of the derivative and integral of Newtonian calculus. An informal derivation of these expressions are as follows:

$$\begin{aligned}(f(y) \ominus_{\exp} f(x)) \oslash_{\exp} (y \ominus_{\exp} x) &= (f(y)/f(x))^{\frac{1}{\ln(y/x)}} \\ &= (f(y)/f(x))^{\frac{1}{y-x}\cdot\frac{y-x}{\ln y-\ln x}} \\ &= \left(e^{\frac{\ln f(y)-\ln f(x)}{y-x}}\right)^{\frac{y-x}{\ln y-\ln x}} \\ &\to e^{\frac{(\ln f(x))'}{(\ln x)'}} = e^{x(\ln f(x))'}\end{aligned}$$

and

$$\begin{aligned}\bigoplus_{i=1}^{n}{}_{\exp} f(c_i) \otimes_{\exp} (x_i \ominus_{\exp} x_{i-1}) &= \prod_{i=1}^{n} f(c_i)^{\ln(x_i/x_{i-1})} \\ &= e^{\sum_{i=1}^{n} \ln f(c_i)(x_i-x_{i-1})\cdot\frac{\ln x_i-\ln x_{i-1}}{x_i-x_{i-1}}} \\ &\to e^{\int_a^b \ln f(x)(\ln x)'dx} = e^{\int_a^b \frac{\ln f(x)}{x}dx}.\end{aligned}$$

These formulae gave rise to two pairs of exp-derivative and exp-integral. Bigeometric derivative and integral or, briefly, $^{\pi}$derivative and $^{\pi}$integral are defined by

$$f^{\pi}(x) = e^{x(\ln f(x))'} \quad \text{and} \quad \int_a^b f(x)^{\mathbf{d}x} = e^{\int_a^b \frac{\ln f(x)}{x}dx}.$$

They are initiated by Grossman [8]. It is seen that if they are applied repeatedly, then the factors x and $1/x$ eliminate each other making $^{\pi}$form the fundamental theorem of calculus.

 ISBN: 978-84-617-8694-7

Deleting these factors simplifies the formulae for $^{\pi}$derivative and $^{\pi}$integral. Consequently, multiplicative derivative and integral or, briefly, *derivative and *integral, which are widely investigated in [1, 2], are defined by

$$f^*(x) = e^{(\ln f(x))'} \quad \text{and} \quad \int_a^b f(x)^{dx} = e^{\int_a^b \ln f(x)\, dx}.$$

Bigeometric calculus or, briefly, $^{\pi}$calculus is based on the $^{\pi}$derivative and $^{\pi}$integral.

3 The field $\mathbb{B}$

Previously, complex calculus was investigated by use of *operations in [3, 4, 5] over the field $\mathbb{C}$ of complex numbers. Deficiencies of the obtained results can be removed if we transfer the field structure of $\mathbb{C}$ to the Riemann surface of complex logarithm and use $^{\pi}$operations.

The Reimann surface of the complex logarithm can be defined in the algebraic form as

$$\mathbb{B} = \{(r, \theta) : r > 0,\ -\infty < \theta < \infty\}.$$

The subset

$$\mathbb{B}_\alpha = \{(r, \theta) : r > 0,\ \alpha - \pi < \theta < \alpha + \pi\}$$

of $\mathbb{B}$ will be called an α-branch of $\mathbb{B}$. We will identify $\mathbb{B}_0$ and $\mathbb{C} \setminus \{0\}$ by

$$\mathbb{B}_0 \ni (r, \theta) = re^{i\theta} \in \mathbb{C} \setminus \{0\},$$

where θ is the principal argument of $z = re^{i\theta} \in \mathbb{C}$. Therefore, $\mathbb{C} \setminus \{0\} \subset \mathbb{B}$. Similarly, $\mathbb{R} \setminus \{0\} \subset \mathbb{B}$ with $x = (x, 0)$ if $x > 0$ and $x = (-x, -\pi)$ if $x < 0$, where $\mathbb{R}$ is the system of real numbers.

We will denote the elements of $\mathbb{B}$ by boldface letters like $\mathbf{z}$. The boldface letters like $\mathbf{f}$ will be used for functions with domain or range essentially in $\mathbb{B}$ as well. The symbols like f will be used for functions with domain and range in $\mathbb{C}$. We will refer to an element from $\mathbb{R}$ as r-number, from $\mathbb{C}$ as c-number, and from $\mathbb{B}$ as b-number for brevity.

The addition and subtraction of c-numbers lose the sense for b-numbers whereas the multiplication and division operations can be modified to $\mathbb{B}$ as follows

$$\mathbf{z}_1\mathbf{z}_2 = (r_1, \theta_1)(r_2, \theta_2) = (r_1 r_2, \theta_1 + \theta_2)$$

and

$$\mathbf{z}_1/\mathbf{z}_2 = (r_1, \theta_1)/(r_2, \theta_2) = (r_1/r_2, \theta_1 - \theta_2),$$

assuming that $\mathbf{z}_1 = (r_1, \theta_1)$ and $\mathbf{z}_2 = (r_2, \theta_2)$. In fact, these are **exp**-addition and **exp**-subtraction on $\mathbb{B}$ if we introduce **exp**- and **log**-functions as follows.

 ISBN: 978-84-617-8694-7

Proposition 1. *The function*

$$\mathbf{E}^z = (e^x, y),\ z = x + iy \in \mathbb{C}, \tag{1}$$

where e^x is a natural exponent of the r-number x, is a bijection from $\mathbb{C}$ onto $\mathbb{B}$. Its inverse is a function from $\mathbb{B}$ to $\mathbb{C}$ defined by

$$\mathbf{Log}\,\mathbf{z} = \ln r + i\theta,\ \mathbf{z} = (r, \theta) \in \mathbb{B}, \tag{2}$$

where $\ln r$ is the natural logarithm of the r-number r. Moreover,

(a) For $\mathbf{z}_1, \mathbf{z}_2 \in \mathbb{B}$, $\mathbf{Log}\,(\mathbf{z}_1\mathbf{z}_2) = \mathbf{Log}\,\mathbf{z}_1 + \mathbf{Log}\,\mathbf{z}_2$.

(b) For $\mathbf{z}_1, \mathbf{z}_2 \in \mathbb{B}$, $\mathbf{Log}\,(\mathbf{z}_1/\mathbf{z}_2) = \mathbf{Log}\,\mathbf{z}_1 - \mathbf{Log}\,\mathbf{z}_2$.

(c) For $z_1, z_2 \in \mathbb{C}$, $\mathbf{E}^{z_1+z_2} = \mathbf{E}^{z_1}\mathbf{E}^{z_2}$.

(d) For $z_1, z_2 \in \mathbb{C}$, $\mathbf{E}^{z_1-z_2} = \mathbf{E}^{z_1}/\mathbf{E}^{z_2}$.

The proof of this proposition is elementary. Note that our motivation to use the symbols $\mathbf{E}^z$ and $\mathbf{Log}\,\mathbf{z}$ in (1) and (2) is as follows. If

$$\bar{\mathbb{B}} = \{(r, \theta) : r \geq 0,\ -\infty < \theta < \infty\},$$

then the periodic extension of $\mathbf{E}^z$ to $\bar{\mathbb{B}}$ has the form

$$\mathbf{e}^{\mathbf{z}} = \mathbf{e}^{(r,\theta)} = (e^{r\cos\theta}, r\sin\theta),\ \mathbf{z} = (r, \theta) \in \bar{\mathbb{B}}.$$

Since the range of $\mathbf{e}^{\mathbf{z}}$ equals to $\mathbb{B}$, the inverse of $\mathbf{e}^{\mathbf{z}}$ is the multivalued function

$$\mathbf{log}\,\mathbf{z} = \left(\sqrt{\ln^2 r + \theta^2}, \mathrm{atan2}\,(\theta, \ln r) + 2\pi n\right),\ n = 0, \pm 1, \ldots,\ \mathbf{z} = (r, \theta) \in \mathbb{B},$$

where $\mathrm{atan2}\,(y, x)$ is the arctan-function of two variables. Therefore, $\mathbf{Log}\,\mathbf{z}$ becomes the principal branch of $\mathbf{log}\,\mathbf{z}$ for $n = 0$. This is very similar to the exponential and logarithmic functions of complex calculus.

By Proposition 1, $\mathbf{z}_1 \oplus_{\mathbf{exp}} \mathbf{z}_2 = \mathbf{e}^{\mathbf{Log}\,\mathbf{z}_1 + \mathbf{Log}\,\mathbf{z}_2} = \mathbf{z}_1\mathbf{z}_2$ and $\mathbf{z}_1 \ominus_{\mathbf{exp}} \mathbf{z}_2 = \mathbf{E}^{\mathbf{Log}\,\mathbf{z}_1 - \mathbf{Log}\,\mathbf{z}_2} = \mathbf{z}_1/\mathbf{z}_2$ which are defined previously. Thus the product and ratio of $\mathbf{z}_1$ and $\mathbf{z}_2$, defined previously, are indeed **exp**-additon and **exp**-subtraction on $\mathbb{B}$, respectively. This motivates to define **exp**-multiplication and **exp**-division on $\mathbb{B}$ by

$$\mathbf{z}_1 \otimes_{\mathbf{exp}} \mathbf{z}_2 = \mathbf{E}^{\mathbf{Log}\,\mathbf{z}_1 \mathbf{Log}\,\mathbf{z}_2} = (e^{\ln r_1 \ln r_2 - \theta_1\theta_2}, \theta_2 \ln r_1 + \theta_1 \ln r_2)$$

and

$$\mathbf{z}_1 \oslash_{\mathbf{exp}} \mathbf{z}_2 = \mathbf{E}^{\mathbf{Log}\,\mathbf{z}_1 / \mathbf{Log}\,\mathbf{z}_2} = \left(e^{\frac{\ln r_1 \ln r_2 + \theta_1\theta_2}{\ln^2 r_2 + \theta_2^2}}, \frac{\theta_1 \ln r_2 - \theta_2 \ln r_1}{\ln^2 r_2 + \theta_2^2}\right),$$

assuming that $\mathbf{z}_1 = (r_1, \theta_1)$ and $\mathbf{z}_2 = (r_2, \theta_2)$. These operations make $\mathbb{B}$ a field with the neutral elements of **exp**-additon and **exp**-multiplication to be $\mathbf{0} = (1, 0)$ and $\mathbf{1} = (e, 0)$, respectively. For breviety, the subscript in the symbols of these operations will be dropped. For example, instead of $\oplus_{\mathbf{exp}}$ we will write $\oplus$.

 ISBN: 978-84-617-8694-7

4 Elementary functions on $\mathbb{B}$

Complex functions have analogs in complex $^{\pi}$calculus. The $^{\pi}$analog of a complex function f will be denoted by $\mathbf{f}$.

The $^{\pi}$analogs of e^z and $\log z$ are the periodic $\mathbf{e^z}$ and multivalued $\mathbf{\log z}$. One can verify the equality

$$\mathbf{E}^z = \mathbf{E}^{e^{\mathbf{Log\, z}}} \quad \text{for} \quad \mathbf{z} = z \in \mathbb{B}_0 \subset \mathbb{B}.$$

This motivates to define the $^{\pi}$analog of a single-valued complex function f by $\mathbf{f}(\mathbf{z}) = \mathbf{E}^{f(\mathbf{Log\, z})}$, $\mathbf{z} \in B \subseteq \mathbb{B}$. In such a way, it can be derived the analogs of the complex trigonometric and hyperbolic functions in the form

$$\begin{aligned}
\mathbf{cos\, z} &= (e^{\cosh\theta \cos\ln r}, -\sinh\theta \sin\ln r),\\
\mathbf{sin\, z} &= (e^{\cosh\theta \sin\ln r}, \sinh\theta \cos\ln r),\\
\mathbf{cosh\, z} &= (e^{\cos\theta \cosh\ln r}, \sin\theta \sin\ln r),\\
\mathbf{sinh\, z} &= (e^{\cos\theta \sinh\ln r}, \sin\theta \cosh\ln r).
\end{aligned}$$

Almost similar rule can be applied to multivalued functions of complex calculus as well. For example, the raising to c-power of b-number is defined by $\mathbf{z}^w = \mathbf{E}^{w\log(\mathbf{Log\, z})}$, which suggests the definition

$$\mathbf{z^w} = \mathbf{e^{w \otimes log\,(log\, z)}}$$

for the raising to b-power. This is a multivalued function.

5 $^{\pi}$Derivative

The following lemma is crucial for setting $^{\pi}$derivative.

Lemma 1. *Let f be a non-vanishing function from some nonempty open connected subset C of $\mathbb{C}$ to $\mathbb{C}$. Assume that f has the algebraic and polar representations*

$$f(z) = u(r,\theta) + iv(r,\theta) = R(r,\theta)e^{i\Theta(r,\theta)} \quad \textit{for} \quad z = re^{i\theta}.$$

If $f'(z)$ exists and, consequently, the Cauchy–Riemann conditions in polar form

$$ru'_r = v'_\theta \quad \textit{and} \quad rv'_r = -u'_\theta$$

hold, then

$$r(\ln R)'_r = \Theta'_\theta \quad \text{and} \quad r\Theta'_r = -(\ln R)'_\theta \tag{3}$$

and

$$z(\log f(z))' = r((\ln R)'_r + i\Theta'_r), \tag{4}$$

assuming that f transfers C into a branch of log-function.

 ISBN: 978-84-617-8694-7

Note that, (3) expresses a version of the Cauchy–Riemann conditions when both argument and value of a complex function are represented in the polar form.

Motivated from the definition of $^{\pi}$derivative in the real case and Lemma 1, the $^{\pi}$derivative of $\mathbf{f}(r,\theta) = (R(r,\theta), \Theta(r,\theta))$ can be defined in the following way.

Definition 1. A function $\mathbf{f}(r,\theta) = (R(r,\theta), \Theta(r,\theta))$ is said to be $^{\pi}$differentiable at $\mathbf{z} = (r,\theta)$ if R and Θ have continuous partial derivatives and the Cauchy–Riemann conditions from (3) hold at (r,θ). If $\mathbf{f}$ is $^{\pi}$differentiable at $\mathbf{z}$, then its $^{\pi}$derivative at $\mathbf{z}$(in accordance to (4)) will be defined by

$$\mathbf{f}^{\pi}(\mathbf{z}) = (e^{r(\ln R)'_r}, r\Theta'_r).$$

$\mathbf{f}$ is said to be $^{\pi}$analytic on $B \subseteq \mathbb{B}$ if $\mathbf{f}$ is $^{\pi}$differentiable at every $\mathbf{z} \in B$.

Theorem 1. *Let* $\mathbf{f}$ *be the* $^{\pi}$*analog of the single-valued function* f*. Then its* $\mathbf{f}^{\pi}$ *and* f' *are related as*

$$\mathbf{f}^{\pi}(\mathbf{z}) = \mathbf{E}^{f'(\mathbf{Log}\,\mathbf{z})},$$

assuming that at least one of them exists.

This theorem establishes a method for calculation of $^{\pi}$derivatives. For example,

- $(\mathbf{a} \otimes \mathbf{z} \oplus \mathbf{b})^{\pi} = \mathbf{a}$.
- $(\mathbf{E}^{z})^{\pi} = \mathbf{E}^{z}$ and also $(\mathbf{e}^{\mathbf{z}})^{\pi} = \mathbf{e}^{\mathbf{z}}$.
- $(\mathbf{sin}\,\mathbf{z})^{\pi} = \mathbf{cos}\,\mathbf{z}$.
- $(\mathbf{cos}\,\mathbf{z})^{\pi} = \mathbf{0} \ominus \mathbf{sin}\,\mathbf{z}$.
- $(\mathbf{sinh}\,\mathbf{z})^{\pi} = \mathbf{cosh}\,\mathbf{z}$.
- $(\mathbf{cosh}\,\mathbf{z})^{\pi} = \mathbf{sinh}\,\mathbf{z}$.

Complex logarithm is multivaliued. But still we have

- $(\mathbf{Log}\,\mathbf{z})^{\pi} = \mathbf{1} \oslash \mathbf{z}$ and also $(\mathbf{log}\,\mathbf{z})^{\pi} = \mathbf{1} \oslash \mathbf{z}$.

Theorem 2. *Assume that* $\mathbf{f}^{\pi}(\mathbf{z})$ *and* $\mathbf{g}^{\pi}(\mathbf{z})$ *exist. Then*

(i) $(\mathbf{z}_0\mathbf{f})^{\pi}(\mathbf{z}) = \mathbf{f}^{\pi}(\mathbf{z})$ *for constant* $\mathbf{z}_0 \in \mathbb{B}$.

(ii) $(\mathbf{fg})^{\pi}(\mathbf{z}) = \mathbf{f}^{\pi}(\mathbf{z})\mathbf{g}^{\pi}(\mathbf{z})$.

(iii) $(\mathbf{f}/\mathbf{g})^{\pi}(\mathbf{z}) = \mathbf{f}^{\pi}(\mathbf{z})/\mathbf{g}^{\pi}(\mathbf{z})$.

(iv) $\mathbf{f}(\mathbf{g}(\mathbf{z}))^{\pi} = \mathbf{f}^{\pi}(\mathbf{g}(\mathbf{z})) \otimes \mathbf{g}^{\pi}(\mathbf{z})$, *assuming additionally that* $\mathbf{f}^{\pi}(\mathbf{g}(\mathbf{z}))$ *exists.*

Moreover, remaining theorems of complex differentiation can be stated and proved in terms of $^{\pi}$derivative.

 ISBN: 978-84-617-8694-7

6 $^{\pi}$Integral

Definition 2. Given $\mathbf{f} : B \subseteq \mathbb{B} \to \mathbb{B}$ by $\mathbf{f}(\mathbf{z}) = (R(r,\theta), \Theta(r,\theta))$ for $\mathbf{z} = (r,\theta)$, we assume that C is a contour in B with a parameterization $\mathbf{z}(t) = (r(t), \theta(t))$, $a \le t \le b$. Then we define the $^{\pi}$integral of $\mathbf{f}$ along the curve C by

$$\int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}} = \mathbf{E}^{\int_C \left(\frac{\ln R}{r}\, dr - \Theta\, d\theta\right) + i \int_C \left(\frac{\Theta}{r}\, dr + \ln R\, d\theta\right)},$$

assuming that the line integrals in the right side exist.

We present the following properties of $^{\pi}$integration.

Theorem 3. *Assume that $\int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}}$ and $\int_C \mathbf{g}(\mathbf{z})^{\mathbf{dz}}$ exist, where C is a contour in the domains of the functions $\mathbf{f}$ and $\mathbf{g}$. Then*

(i) $\int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}} = \int_{C_1} \mathbf{f}(\mathbf{z})^{dz} \int_{C_2} \mathbf{f}(\mathbf{z})^{\mathbf{dz}}$, where $C = C_1 + C_2$.

(ii) $\int_C (\mathbf{f}(\mathbf{z})\mathbf{g}(\mathbf{z}))^{\mathbf{dz}} = \int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}} \int_C \mathbf{g}(\mathbf{z})^{\mathbf{dz}}$.

(iii) $\int_C (\mathbf{f}(\mathbf{z})/\mathbf{g}(\mathbf{z})^{\mathbf{dz}} = \int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}} / \int_C \mathbf{g}(\mathbf{z})^{\mathbf{dz}}$.

Theorem 4. *Let $\mathbf{f} : B \subseteq \mathbb{B} \to \mathbb{B}$ be $^{\pi}$analytic and let C be a contour in a connected set B with the initial and end points $\mathbf{z}_1$ and $\mathbf{z}_2$, respectively. Then*

$$\int_C \mathbf{f}^{\pi}(\mathbf{z})^{\mathbf{dz}} = \frac{\mathbf{f}(\mathbf{z}_2)}{\mathbf{f}(\mathbf{z}_1)}.$$

Note that if C_1 and C_2 are two contours in the simply connected set $B \subseteq \mathbb{B}$ with the same initial and end points $\mathbf{z}_1$ and $\mathbf{z}_2$, respectively, and $\mathbf{f}$ is $^{\pi}$analytic on B, then

$$\int_{C_1} \mathbf{f}(\mathbf{z})^{\mathbf{dz}} = \int_{C_2} \mathbf{f}(\mathbf{z})^{\mathbf{dz}},$$

that means the $^{\pi}$integral is independent on the shape of the contours. Therefore, this integral can be denoted as

$$\int_{\mathbf{z}_1}^{\mathbf{z}_2} \mathbf{f}(\mathbf{z})^{\mathbf{dz}}.$$

Theorem 5. *If $\mathbf{f}$ is $^{\pi}$analytic on a connected set $B \subseteq \mathbb{B}$ and C is a closed contour in B, then*

$$\oint_C \mathbf{f}^{\pi}(\mathbf{z})^{\mathbf{dz}} = (1,0) = \mathbf{0}.$$

Theorem 6. *Let $\mathbf{f} : B \subseteq \mathbb{B} \to \mathbb{B}$ be the $^{\pi}$analog of the complex function f and let C be a contour in B. Denote $\mathbf{Log}\, C = \{\mathbf{Log}\, \mathbf{z} : \mathbf{z} \in C\}$. If $\int_{\mathbf{Log}\, C} f(z)\, dz$ exists, then $\int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}}$ exists*

$$\int_C \mathbf{f}(\mathbf{z})^{\mathbf{dz}} = \mathbf{E}^{\int_{\mathbf{Log}\, C} f(z)\, dz}. \tag{5}$$

 ISBN: 978-84-617-8694-7

Example 1. Since $(\mathbf{a}\otimes\mathbf{z})^{\pi}=\mathbf{a}$, By Theorem 4,

$$\int_{\mathbf{z}_1}^{\mathbf{z}_2}\mathbf{a}^{\mathbf{dz}}=\frac{\mathbf{a}\otimes\mathbf{z}_2}{\mathbf{a}\otimes\mathbf{z}_1}=\frac{\mathbf{E}^{\mathbf{Log\,a\,Log\,z}_2}}{\mathbf{E}^{\mathbf{Log\,a\,Log\,z}_1}}=\mathbf{E}^{\mathbf{Log\,a\,(Log\,z}_2-\mathbf{Log\,z}_1)}=\mathbf{a}\otimes(\mathbf{z}_2\ominus\mathbf{z}_2).$$

Example 2. The equality $(\mathbf{log}\,\mathbf{z})^{\pi}=\mathbf{1}\oslash\mathbf{z}$ is a complex $^{\pi}$version of $(\ln x)'=1/x$. Based on this we would like to find $^{\pi}$version of the important formula

$$\oint_{|z|=a}\frac{dz}{z}=2\pi i\ \text{ for }\ a>0,$$

where the orientation on the circle $|z|=a$ is counterclockwise. This circle has the parameterisation $z(t)=a\cos t+ia\sin t$, $-\pi\le t\le\pi$. Therefore, we will look to the closed curve C in $\mathbb{B}$ with parameterisation $\mathbf{z}(t)=(e^{a\cos t},a\sin t)$, $-\pi\le t<\pi$. Then the $^{\pi}$analog of the preceding integral is

$$\oint_C(\mathbf{1}\oslash\mathbf{z})^{\mathbf{dz}}.$$

Theorem 5 is not applicable to this integral since the function $\mathbf{f}(\mathbf{z})=\mathbf{1}\oslash\mathbf{z}$ has a singularity at $\mathbf{0}=(1,0)$ located inside C. Therefore, this $^{\pi}$integral will be calculated in accordance to Theorem 6 as follows:

$$\oint_C(\mathbf{1}\oslash\mathbf{z})^{\mathbf{dz}}=\mathbf{E}^{\oint_{\mathbf{Log}\,C}\frac{1}{z}dz}=\mathbf{E}^{\oint_{|z|=a}\frac{1}{z}dz}=\mathbf{E}^{2\pi i}=(e^0,2\pi)=(1,2\pi).$$

This example demonstrates that the $^{\pi}$integrals respond to residues.

7 Conclusion

Resuming, we see that the formulae of complex $^{\pi}$calculus are identical to those of complex calculus. Although this is verified only for its starting elements, there is no doubts that this expands to the whole. The identity is achieved by implementing the following three actions:

- Transferring the field structure of $\mathbb{C}$ to the larger set $\mathbb{B}$.
- Changing the sense of derivative and integral $^{\pi}$sense.
- Considering $^{\pi}$analogs of functions of complex calculus.

One can think that complex $^{\pi}$calculus is a small part of complex calculus on Riemann surfaces since $\mathbb{B}$ is the Riemann surface of the complex logarithm. This thought is misleading because complex $^{\pi}$calculus is based on rather easy concepts of $^{\pi}$derivative and $^{\pi}$integral and does not use the heavy machinery of integration and differentiation on manifolds. Additionally, complex $^{\pi}$calculus still considers multivalued logarithmic and power functions while they are single-valued in complex calculus on the Riemann surface of complex logarithm.

 ISBN: 978-84-617-8694-7

Since every α-calculus, including $^{\pi}$calculus as well, transfers a structure over $\mathbb{R}$ to an identical structure, it should not be surprising in the complex case as well. But unlike to the real case, complex $^{\pi}$calculus is a nontrivial transformation of complex calculus because it requires setting the new exponential function $\mathbf{E}^z$ with the range $\mathbb{B}$ being a supset of $\mathbb{C} \setminus \{0\}$ while in the real case the range of e^x is the subset $(0, \infty)$ of $\mathbb{R}$.

We think that most interesting element of complex $^{\pi}$calculus is the clear meaning of the variable (r, θ), which is the polar components if a complex variable and in the use in complex calculus as well, for example, to prove Moivre-Laplace formula establishing n different nth roots a nonzero complex number. In terms of cosmology, there are two universes—complex calculus and $^{\pi}$calculus. They behave identically, but have interaction. This can be used to obtain polar form of different formulae of complex calculus. Just replace the algebraic components x and y by polar components r and θ and transform the formula back from $^{\pi}$calculus to complex calculus. In this regard it is interesting to investigate Navier–Stokes equations. There is a believe (while not yet proved) that Navier–Stokes equations include the turbulence property of fluid flow. Roughly speaking, turbulence appears when the angular velocity of liquid is essentially nonzero. Since the derivative in θ presents the angular velocity (while in r the radial velocity) it is interesting to obtain Navier–Stokes equations in terms of r and θ.

Also, complex $^{\pi}$calculus can be included to textbooks on complex calculus in the form of exercises or research projects. It could serve as an introductory element to Riemann surfaces.

Probabilistic Evolution Theoretical Formulation of Anharmonic Symmetric Quantum Oscillator by Using Quantum Evolver Dynamics

Semra BAYAT ÖZDEMİR[1] and Metin DEMİRALP[1]

[1] *Computational Science and Engineering Department, Informatics Institute, Istanbul Technical University*

emails: bayat@itu.edu.tr, metin.demiralp@gmail.com

Abstract

This work focuses on the construction of evolver dynamics equations for an exponential quantum anharmonic oscillator. We also focus on the point that how squarification is used to solve the obtained second degree ordinary differential equation system. Space extension concept is used for creating the PREVTH specific system vector which is composed of a set conically closed under Poisson bracketing. A super ODE system on operators is obtained but third degree products obtained at the first attempt on the right hand sides force us to apply an improved version of space extension is again to get second degree multinomiality. A method called squarification, which is developed by our group members, helps us to get a recursive equation to solve the obtained equations for expectation values of the operators.

Key words: PREVTH, Evolver Dynamics, Space Extension, CASE, Squarification, Anharmonic Symmetric Quantum Oscillator

1 Introduction

Solution of Schrödinger equation is one of the most challenging problem in Quantum Mechanics. Several methodologies are studied for the general solution and for the special systems. But a method to meet all the needs could not have been developed. General expression for the Schrödinger equation [1] is given below.

$$i\hbar \frac{\partial \psi(\mathbf{x},t)}{\partial t} = \widehat{H}\psi(\mathbf{x},t), \quad \psi(\mathbf{x},0) = \psi_0(\mathbf{x}) \tag{1}$$

 ISBN: 978-84-617-8694-7

where $\psi(\mathbf{x},t)$ denotes the wave function and ψ_0 symbolizes the initial form of it. $\hbar$ is the reduced Planck constant. The Hamiton operator $\widehat{H}$ defines the behaviour of the quantum systems. The system studied in this work is anharmonic symmetric quantum operator which is given with the following Hamiltonian

$$\widehat{H} \equiv \frac{1}{2\mu}\widehat{p}^2 + \alpha\left(\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^{\,2}} - \widehat{I}\right) \qquad \alpha,\kappa > 0 \tag{2}$$

$$\widehat{p}g(x) \equiv -i\hbar g'(x), \quad \widehat{q}g(x) \equiv xg(x), \quad \widehat{I}g(x) \equiv g(x) \qquad x \in (-\infty,\infty) \tag{3}$$

where $\widehat{I}$, $\widehat{p}$, $\widehat{q}$ denote the identity, momentum, position operators and μ, α, κ stand for the mass, potential amplitude and anharmonicity constant respectively.

Evaluation of the wave equation is painfull when working on that partial differential equation (1). But construction of ordinary differential equations (ODEs) over expectation values of the operators may facilitates the analysis [2–4]. This approach is called "Quantum Expectation Value Dynamics". Our group have numerous studies on this subject. Recently developed methodology "Probabilistic Evolution Theory (PREVTH)" [5–13] is based on the idea of constructing an infinite set of linear homogeneous ODE or ODE set over the expectation values of the basis operators. First of all, an appropriate system vector is defined for the basis operators and then its Kronecker powers are obtained for use in the solution equation.

2 System Vector of Operators for PREVTH

To define a compact equation for poisson bracket of Hamiltonian with the operators, first of all, we have to define a system vector ($\widehat{\mathbf{s}}$) composed of the necessary operators. The exponential part seen in the potential term of Hamiltonian forces us to define a new independent variable s_3 which ease to handle the singularity at infinity.

$$\widehat{\mathbf{s}} \equiv \begin{bmatrix} \widehat{s}_1 \\ \widehat{s}_2 \\ \widehat{s}_3 \end{bmatrix} \equiv \begin{bmatrix} \widehat{p} \\ \widehat{q} \\ \mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2} \end{bmatrix} \tag{4}$$

Poisson brackets of Hamiltonian and system vector elements can be written as below.

$$\left\{\widehat{H},\widehat{s}_1\right\} = \left\{\widehat{H},\widehat{p}\right\} = \frac{1}{2\mu}\left\{\widehat{p}^2,\widehat{p}\right\} + \alpha\left\{\left(\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2} - 1\right),\widehat{p}\right\} = -\alpha\kappa\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2} = -\alpha\kappa\widehat{s}_2\widehat{s}_3 \tag{5}$$

$$\left\{\widehat{H},\widehat{s}_2\right\} = \left\{\widehat{H},\widehat{q}\right\} = \frac{1}{2\mu}\left\{\widehat{p}^2,\widehat{q}\right\} + \alpha\left\{\left(\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2} - 1\right),\widehat{q}\right\} = \frac{1}{\mu}\widehat{p} = \frac{1}{\mu}\widehat{s}_1 \tag{6}$$

 ISBN: 978-84-617-8694-7

$$\begin{aligned}\left\{\widehat{H},\widehat{s}_3\right\} &= \left\{\widehat{H},\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}=\frac{1}{2\mu}\left\{\widehat{p}^2,\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}+\alpha\left\{\left(\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}-1\right),\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}\\ &= \frac{1}{2\mu}\left(\widehat{p}\left\{\widehat{p},\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}+\left\{\widehat{p},\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}\widehat{p}\right)\\ &= \frac{\kappa}{2\mu}\left(\widehat{p}\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}+\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\widehat{p}\right)\\ &= \frac{\kappa}{2\mu}\left(\widehat{s}_1\widehat{s}_2\widehat{s}_3+\widehat{s}_2\widehat{s}_3\widehat{s}_1\right)\end{aligned} \tag{7}$$

Triple multiplications of the operators are present in (7). The degree of the right hand side polynomials can be reduced to two by space extension [14, 15]. To write a compact second degree multinomial equation from above equations, we have to define new independent variables s_4 and s_5 which are multiplications of two operators.

$$\widehat{s}_4 \equiv \widehat{s}_2\widehat{s}_3 = \widehat{s}_3\widehat{s}_2 \tag{8}$$

$$\widehat{s}_5 \equiv \widehat{s}_2\widehat{s}_1 \tag{9}$$

New augmented 1×5 system vector $\widehat{\mathbf{s}}_{aug}$ is created by adding new variables to the original system vector $\widehat{\mathbf{s}}$ (4). Its Kronecker square is 1×5^2 type vector which is labeled as $\widehat{\mathbf{s}}^{\otimes 2}_{aug}$.

$$\begin{aligned}\widehat{\mathbf{s}}_{aug} &\equiv \left[\begin{array}{ccccc}\widehat{s}_1 & \widehat{s}_2 & \widehat{s}_3 & \widehat{s}_4 & \widehat{s}_5\end{array}\right]^T\\ \widehat{\mathbf{s}}^{\otimes 2}_{aug} &\equiv [\widehat{s}_1^2 \;\; \widehat{s}_1\widehat{s}_2 \;\; \widehat{s}_1\widehat{s}_3 \;\; \widehat{s}_1\widehat{s}_4 \;\; \widehat{s}_1\widehat{s}_5 ...\\ &\quad \widehat{s}_2\widehat{s}_1 \;\; \widehat{s}_2^2 \;\; \widehat{s}_2\widehat{s}_3 \;\; \widehat{s}_2\widehat{s}_4 \;\; \widehat{s}_2\widehat{s}_5 ...\\ &\quad \widehat{s}_3\widehat{s}_1 \;\; \widehat{s}_3\widehat{s}_2 \;\; \widehat{s}_3^2 \;\; \widehat{s}_3\widehat{s}_4 \;\; \widehat{s}_3\widehat{s}_5 ...\\ &\quad \widehat{s}_4\widehat{s}_1 \;\; \widehat{s}_4\widehat{s}_2 \;\; \widehat{s}_4\widehat{s}_3 \;\; \widehat{s}_4^2 \;\; \widehat{s}_4\widehat{s}_5 ...\\ &\quad \widehat{s}_5\widehat{s}_1 \;\; \widehat{s}_5\widehat{s}_2 \;\; \widehat{s}_5\widehat{s}_3 \;\; \widehat{s}_5\widehat{s}_4 \;\; \widehat{s}_5^2]^T\end{aligned} \tag{10}$$

Poisson brackets of newly defined operators and Hamitonian can be written as

$$\begin{aligned}\left\{\widehat{H},\widehat{s}_4\right\} &= \left\{\widehat{H},\widehat{s}_2\widehat{s}_3\right\}=\left\{\widehat{H},\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}=\left\{\widehat{H},\widehat{q}\right\}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}+\widehat{q}\left\{\widehat{H},\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\right\}\\ &= \frac{1}{\mu}\widehat{p}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}+\widehat{q}\frac{\kappa}{2\mu}\left(\widehat{p}\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}+\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\widehat{p}\right)\\ &= \frac{1}{\mu}\widehat{s}_1\widehat{s}_3+\frac{\kappa}{2\mu}\left(\widehat{s}_2\widehat{s}_1\widehat{s}_2\widehat{s}_3+\widehat{s}_2^2\widehat{s}_3\widehat{s}_1\right)\\ &= \frac{1}{\mu}\widehat{s}_1\widehat{s}_3+\frac{\kappa}{2\mu}\left(\widehat{s}_2\widehat{s}_1\widehat{s}_2\widehat{s}_3+\widehat{s}_2\widehat{s}_3\widehat{s}_2\widehat{s}_1\right)\end{aligned} \tag{11}$$

$$\begin{aligned}\left\{\widehat{H},\widehat{s}_5\right\} &= \left\{\widehat{H},\widehat{s}_2\widehat{s}_1\right\}=\left\{\widehat{H},\widehat{q}\widehat{p}\right\}=\left\{\widehat{H},\widehat{q}\right\}\widehat{p}+\widehat{q}\left\{\widehat{H},\widehat{p}\right\}\\ &= \frac{1}{\mu}\widehat{p}^2-\alpha\kappa\widehat{q}\widehat{q}\mathrm{e}^{\frac{\kappa}{2}\widehat{q}^2}\\ &= \frac{1}{\mu}\widehat{s}_1^2-\alpha\kappa\widehat{s}_2\widehat{s}_2\widehat{s}_3\end{aligned} \tag{12}$$

 ISBN: 978-84-617-8694-7

For convenience, all the poisson bracket results can be seen in the system form.

$$\begin{aligned}
\left\{\widehat{H},\widehat{s}_1\right\} &= -\alpha\kappa\widehat{s}_4 \\
\left\{\widehat{H},\widehat{s}_2\right\} &= \frac{1}{\mu}\widehat{s}_1 \\
\left\{\widehat{H},\widehat{s}_3\right\} &= \frac{\kappa}{2\mu}\left(\widehat{s}_1\widehat{s}_4+\widehat{s}_4\widehat{s}_1\right) \\
\left\{\widehat{H},\widehat{s}_4\right\} &= \frac{1}{\mu}\widehat{s}_1\widehat{s}_3+\frac{\kappa}{2\mu}\left(\widehat{s}_5\widehat{s}_4+\widehat{s}_4\widehat{s}_5\right) \\
\left\{\widehat{H},\widehat{s}_5\right\} &= \frac{1}{\mu}\widehat{s}_1^2-\alpha\kappa\widehat{s}_2\widehat{s}_4
\end{aligned} \tag{13}$$

To gather all the coefficients of the equations (13) in matrices, we have two define $\mathbf{H}_1$ and $\mathbf{H}_2$ with the help of unit vectors of cartesian space.

$$\begin{aligned}
\mathbf{H}_1 &\equiv \mathbf{e}_2\mathbf{e}_1^T-\alpha\kappa\mathbf{e}_1\mathbf{e}_4^T \\
\mathbf{H}_2 &\equiv \frac{\kappa}{2\mu}\mathbf{e}_3\left(\mathbf{e}_1\otimes\mathbf{e}_4+\mathbf{e}_4\otimes\mathbf{e}_1\right)^T+\frac{1}{\mu}\mathbf{e}_4\left(\mathbf{e}_1\otimes\mathbf{e}_3+\frac{\kappa}{2}\left(\mathbf{e}_4\otimes\mathbf{e}_5+\mathbf{e}_5\otimes\mathbf{e}_4\right)\right)^T \\
&\quad +\frac{1}{\mu}\mathbf{e}_5\left(\mathbf{e}_1\otimes\mathbf{e}_1-\alpha\kappa\mathbf{e}_2\otimes\mathbf{e}_4\right)^T
\end{aligned} \tag{14}$$

A compact equation can be written as below to express the equations in (13).

$$\left\{\widehat{H},\widehat{\mathbf{s}}_{aug}\right\}=\mathbf{H}_1\widehat{\mathbf{s}}_{aug}\left(t\right)+\mathbf{H}_2\widehat{\mathbf{s}}_{aug}\left(t\right)^{\otimes 2} \tag{15}$$

3 Constancy Adding Space Extension (CASE)

The expression given in the (15) is not unique. By defining a constant as a new vector element for $\widehat{\mathbf{s}}_{aug}$, the equations in (13) can be rewritten in a way that will not affect the final result. This method is called "Constancy Adding Space Extension (CASE)"which is developed in our group [16–19]. With appropriate choices, the coefficient of first term of (15) can be obtained as identity matrix multiplied by a constant. Thus, the obtained dynamic equation can be solved easily.

Let's start by defining $\widehat{s}_6$ as unit operator multiplied by nonzero constant a.

$$\widehat{s}_6\equiv a\widehat{I} \tag{16}$$

$$\left\{\widehat{H},\widehat{s}_6\right\}=0 \tag{17}$$

$$\widehat{I}=\frac{1}{a}\widehat{s}_6 \qquad \Longrightarrow \qquad \frac{1}{a^2}\widehat{s}_6^2-\frac{1}{a}\widehat{s}_6=0 \qquad \Longrightarrow \qquad \beta\widehat{s}_6-\frac{\beta}{a}\widehat{s}_6^2=0 \tag{18}$$

 ISBN: 978-84-617-8694-7

Multiplying both sides of the equation with a nonzero constant β does not change the result as it is seen in the third equation of (18).

$$\widehat{\mathbf{s}}_{ca} \equiv \left[\begin{array}{cccccc} \widehat{s}_1 & \widehat{s}_2 & \widehat{s}_3 & \widehat{s}_4 & \widehat{s}_5 & \widehat{s}_6 \end{array} \right]^T \tag{19}$$

$\widehat{\mathbf{s}}_{ca}$ is an augmented system vector which is created by CASE. We can write the Kronecker square of $\widehat{\mathbf{s}}_{ca}$ as

$$\begin{array}{rl} \widehat{\mathbf{s}}_{ca}^{\otimes 2} = & [\widehat{s}_1^2 \;\; \widehat{s}_1\widehat{s}_2 \;\; \widehat{s}_1\widehat{s}_3 \;\; \widehat{s}_1\widehat{s}_4 \;\; \widehat{s}_1\widehat{s}_5 ... \\ & \widehat{s}_2\widehat{s}_1 \;\; \widehat{s}_2^2 \;\; \widehat{s}_2\widehat{s}_3 \;\; \widehat{s}_2\widehat{s}_4 \;\; \widehat{s}_2\widehat{s}_5 ... \\ & \widehat{s}_3\widehat{s}_1 \;\; \widehat{s}_3\widehat{s}_2 \;\; \widehat{s}_3^2 \;\; \widehat{s}_3\widehat{s}_4 \;\; \widehat{s}_3\widehat{s}_5 ... \\ & \widehat{s}_4\widehat{s}_1 \;\; \widehat{s}_4\widehat{s}_2 \;\; \widehat{s}_4\widehat{s}_3 \;\; \widehat{s}_4^2 \;\; \widehat{s}_4\widehat{s}_5 ... \\ & \widehat{s}_5\widehat{s}_1 \;\; \widehat{s}_5\widehat{s}_2 \;\; \widehat{s}_5\widehat{s}_3 \;\; \widehat{s}_5\widehat{s}_4 \;\; \widehat{s}_5^2 ... \\ & a\widehat{s}_1 \;\; a\widehat{s}_2 \;\; a\widehat{s}_3 \;\; a\widehat{s}_4 \;\; a\widehat{s}_5]^T \end{array} \tag{20}$$

The Poisson bracket equations can be written as below.

$$\begin{aligned} \left\{\widehat{H}, \widehat{s}_1\right\} &= -\alpha\kappa\widehat{s}_4\frac{\widehat{s}_6}{a} + \beta\widehat{s}_1 - \frac{\beta}{a}\widehat{s}_1\widehat{s}_6 \\ \left\{\widehat{H}, \widehat{s}_2\right\} &= \frac{1}{\mu}\widehat{s}_1\frac{\widehat{s}_6}{a} + \beta\widehat{s}_2 - \frac{\beta}{a}\widehat{s}_2\widehat{s}_6 \\ \left\{\widehat{H}, \widehat{s}_3\right\} &= \frac{\kappa}{2\mu}\left(\widehat{s}_1\widehat{s}_4 + \widehat{s}_4\widehat{s}_1\right) + \beta\widehat{s}_3 - \frac{\beta}{a}\widehat{s}_3\widehat{s}_6 \\ \left\{\widehat{H}, \widehat{s}_4\right\} &= \frac{1}{\mu}\widehat{s}_1\widehat{s}_3 + \frac{\kappa}{2\mu}\left(\widehat{s}_5\widehat{s}_4 + \widehat{s}_4\widehat{s}_5\right) + \beta\widehat{s}_4 - \frac{\beta}{a}\widehat{s}_4\widehat{s}_6 \\ \left\{\widehat{H}, \widehat{s}_5\right\} &= \frac{1}{\mu}\widehat{s}_1^2 - \alpha\kappa\widehat{s}_2\widehat{s}_4 + \beta\widehat{s}_5 - \frac{\beta}{a}\widehat{s}_5\widehat{s}_6 \\ \left\{\widehat{H}, \widehat{s}_6\right\} &= \beta\widehat{s}_6 - \frac{\beta}{a}\widehat{s}_6^2 \end{aligned} \tag{21}$$

All the coefficients at the right hand side can be written in the following matrix forms.

$$\begin{aligned} \mathbf{F}_1 &\equiv \beta\mathbf{I}_6 \\ \mathbf{F}_2 &\equiv -\frac{\alpha\kappa}{a}\mathbf{e}_1\left(\mathbf{e}_4 \otimes \mathbf{e}_6\right) + \frac{1}{a\mu}\mathbf{e}_2\left(\mathbf{e}_1 \otimes \mathbf{e}_6\right) + \frac{\kappa}{2\mu}\mathbf{e}_3\left(\mathbf{e}_1 \otimes \mathbf{e}_4 + \mathbf{e}_4 \otimes \mathbf{e}_1\right)^T \\ &\quad + \frac{1}{\mu}\mathbf{e}_4\left(\mathbf{e}_1 \otimes \mathbf{e}_3 + \frac{\kappa}{2}\left(\mathbf{e}_4 \otimes \mathbf{e}_5 + \mathbf{e}_5 \otimes \mathbf{e}_4\right)\right)^T + \frac{1}{\mu}\mathbf{e}_5\left(\mathbf{e}_1 \otimes \mathbf{e}_1 - \alpha\kappa\mathbf{e}_2 \otimes \mathbf{e}_4\right)^T \\ &\quad - \frac{\beta}{a}\left(\mathbf{e}_1(\mathbf{e}_1 \otimes \mathbf{e}_6 + \mathbf{e}_4 \otimes \mathbf{e}_6) + \mathbf{e}_2(\mathbf{e}_2 \otimes \mathbf{e}_6 + \mathbf{e}_1 \otimes \mathbf{e}_6)\right. \\ &\qquad \left. + \mathbf{e}_3(\mathbf{e}_3 \otimes \mathbf{e}_6) + \mathbf{e}_4(\mathbf{e}_4 \otimes \mathbf{e}_6) + \mathbf{e}_5(\mathbf{e}_5 \otimes \mathbf{e}_6) + \mathbf{e}_6(\mathbf{e}_6 \otimes \mathbf{e}_6)\right) \end{aligned} \tag{22}$$

 ISBN: 978-84-617-8694-7

which shows that an appropriate choice of $\mathbf{F}_2$ enables us to get $\mathbf{F}_1$ as the product of 6×6 identity matrix, $(\mathbf{I}_6)$, with the scalar β.

These coefficient matrices $\mathbf{F}_1$ and $\mathbf{F}_2$ allow the equations in (21) to be written in the following compact form.

$$\left\{\widehat{H}, \widehat{\mathbf{s}}_{ca}\right\} \;=\; \mathbf{F}_1\,\widehat{\mathbf{s}}_{ca} + \mathbf{F}_2\,\widehat{\mathbf{s}}_{ca}^{\otimes 2} = \beta\,\widehat{\mathbf{s}}_{ca} + \mathbf{F}\,\widehat{\mathbf{s}}_{ca}^{\otimes 2} \tag{23}$$

Since $\mathbf{F}_1$ does not appear at the rightmost part of these equations we have also dropped the index 2 from $\mathbf{F}_2$.

4 Evolver Dynamics

(23) is not a set of ODE which is an expected issue for PREVTH. Hence we need to produce a set of ODE on which PREVTH can be applied. To this end, we can start by defining the transition operators as follows

$$\psi(\mathbf{x}, t) = \widehat{T}\,(t_0, t)\,\psi\,(\mathbf{x}, t_0) \tag{24}$$

$$\frac{d\widehat{T}}{dt}\,(t_0, t) = -\frac{i}{\hbar}\widehat{H}(t)\widehat{T}\,(t_0, t)\,, \qquad \widehat{T}\,(t_0, t_0) = \widehat{I} \tag{25}$$

$\widehat{T}\,(t_0, t)$ denotes the transition operator of a quantum system under consideration without any specification about its interaction with its environment.

We can also define an Evolver superoperator as follows.

$$\widehat{\mathbb{E}}(\widehat{o})(t) \equiv \widehat{T}\,(t, t_0)^{\dagger}\,\widehat{o}(t)\widehat{T}\,(t, t_0)\,. \tag{26}$$

$\widehat{\mathbb{E}}(\widehat{o})(t)$ maps from the operator space where $\widehat{o}(t)$ resides to the same space. Therefore it is a superoperator whose operand is denoted as its first argument. It evolves in time because of not only its temporal dependence coming from interaction operator but also from the possible dependence of the operand $\widehat{o}(t)$. All these dependencies are shown in the second but separate argument.

The equation needed for PREVTH solution can be constructed as

$$\frac{d\widehat{\mathbb{E}}(\,\widehat{\mathbf{s}}_{ca})(t)}{dt} = \beta\widehat{\mathbb{E}}(\,\widehat{\mathbf{s}}_{ca})(t) + \mathbf{F}\widehat{\mathbb{E}}(\,\widehat{\mathbf{s}}_{ca})\,(t)^{\otimes 2} \qquad\qquad \widehat{\mathbb{E}}(\,\widehat{\mathbf{s}}_{ca})\,(t_0) = \widehat{\mathbf{s}}_{ca}. \tag{27}$$

This is the desired super ODE set on operator unknowns and in PREVTH format. Hence the rest is just to get the PREVTH solution.

 ISBN: 978-84-617-8694-7

5 Constructing the PREVTH Solution

The PREVTH solution of (27) is constructed by using an integral recursion between positive integer Kronecker powers of the unknown evolver. Details are given in our relevant publications [20–23]. PREVTH solution can be explicitly given below

$$\mathbb{E}\left(\widehat{\mathbf{s}}_{ca}\right)(t) = \mathrm{e}^{\beta(t-t_0)} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta(t-t_0)} - 1}{\beta} \right)^{j} \mathbf{T}_j \, \widehat{\mathbf{s}}_{ca}^{\otimes (j+1)} \tag{28}$$

where $\widehat{\mathbf{s}}_{ca}$ is the augmented initial system vector formed through CASE and telescope matrix, $\mathbf{T}_j$, is defined as

$$\mathbf{T}_j \equiv \mathbf{M}_1 ... \mathbf{M}_j, \quad \mathbf{T}_0 \equiv \mathbf{I}_n, \quad j = 0, 1, 2, ... \tag{29}$$

where the monocular matrices, $\mathbf{M}_k$s, whose cascaded forms form the telescope matrices, are also defined as

$$\mathbf{M}_k \equiv \sum_{\ell=0}^{k-1} \mathbf{I}_n^{\otimes \ell} \otimes \mathbf{F} \otimes \mathbf{I}_n^{\otimes (k-1-\ell)}, \qquad k = 1, 2, ... \tag{30}$$

Here $\mathbf{F}$ is the $\mathbf{F}_2$ matrix obtained in the previous section. It is in the form of $n \times n^2$ type matrices. We can rewrite it as the sum of Kronecker product of Cartesian unit vectors with $n \times n$ submatrices ($\mathbf{F}^{(i)}$) as below.

$$\mathbf{F} = \sum_{i=1}^{n} \mathbf{e}_i^T \otimes \mathbf{F}^{(i)} \tag{31}$$

Let us represent the squarified telescope matrix (SquTelMat) $\widehat{\mathbf{S}}_j\left(\widehat{\mathbf{s}}_{ca}\right) \widehat{\mathbf{s}}_{ca}$ through the following formula

$$\mathbf{T}_j \, \widehat{\mathbf{s}}_{ca}^{\otimes (j+1)} = \mathbf{S}_j(\widehat{\mathbf{s}}_{ca}) \, \widehat{\mathbf{s}}_{ca} \qquad j = 0, 1, 2, ... \tag{32}$$

where each SquTelMat is a square matrix of $n \times n$. For a given $\mathbf{F}$ rectangular matrix of $n \times n^2$ and an n-element vector $\mathbf{a}$, the squarification is defined as follows

$$\lfloor \mathbf{F}, \mathbf{a} \rceil \equiv \sum_{i=1}^{n} a_i \mathbf{F}^{(i)}, \tag{33}$$

where a_is are the elements of the vector $\mathbf{a}$.

As we could have been able to show quite recently, the SquTelMats satisfy the following recursion

$$\widehat{\mathbf{S}}_j\left(\widehat{\mathbf{s}}_{ca}\right) = \sum_{i=1}^{j-1} \binom{j-1}{k} \lfloor \mathbf{F}, \widehat{\mathbf{S}}_k\left(\widehat{\mathbf{s}}_{ca}\right) \widehat{\mathbf{s}}_{ca} \rceil \widehat{\mathbf{S}}_{j-1-k}\left(\widehat{\mathbf{s}}_{ca}\right), \quad \widehat{\mathbf{S}}_0\left(\widehat{\mathbf{s}}_{ca}\right) = \widehat{\mathbf{I}}, \quad j = 1, 2, ... \tag{34}$$

 ISBN: 978-84-617-8694-7

where $\widehat{\mathbf{I}}$ is the identity matrix operator whose diagonal elements are identity operator, $\widehat{I}$.

(34) is a matrix recursion and therefore its computational complexity may be desired to be further suppressed. To this end, we can define

$$\widehat{\mathbf{v}}_j\left(\widehat{\mathbf{s}}_{ca}\right) \equiv \mathbf{S}_j\left(\widehat{\mathbf{s}}_{ca}\right) \widehat{\mathbf{s}}_{ca}, \qquad j = 0, 1, 2, ... \tag{35}$$

and rewrite (34) as follows in terms of $\widehat{\mathbf{v}}_j$s instead of $\widehat{\mathbf{S}}_j$s.

$$\widehat{\mathbf{v}}_j\left(\widehat{\mathbf{s}}_{ca}\right) = \sum_{i=1}^{j-1} \binom{j-1}{k} \lfloor \mathbf{F}, \widehat{\mathbf{v}}_k\left(\widehat{\mathbf{s}}_{ca}\right) \rceil \widehat{\mathbf{v}}_{j-1-k}\left(\widehat{\mathbf{s}}_{ca}\right), \quad \widehat{\mathbf{v}}_0\left(\widehat{\mathbf{s}}_{ca}\right) = \widehat{\mathbf{s}}_{ca}, \quad j = 1, 2, ... \tag{36}$$

Now the use of (35) in (28) produces

$$\mathbb{E}\left(\widehat{\mathbf{s}}_{ca}\right)(t) = \mathrm{e}^{\beta(t-t_0)} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta(t-t_0)} - 1}{\beta}\right)^j \widehat{\mathbf{v}}_j\left(\widehat{\mathbf{s}}_{ca}\right) \tag{37}$$

6 System Expectation Values at No Fluctuation Limit

The expectation value of the system vector with operator elements can be evaluated by taking the expectation values of both sides in (37) under the initial wave function. This requires the evaluation of $\widehat{\mathbf{v}}_j$'s expectation values, which can be accomplished by using the both-sides'-expectation-value in the recursion (36). However, this expectation valued recursion form is not so practical for applications. Hence we can use the no fluctuation approximation which is based on the fluctuationlessness theorem which was conjectured and proven in our group studies. Fluctuationlessness Theorem dictates us that "The expectation value of a multivariate function depending on various linear operators is equal to the image of those operators' expectation values under the same function at the no fluctuation limit" [24–30] This theorem implies that the equality obtained by taking expectation values of both sides in an equality can be approximated by replacing each argument operator with its expectation values under the same initial wave function. Thus we can write the following approximate equality by taking both sides' expectation value and then using no fluctuation approximation from (36)

$$\widehat{\mathbf{v}}_j\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right) = \sum_{i=1}^{j-1} \binom{j-1}{k} \lfloor \mathbf{F}, \widehat{\mathbf{v}}_k\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right) \rceil \widehat{\mathbf{v}}_{j-1-k}\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right), \ \widehat{\mathbf{v}}_0\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right) = \langle \widehat{\mathbf{s}}_{ca} \rangle, \ j = 1, 2, .. \tag{38}$$

On the other hand, we can write the following equality from (37) by taking expectation value of its both sides and then using no fluctuation approximation

$$\mathbb{E}\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right)(t) = \mathrm{e}^{\beta(t-t_0)} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta(t-t_0)} - 1}{\beta}\right)^j \widehat{\mathbf{v}}_j\left(\langle \widehat{\mathbf{s}}_{ca} \rangle\right) \tag{39}$$

 ISBN: 978-84-617-8694-7

All these equalities convert all operator elemented system vectors to standard linear algebraic vectors depending on the ordinary linear algebraic system vector which is the expectation value of the system vector with operator elements.

7 Fluctuation Expansion and Initial Wave Function Selection

No fluctuation approximation brings the question: How can we construct a scheme which brings corrections to the non fluctuation expansion systematically? The answer can be based on the following fluctuation identities for our present case where there are six system operators:

$$\widehat{s}_i \equiv \langle\, \widehat{s}_i \,\rangle\, \widehat{I} + \widehat{\phi}_i, \qquad i = 1, 2, ..., 6 \tag{40}$$

which are fluctuation operator defining equations at the same time. These definition urge us to define the following system fluctuation operator:

$$\widehat{\boldsymbol{\phi}} \equiv \left[\begin{array}{cccc} \widehat{\phi}_1 & ... & \widehat{\phi}_6 \end{array} \right]^T \tag{41}$$

Now Mathematical Fluctuation Theory dictates us that the expectation values encountered in PREVTH can be expanded to expectation values of Kronecker power series (nonnegative Kronecker powers) of the fluctuation. The initial wave function structure to be used in the fluctuations gains great importance for the convergence of relevant Kronecker power series. To get uniform convergence the basis function for representing the initial wave function must have an appropriate weight function such that all terms' expectation values should be finite and preferably analytically calculable. This issue may need to be elaborately investigated, even though we are not going to attempt to do so here and then report the results since it is somehow out of the conceptuality which is basic goal of this presentation.

8 Concluding Remarks

In this work we have developed evolver dynamics for a quantum system of exponential anharmonic oscillator. This work is dominated by conceptuality because of its importance. Hence we do not present any illustrative implementation in this proceeding paper even though we are going to realize a much more comprehensive presentation in the conference and we are planning to write an extended paper for some journals with more satisfactory and detailed content in close future.

Abstract

This work takes into consideration a single variable function to be approximated. To start with, Taylor expansion of the considered function is taken. The remainder term is explicitly expressed in integral form. Then making a series of transformations on the integrand, it is represented as a contour integral where the new kernel fuction is expressed in terms of two variables. This new representation allows us to apply Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR) method onto it and provides us with a good approximation of the kernel function which then is integrated to obtain an approximation for the initially transformed integrand. Then a final step allows us to calculate the approximation to the univariate function under consideration. Because of the overall conceptual approach to the problem through this article, applications are intended to be given during the oral representation.

Key words: Univariate Approximation, multivariate approximation, EMPR, TKEMPR, Contour integrals, Taylor Expansion
MSC 2000: 00A69, 15A12, 65D15

1 Introduction

This work consists of using the TKEMPR method which decomposes a linear integral operator on univariate functions by using high dimensional modelling with the basic idea

to use Enhanced Multivariance Products Representation (EMPR) [1-18] technique created and conjectured by Demiralp. The representation used here is not based on the general EMPR and is a specific EMPR construction for bivariate function decomposition We call this decomposition Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR) [19-24]. It uses EMPR bivariate function decomposition consecutively such that in each step the remainder term is expanded to again a bivariate EMPR but with different support functions. To make a function approximation using TKEMPR, first we represent our function in terms of a Taylor expansion whose remainder term is expressed in integral form. Then after making necessary manipulations the kernel of the integral in question is written in terms of a contour integration, then following a procedure which allows us to obtain the kernel to be used in TKEMPR, we obtain a two variable form and finally use it to approximate our function.

2 Basics of EMPR

Enhanced Multivariance Products Representation (EMPR) is a decomposition method recently developed by M. Demiralp. For a given multivariate function $f(x_1, ..., x_N)$ it can be written as

$$\begin{aligned} f(x_1, ..., x_N) \;=\; & f_0 \prod_{i=1}^{N} s_i(x_i) + \sum_{j=1}^{N} f_j(x_j) \prod_{i=1, i\neq j}^{N} s_i(x_i) \\ & + \sum_{\substack{j_1, j_2 = 1 \\ j_1 < j_2}}^{N} f_{j_1, j_2}(x_{j_1}, x_{j_2}) \prod_{i=1, i\neq j_1, j_2}^{N} s_i(x_i) \\ & + \cdots + f_{1,2,...,N}(x_1, x_2, ..., x_N) \end{aligned} \tag{1}$$

where f_js stand for the EMPR components ordered in ascending multivariance. The univariate functions denoted by s_i are called support functions and x_js are elements of the corresponding interval $[\, a_j, b_j \,]$

There are 2^N unknown components given in a single equation. Some constraints apply to uniquely determine EMPR components. These constraints are constructed via vanishing integrals over the EMPR components except f_0. To define these integrals univariate weight functions the product of which defines a single multivariate weight function, are used.

$$W(x_1, ..., x_N) \equiv \prod_{i=1}^{N} W_i(x_i)\,. \tag{2}$$

These univariate weight function integrals over the relevant intervals given above are set equal to 1 to facilitate further analysis; these constraints are not necessary but provide the

averaging property to the weight function.

$$\int_{a_i}^{b_i} dx_i W_i\left(x_i\right) = 1, \qquad i = 1, ..., N \tag{3}$$

In order to be able to calculate the constant term f_0, the univariate terms $f_i(x_i)$, bivariate terms $f_{i_1 i_2}\left(x_{i_1}, x_{i_2}\right)$ and other multivariate terms the normalization condition defined by

$$\int_{a_i}^{b_i} dx_i W_i(x_i) s_i(x_i)^2 = 1; \quad i = 1, ..., N \tag{4}$$

and the vanishing condition defined by

$$\int_{a_i}^{b_i} dx_i W_i\left(x_i\right) s_i\left(x_i\right) f_{i_1 ... i_k}\left(x_{i_1}, ..., x_{i_k}\right) = 0, \;\; x_i \in \left(x_{i_1}, ..., x_{i_k}\right), \; 1 \leq i \leq k \leq N \tag{5}$$

are to be used.

3 EMPR for Bivariate Functions

A new matrix decomposition method called "Tridiagonal Matrix Enhanced Multivariance Products Representation ", has been developed. The elements of a matrix being indicated by two indices which take positive integer values, independently from the other index values, this allows us to construct, so-called "Discrete Bivariate EMPR, over the matrices. Following this step we have to search for a method to apply this construction to corresponding bivariate functions. To this end we can write the following equality for a given bivariate function $f\left(x, y\right)$

$$f\left(x, y\right) = f_0 u(x) v(y) + f_1(x) v(y) + f_2(y) u(x) + f_{1,2}(x, y) \tag{6}$$

where u and v are the support functions. In this construction we will use the unit interval $\left[\, 0, 1 \,\right]$ for both independent variables, x and y without any loss of generality Beyond that the weight factors are defined as follows

$$W_1\left(x\right) \equiv 1, \;\; W_2\left(y\right) \equiv 1, \qquad x, y \in \left[\, 0, 1 \,\right]. \tag{7}$$

The support functions are assumed to have unit norms over the above intervals and under the above weights

$$\int_0^1 dx u\left(x\right)^2 = 1, \qquad \int_0^1 dy v\left(y\right)^2 = 1 \tag{8}$$

 ISBN: 978-84-617-8694-7

For this case the vanishing conditions should be taken as constraints imposed on $f_1(x)$, $f_2(y)$ and, $f_{1,2}(x,y)$. They can be written as follows

$$\int_0^1 dx f_1(x)u(x) = 0, \qquad \int_0^1 dy f_2(y)v(y) = 0 \tag{9}$$

$$\int_0^1 dx f_{1,2}(x,y)u(x) = 0, \qquad \int_0^1 dy f_{1,2}(x,y)v(y) = 0 \tag{10}$$

These equations allow us to evaluate the EMPR terms uniquely as

$$f_0 = \int_0^1 dx \int_0^1 dy f(x,y)\, u(x)\, v(y) \tag{11}$$

$$f_1(x) = \int_0^1 dy f(x,y)\, v(y) - f_0 u(x) \tag{12}$$

$$f_2(y) = \int_0^1 dx f(x,y)\, u(x) - f_0 v(y) \tag{13}$$

$$f_{1,2}(x,y) = f(x,y) - f_0 u(x)\, v(y) - f_1(x)\, v(y) - f_2(y)\, u(x). \tag{14}$$

These four equations can be used to obtain more concise expressions for EMPR terms and EMPR's itself.

EMPR is an orthogonal decomposition of the target function into two components in the space spanned by $u(x)$ and in its complementary space and another two components in the space spanned by $v(y)$ and in its complementary space. Therefore "EMPR is a decomposition projecting onto the spaces spanned by support functions and their complementary spaces.

Finally to reach (TKEMPR) construct which consists of using EMPR bivariate function decomposition consecutively such that in each step the remainder term is expanded to again a bivariate EMPR but with different support functions.

4 Contour Integration

n-th order derivative of a function can be expressed in terms of a contour integral as follows

$$f^{(n)}(x) = \frac{n!}{2\pi i} \oint_C d\xi \frac{f(\xi)}{(\xi - x)^{n+1}}, \tag{15}$$

 ISBN: 978-84-617-8694-7

where we can make a change of variable

$$\xi = x + re^{i\theta}, \qquad d\xi = ire^{i\theta}d\theta \tag{16}$$

Thus we obtain a new expression of the nth derivative of the function followed by separation of the integration interval into two

$$\begin{aligned} f^{(n)}(x) &= \frac{in!r}{2\pi i}\int_0^{2\pi} d\theta \frac{e^{i\theta} f\left(x + re^{i\theta}\right)}{r^{n+1}e^{i(n+1)\theta}} \\ &= \frac{n!}{2\pi r^n}\int_0^{2\pi} d\theta e^{-in\theta} f\left(x + re^{i\theta}\right) \\ &= \frac{n!}{2\pi r^n}\int_0^{\pi} d\theta e^{-in\theta} f\left(x + re^{i\theta}\right) + \frac{n!r}{2\pi r^n}\int_{\pi}^{2\pi} d\theta e^{-in\theta} f\left(x + re^{i\theta}\right) \end{aligned} \tag{17}$$

Making another change of variable for the second of the integrals

$$\theta \to 2\pi - \theta, \qquad d\theta \to -d\theta \tag{18}$$

and factoring out the constants and rearranging all the rest, we obtain the below expression

$$\begin{aligned} f^{(n)}(x) &= \frac{n!}{2\pi r^n}\left[\int_0^{\pi} d\theta e^{in\theta} f\left(x + re^{i\theta}\right) + \int_0^{\pi} d\theta e^{-in\theta} f\left(x + re^{-i\theta}\right)\right] \\ &= \frac{n!}{\pi r^n}\int_0^{\pi} d\theta \frac{1}{2}\left[e^{in\theta} f\left(x + re^{i\theta}\right) + e^{-in\theta} f\left(x + re^{-i\theta}\right)\right] \end{aligned} \tag{19}$$

Now, setting $\theta = \pi\theta$ gives

$$f^{(n)}(x) = \frac{n!}{r^n}\int_0^{1} d\theta \frac{1}{2}\left[e^{in\pi\theta} f\left(x + re^{i\pi\theta}\right) + e^{-in\pi\theta} f\left(x + re^{-i\pi\theta}\right)\right] \tag{20}$$

To proceed let us define the following function

$$1_f \equiv \begin{cases} 1 & 0 \le \theta \le 1 \\ 0 & other \end{cases} \tag{21}$$

Therefore same expression can be written as

$$f^{(n)}(x) = \frac{n!}{r^n}\int_0^{1} d\theta K(\theta, x) 1_f \tag{22}$$

where $K(\theta, x)$ is the bivariate kernel function necessary for us to apply TKEMPR

$$K(\theta, x) \equiv \frac{1}{2}\left[e^{in\pi\theta} f\left(x + re^{i\pi\theta}\right) + e^{-in\pi\theta} f\left(x + re^{-i\pi\theta}\right)\right] \tag{23}$$

 ISBN: 978-84-617-8694-7

5 Method

Let us consider the following identity

$$f(x) = f(a) + \int_a^x dt f'(t) \tag{24}$$

which can be rewritten as follows

$$f(x) = f(a) - \int_a^x d(x-t) f'(t) \tag{25}$$

and via integration by parts

$$f(x) = f(a) + f'(a)(x-a) + \int_a^x dt(x-t) f''(t) \tag{26}$$

Finally via repeated use of integration by parts the following expression is obtained

$$f(x) = f(a) + f'(a)(x-a) + \ldots + \frac{1}{k!} f^{(k)}(a)(x-a)^k + \frac{1}{k!} \int_a^x dt(x-t)^k f^{(k+1)}(t) \tag{27}$$

The integral at the end of the above expression can also be written as

$$\int_a^x dt(x-t)^k f^{(k+1)}(t) = \frac{(x-a)^{k+1}}{k+1} \int_0^1 dt(k+1)(1-t)^k f^{(k+1)}\left((x-a)t + a\right) \tag{28}$$

Now after constructing a bivariate form for the integrand we have to adapt it to the proper form mentioned in bivariate (EMPR)

At this stage, this is again a bivariate function which needs our attention in terms of (EMPR). This process can be repeated as many times as we need and each time we add a new step a better approximation will be obtained.

A final step after making sufficient number of iterations to approximate the bivariate function $K(\theta, x)$ is to integrate the latter over the interval $[0, 1]$ to obtain back the intended approximation of our original integrand $f^{(k+1)}(x)$

6 Conclusion

The decomposition obtained by applying (TKEMPR) to a univariate function expanded to Taylor series, after having obtained a bivariate counterpart of the integrand it via contour integration provides us with a good approximation to the bivariate kernel. Finally if we integrate this kernel over the unit interval we obtain an approximation to the original function.

Abstract

In this paper a general formulation for the kinetics of multi-step enzymatic reactions is presented. The optimal enzyme and metabolite concentrations are studied for the problem of minimizing the operation time in which the substrate is converted into the product. We give an analytic solution for three different kinetic models for both the unbranched and branched cases. Sufficient conditions for the optimality of the solution are studied. Several examples are presented.

Key words: Optimal Control, Kinetic models
MSC 2000: 49J30, 49M05, 80A30.

1 Introduction

The kinetics of multi-step enzymatic reactions is an ongoing research topic and, in it, the minimization of the operation time in which the substrate is transformed into the product is one of the classical problems which is being currently studied. In it, one measures the optimal profiles of both the enzyme and the metabolite. Our aim in this work is to obtain a general analytic solution for this problem. This way, we avoid the unwieldy numerical solutions, which are always tainted by the specific traits of each particular problem.

In the last years, several results have been presented on the topic. In many of them, an unbranched reaction chain of n irreversible reaction steps is studied (e.g. [1], where an explicit solution for the simplest case, $n = 2$ with linear kinetic model, is given). A mathematical model of an unbranched reaction chain with $n = 3$ and obeying the Michaelis-Menten (MM) kinetic model is used in [2]. In [3], a quasi-analytic solution is found for $n = 3$

and linear kinetics. In [4], the general case of n steps with MM kinetic model is analyzed and quantitative properties are presented, although the authors do not give an explicit analytical solution. In [5], we use a linear kinetic model for the solution of the general case of n steps. Later, in [6], we improve our results with a quasi-analytical solution for the n-steps MM model using the Lambert W-function.

Branched pathways have also been studied, certainly, but only specific cases. In [7], a network inspired in the glycolysis, with the MM model, is considered. The same example is revisited in [8] and a new pathway with two outputs is presented. Other objective functionals may also be considered, like maximizing the productivity of the metabolite [9] or the flux of a particular metabolite [10]. However, in this work we shall minimize the operation time to obtain a specified concentration of the final product.

The numerical methods for the solution of our dynamic optimization problem are usually classified into two groups: direct and indirect methods. Direct methods include complete parametrization [11], multiple shooting [12] or control vector parametrization [13]. In all of them, the basic idea is to transform the original problem into a non-linear programming problem by discretizing and approximating the control and the state variables.

On the other hand, the indirect methods solve the optimization problem using Pontryagin's Minimum Principle (PMP) taking into account the necessary optimality conditions. In this paper, the problem is stated as an Optimal Control Problem (OCP) and using PMP [14] we obtain the solution. Even more (and this is unusual in the literature), we shall also study the sufficient conditions to obtain an optimum. We also remark that we allow the possibility of using three different kinetic models in the same example. Finally, we consider not only an unbranched metabolic pathway but also a branched scheme. We obtain general, model-independent laws, for the first time.

The paper is organized as follows. In Section 2 we present the statement of the problem. The general laws of the optimal solution are obtained in Section 3, and a new kinetic model, the power law, is also presented. Section 4 contains a study on the verification of the sufficient conditions. Then we generalize the problem to the branched case with a statement valid for any graph satisfying some specific conditions. In Section 6 we present a model based on glycolysis which we aim to study numerically.

2 Statement of the problem

For the sake of simplicity we start with the simplest case of an unbranched metabolic pathway composed of n irreversible reaction steps converting substrate x_1 into product p. The value $x_1(t)$ is the substrate concentration at time t, $p(t)$ the concentration of the final product, $x_i(t), (i = 2, \ldots, n)$ the concentration of the intermediate compounds, and $u_i(t)$ $(i = 1, \ldots, n)$ the concentration of the enzyme catalyzing the i-th reaction (see Fig. 1).

 ISBN: 978-84-617-8694-7

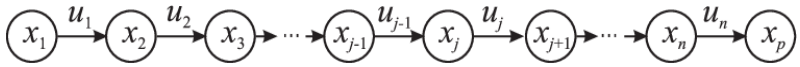

Fig. 1. Unbranched scheme.

Once we have fully studied this case, we shall perform the generalization to the branched one. The rate of the i-th reaction, $v_i(x_i(t), u_i(t))$ is linear in the enzyme concentrations, u_i:

$$v_i(x_i(t), u_i(t)) = w_i(x_i(t)) \cdot u_i(t) \tag{1}$$

The following are frequently used kinetic models:

$$\begin{aligned} w_i(x_i) &= k_i x_i && \text{(Mass action)} \\ w_i(x_i) &= \frac{k_i x_i}{K_i + x_i} && \text{(Michaelis-Menten)} \\ w_i(x_i) &= k_i x_i^c && \text{(Power law)} \end{aligned} \tag{2}$$

The dynamical model for the pathway is given by the law of conservation of mass:

$$\dot{x}_i(t) = v_{i-1}(x_{i-1}(t), u_{i-1}(t)) - v_i(x_i(t), u_i(t)); \ (i = 1, \ldots, n). \tag{3}$$

The objective is to transform x_1 into p as fast as possible; we denote t_f the final time. We assume an exhaustible initial substrate, x_1, and imposing $p(t_f) = C_f$ $(0 < C_f < 1)$, we obtain:

$$x_1(t_f) + x_2(t_f) + \ldots + x_n(t_f) = 1 - C_f \tag{4}$$

so that the optimization problem may thus be stated as the control problem (Pr):

$$\begin{aligned} &\text{(Pr):} && \tau_{C_f} = \min_{u_1, \ldots u_n} \int_0^{t_f} dt = \min_{u_1, \ldots u_n} t_f \\ &\text{subject to:} && (3), (4) \\ & && u_1 \geq 0, \ldots u_n \geq 0; \ u_1 + \ldots + u_n \leq 1 \end{aligned} \tag{5}$$

3 Optimal Solution

In two previous papers, we used PMP to obtain the solution to (Pr) for the mass action model [5] and for the MM model [6]. When the control appears linearly, as is the case for the problem under consideration, the control switches between its upper and lower bounds at discrete instants: the optimal control is said to be a *bang-bang type control* and those instants are called the *switching times*. The general form of the solution can be described

as follows: there exist n switching times, as many as enzymes, so that the optimal i-enzyme profile is proved to be of bang-band type and satisfies:

$$u_i(t) = \begin{cases} 1 & \text{for} \quad t \in [t_{i-1}, t_i) \\ 0 & \text{for} \quad t \notin [t_{i-1}, t_i) \end{cases} \; ; \; i = 1, \ldots, n \tag{6}$$

where $\{t_0, t_1, t_2, ..., t_n\}$ are the switching times, with $t_0 = 0$ and $t_n = t_f$.

We shall denote by $x_{ji}(t)$ (for $i, j = 1, \ldots, n$) the optimal j-th metabolite concentration, in the i-th interval $[t_{i-1}, t_i]$. The optimal solution of the complete system can be described on each interval, knowing that on the i-th interval, $[t_{i-1}, t_i]$ (for $i = 2, \ldots, n-1$), there are 4 laws governing the metabolite concentrations:

(a) Metabolites before the i-th remain at a constant value given by:

$$x_{ji}(t) = x_{jj}(t_j) \text{ for } j = 1, \ldots, i-1 \tag{7}$$

(b) The i-th metabolite follows a law given by a function depending on: the parameters of the model, the previous switching time, and the value of the i-th metabolite on the previous interval:

$$x_{ii}(t) = f(x_{ii-1}(t_{i-1}), t_{i-1}, t) \tag{8}$$

(c) The $i+1$-th metabolite follows a law obtained from the one of the previous metabolite as follows:

$$x_{i+1i}(t) = x_{ii-1}(t_{i-1}) - x_{ii}(t) \tag{9}$$

(d) Metabolites from the $i+2$-th on have not been activated yet, so that their value is zero:

$$x_{ji}(t) = 0 \text{ for } j = i+2, \ldots, n \tag{10}$$

A schematic idea is shown in Fig. 2.

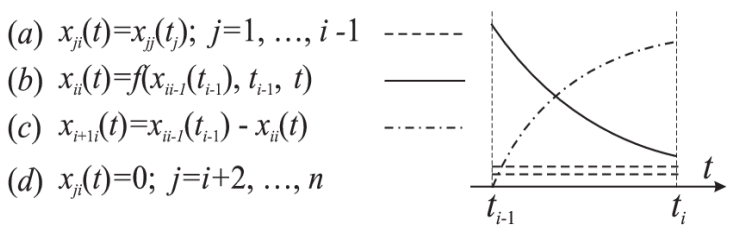

Fig. 2. Optimal concentration laws for the metabolites.

On the first interval ($i = 1$), letting $x_{10}(t_0) = 1$, only Laws (b), (c) and (d) apply; on the last-but-one ($i = n-1$), only Laws (a), (b) and (c) apply; whereas on the last one ($i = n$), only Laws (a) and (b).

 ISBN: 978-84-617-8694-7

Notice that the formulas above are general and they only depend on the kinetic model (Law (b)). In [5] we obtained the law for the mass action model (i.e. the linear one), getting:

$$x_{ii}(t) = f(x_{ii-1}(t_{i-1}), t_{i-1}, t) = x_{ii-1}(t_{i-1}) \exp(-k_i(t - t_{i-1})) \tag{11}$$

Elsewhere, in [6], we obtained the law for the Michaelis-Menten model, which gives:

$$\begin{aligned} x_{ii}(t) &= f(x_{ii-1}(t_{i-1}), t_{i-1}, t) & (12)\\ &= K_{mi} W\left(\frac{x_{ii-1}(t_{i-1})}{K_{mi}} \exp\left(\frac{x_{ii-1}(t_{i-1})}{K_{mi}}\right) \exp\left(-\frac{k_i}{K_{mi}}(t - t_{i-1})\right)\right) & (13)\end{aligned}$$

where W is the Lambert W-function.

We present, for the first time, in this paper, the expression of Law (b) for the kinetic model given by the power law. The expression is now:

$$\begin{aligned} x_{ii}(t) &= f(x_{ii-1}(t_{i-1}), t_{i-1}, t) & (14)\\ &= \left[(x_{ii-1}(t_{i-1}))^{1-c} - (1-c)k_i(t - t_{i-1})\right]^{(1-c)^{-1}} & (15)\end{aligned}$$

The method for computing this optimal solution is analogous to the one we shown in our previous papers, and we refer the reader to them (mainly Appendix 1 in [6], where it is given in detail).

The idea is to define the Hamiltonian $H(x_1, \ldots, x_n, u_1, \ldots, u_n, \lambda_1 \ldots, \lambda_n, t)$ associated to the problem (Pr):

$$\begin{aligned} H &= 1 + \sum_{i=1}^{n} \lambda_i \dot{x}_i(t) & (16)\\ &= 1 + \sum_{i=1}^{n} \lambda_i \left[w_{i-1}(x_{i-1}(t)) \cdot u_{i-1}(t) - w_i(x_i(t)) \cdot u_i(t)\right] & (17)\end{aligned}$$

and compute the optimum values for x_i and u_i applying the necessary conditions in PMP on that Hamiltonian. In this case:

$$\begin{aligned} &\text{(i)} \quad \dot{\lambda}_i(t) = -\frac{\partial H}{\partial x_i}; \lambda_i(t_f) = 0,\ i = 1, ..., n\\ &\text{(ii)} \quad \min_{u_1, \ldots u_n} H\\ &\text{(iii)} \quad \dot{x}_i(t) = w_{i-1}(x_{i-1}(t)) \cdot u_{i-1}(t) - w_i(x_i(t)) \cdot u_i(t);\ x_i(0) = x_{i0},\ i = 1, ..., n\\ &\text{(iv)} \quad H(x_1, \ldots, x_n, u_1, \ldots, u_n, , \lambda_1 \ldots, \lambda_n, t_f) = 0\end{aligned} \tag{18}$$

Our system is autonomous, so that $H_t \equiv 0 \Rightarrow H(t) = cte$. This condition together with (iv) implies that $H(t) = 0$.

 ISBN: 978-84-617-8694-7

We obtain the optimal solution constructively by intervals, starting at $t = 0$ and concatenating the results. Once these values are computed, one still needs to calculate the switching times $t_1, t_2, \ldots, t_{n-1}$ and the operation time t_f. To this end, we use the restriction (4) and define the augmented functional:

$$L(t_1, t_2, \ldots, t_{n-1}, t_f, \beta) = t_f + \beta(x_{1n}(t_f) + x_{2n}(t_f) + \cdots + x_{nn}(t_f) - C_f) \tag{19}$$

where the values of the concentrations $x_{1n}(t_f) = x_{1n}(t_1)$, $x_{2n}(t_f) = x_{2n}(t_2)$, $\ldots, x_{nn}(t_f)$ are given, and where the unknowns $t_1, t_2, \ldots, t_{n-1}$ and t_f appear. Then we solve the non-linear system:

$$\frac{\partial L}{\partial t_1} = 0; \frac{\partial L}{\partial t_2} = 0; \ldots; \frac{\partial L}{\partial t_{n-1}} = 0; \frac{\partial L}{\partial t_f} = 0; \frac{\partial L}{\partial \beta} = 0 \tag{20}$$

Once the optimal values of the switching times $t_1, t_2, \ldots, t_{n-1}$ and t_f are obtained numerically, the remaining values of the solution are immediately obtained analytically using the closed-form formulas (a) to (d), and the problem is completely solved.

Notice that, remarkably, the laws given above allow the simultaneous consideration of several models when studying the pathway: one just needs to use the appropriate function $f(x_{ii-1}(t_{i-1}), t_{i-1}, t)$ in Law (b).

4 Sufficient Conditions

Considering the optimal control problem, with $x(t)$ and $u(t)$ denoting n-dimensional vectors:

$$\min_{u(t)} J = \int_0^T F(x(t), u(t), t)dt + B[T, x(T)] \tag{21}$$

$$\dot{x}(t) = f(x(t), u(t), t);\ x(0) = x_0 \tag{22}$$

$$u(t) \in U(t),\ 0 \leq t \leq T \tag{23}$$

we can guarantee the sufficient conditions for the existence of an optimal solution using Arrow's Theorem [14] (this sufficiency is not considered in the previous works [4], [5], [6]).

In our case:

$$\min_{u(t)} J = \min_{u_1, \ldots u_n} \int_0^{t_f} dt \tag{24}$$

$$\dot{x}_i(t) = w_{i-1}(x_{i-1}(t)) \cdot u_{i-1}(t) - w_i(x_i(t)) \cdot u_i(t), \quad i = 1, \ldots, n \tag{25}$$

$$u_1 \geq 0, \ldots, u_n \geq 0;\ u_1 + \ldots + u_n \leq 1 \tag{26}$$

Upon minimizing $H(x, u, \lambda, t)$ in $u \in U(t)$ one obtains a function $u = u^0(x, \lambda, t)$ from which $H^0(x, u^0(x, \lambda, t), \lambda, t)$ can be computed. In each case, the equations of the model (Mass action, Michaelis-Menten and Power law) provide the sufficient conditions in one way or another.

 ISBN: 978-84-617-8694-7

5 Generalization

We present a generalization for branched pathways. The cases we cover are pathways whose graph of *temporal dependencies* satisfies a specific property (which essentially says that the i-th metabolite follows temporally the j-th one if and only if vertex j is joined with vertex i by a directed path (see [15] for the elementary notions).

These graphs represent the fact that the synthesis of one enzyme requires the degradation of *all the previous ones*; this is the case, for example, of the glycolysis, see [8]. Following that paper, we assume that the optimal profile follows a pattern matching the topology of the pathway, reflecting the fact that the enzymes are activated sequentially. Notice that the type of graphs we deal with have a strictly upper-triangular adjacency matrix (and more conditions, but this one is easy to verify).

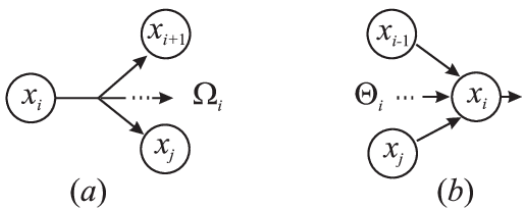

Fig. 3. Branched pathways.

With the same notation as above, the optimal solution of these branched systems can be described on the i-th interval $[t_{i-1}, t_i]$ ($i = 2, \ldots, n-1$) with these 4 laws:

- (a') For the metabolites before the $i-$th one:

$$x_{ji}(t) = x_{jj}(t_j) \text{ for } j = 1, \ldots, i-1 \tag{27}$$

- (b') For the i-th metabolite:

$$x_{ii}(t) = f(x_{ii-1}(t_{i-1}), t_{i-1}, t) \tag{28}$$

- (c') All the metabolites $j \in \Omega_i$ follow the same law:

$$x_{ji}(t) = x_{ji-1}(t_{i-1}) + x_{ii-1}(t_{i-1}) - x_{ii}(t) \tag{29}$$

- (d') The metabolites j-th such that $i < \min \Theta_j$, have not been activated yet:

$$x_{ji}(t) = 0 \tag{30}$$

The only differences with the unbranched system appear in (c') and (d').

 ISBN: 978-84-617-8694-7

6 Numerical Examples

We provide several simulations which illustrate the general formulations above. We shall use a test example already studied by several authors and inspired by the upper part of glycolysis. The original problem was stated by Bartl et al. in [7] and was also considered in [8] with a new formulation incorporating the enzyme dynamics.

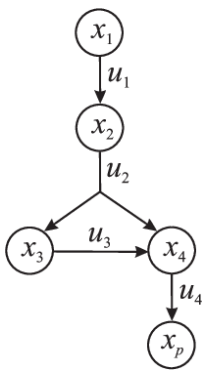

Fig. 4. Glycolysis inspired network.

The pathway (Fig. 4) consists of four enzymatic reactions with one branch. Recall that x_1 corresponds to the substrate, x_2, x_3 and x_4 are the intermediate metabolites and x_p represents the product. The alternative route of the glycolysis is represented by u_2 (corresponding to the enzyme aldolase) metabolizing the intermediate x_2 to x_3 and x_4.

The single aim is to minimize the time needed to transform the substrate x_1 into a fixed amount (90%) of product x_p, (i.e. $C_f = 0.9$). We assume unbuffered or exhaustible substrate x_1 (i.e. the substrate is consumed during the process) and enzymes are assumed to become activated instantaneously (just-in-time activation). The following initial conditions at $t = 0$: $x_0 = [1, 0, 0, 0, 0]^T$; $u_0 = [0, 0, 0, 0]^T$ are imposed. Metabolites and enzymes are expressed in concentration units and time in seconds.

Additionally, restrictions on enzyme concentrations and their total amount are introduced in a normalized form as:

$$u_1 \geq 0, \ldots u_n \geq 0; \; u_1 + \ldots + u_n \leq 1 \tag{31}$$

This is in agreement with the assumption that the cell can only allocate a certain amount of protein to a pathway, and with experimental observations [16] in Escherichia coli.

The classical theoretical studies ([7], [8]) are based on the Michaelis–Menten kinetics:

$$w_i(x_i) = \frac{k_i x_i}{K_i + x_i} \tag{32}$$

with unity rate constants for k_i and K_i: $k_i = 1(s^{-1})$, $K_i = 1(mM)$. However, we also give results for the other two laws we have studied: mass action and the power law.

Abstract

This work deals with a modified continuous time Leslie-Gower type predator-prey model, assuming the functional response is of sigmoid type and prey is affected by a double Allee effect. The main characteristic of this type of models is that the growth predator equation is a modification of the equation logistic, considering the environmental carrying capacity of predators proportional to the amount of available prey.

It may be observed the modified system has different dynamics which appear according to the parameter values; the existence of one, two or three equilibrium points can be proven; also, the existence of a limit cycle surrounding a unique positive equilibrium point may exist.

The existence of separatrix curves on the phase plane dividing the behavior of the trajectories is also demonstrated, which imply that two solutions very closed can have different $\omega - limit$; as consequence, solutions near of these separatrix curves, are highly sensitive to initial conditions.

Key words: Predator–prey model, functional response, bifurcation, limit cycle, separatrix curve, stability.

MSC 2000: AMS codes 92D25; 34C23; 58F14; 58F21

1 Introduction

In this work a modified Leslie-Gower predator-prey model is analyzed, which is described by an autonomous differential equation system, considering the following aspects:

i) the prey population is affected by a double Allee effect [11, 30],

ii) the functional response or predator consumption rate is sigmoid [27, 33], and

 ISBN: 978-84-617-8694-7

iii) the equation for predator growth is the logistic type. [1, 28, 33].

In this type of model, the conventional environmental carrying capacity for predators K_y is a function of the available prey quantity [2, 16, 25], in which K_y is proportional to prey abundance $x = x(t)$, that is, $K_y = K(x) = nx$. Denoting by $y = y(t)$ the predator population size in the logistic predator model, the quotient $\frac{y}{nx}$ is called the Leslie-Gower term. It measures the loss in the predator population due to scarce availability (per capita $\frac{y}{x}$) of its favorite food.

The formulation of the Leslie-Gower type predator-prey model is based on the assumption that reduction in a predator population has a reciprocal relationship with per capita availability of its preferred food. The importance of this model is highlighted by Collings [10] assuring that it provides a way to avoid the biological control paradox.

The Leslie-Gower type model may present anomalies in its predictions, as it can deduce that even in very low prey population density, when the consumption rate per predator is almost zero, predator population might increase, if the predator/prey ratio is very small [33]. This type of model has been used in different recent articles as [1, 17, 22, 23].

A important factor in the predation model is the predator functional response or consumption function, which refers to the change in attacked prey density per unit of time per predator when the prey population size changes [27]. In many predator-prey models it is assumed that the functional response grows monotonic, being the inherent assumption the more prey in the environment, the better for the predator [33].

We will consider that the predator consumption function is expressed by the sigmoid function $h(x) = \frac{q\ x^2}{x^2 + a^2}$ [5, 32], corresponding to the Holling type III [27]. The parameter a is a measure of the abruptness on the functional response [15]. If $a \to 0$, the curve grows quickly, while if $a \to K$, the curve grows slowly, i.e., a bigger amount of prey is required to attain $\frac{q}{2}$ [19].

On the other hand, Allee effects occur whenever fitness of an individual in a small or sparse population decreases as the population size or density also declines.

Various mechanisms generate Allee effects, for example: mate finding, reproductive facilitation, cooperative antipredator behaviour, predator dilution, etc. It can also be represented by many mathematical expressions [7, 16].

In [6, 12] it is suggested two or more Allee effects act simultaneously in the same population; the combined influence of this phenomenon has been named *multiple Allee effect* [6]. In [7] is proposed the equation

$$\frac{dx}{dt} = r\left(1 - \frac{x}{K}\right)\left(1 - \frac{m+b}{x+b}\right)x,$$

Here, if $m > 0$ it has a *strong Allee effect* and if $m = 0$ we have a special case of *weak Allee effect* [8, 34]. Algebraically, this equation can be rewritten as:

$$\frac{dx}{dt} = \frac{rx}{x+b}\left(1 - \frac{x}{K}\right)(x - m),$$

which represents a double Allee effect in prey [3, 20]. since the factor $r(x) = \frac{rx}{x+b}$ indicates the impact of a second Allee effect exerted by the non-fertile population, represented

 ISBN: 978-84-617-8694-7

by the parameter b.

In order to establish the local stability of the equilibrium points, the well-known results on the phase portraits of the planar systems near equilibria are utilized, determining the signs of the determinants and trace of the Jacobian matrix at the equilibria [5, 9, 24].

2 THE MODEL

The model to be analyzed is described by the following autonomous bidimensional differential equation system of Kolmogorov type [14]

$$X_\mu : \left\{ \begin{array}{rcl} \frac{dx}{dt} & = & \left(r\left(1-\frac{x}{K}\right)\left(1-\frac{m+b}{x+b}\right) - \frac{qxy}{x^2+a^2} \right) x \\ \frac{dy}{dt} & = & s\left(1-\frac{y}{nx}\right) y \end{array} \right. , \tag{1}$$

where $x = x(t)$ and $y = y(t)$ indicate the prey and predator population sizes respectively for $t \geq 0$, measure as the number of individuals, density or biomass. Clearly, system (1) can be rewritten as

$$X_\mu : \left\{ \begin{array}{rcl} \frac{dx}{dt} & = & \left(\frac{r}{x+b}\left(1-\frac{x}{K}\right)(x-m) - \frac{qxy}{x^2+a^2} \right) x \\ \frac{dy}{dt} & = & s\left(1-\frac{y}{nx}\right) y \end{array} \right. , \tag{2}$$

The parameters are all positive, i.e., $\mu = (r, K, q, a, s, n, b, m) \in \mathbb{R}^7_+ \times]-K, K[$ and for biological reasons $a, b < K$, having the following meanings:

r is the intrinsic prey growth rate or biotic potential,

K is the prey environmental carrying capacity,

b is the fraction of sterile population members,

m is the strong Allee effect threshold or minimum of viable prey population,

q is the maximum number of prey that can be eaten by a predator at each time unit (satiation rate),

a is the amount of prey to achieve one-half of the maximum rate q (the half saturation rate),

s is the intrinsic predator growth rate,

n is a measure of the food quality indicating how the predators turn eaten prey into new predator births.

The analysis must be made separately for $m > 0$, $m = 0$ and $m < 0$, because the properties of the system can change with respect to this parameter; however, due to the algebraic difficulties, we analyzed the model when $m = 0$ and partially when $m > 0$.

Clearly in system (1), the predator carrying capacity is $K(x) = nx$. It is interesting to note that the system is not defined at $x = 0$, but later will show that the point $(0, 0)$ has a strong influence on the dynamics of the system.

System (1) or vector field X_μ is defined at

$\Omega = \left\{(x,y) \in \mathbb{R}^2 / \ x > 0, \ y \geq 0\right\} = \mathbb{R}^+ \times \mathbb{R}_0^+$.

The equilibrium points are $(0,0)$, $(m,0)$ $(K,0)$ and (x_e, y_e) satisfying the equation of the isoclines $y = nx$ and $y = \frac{r}{qx(x+b)}\left(1-\frac{x}{K}\right)(x-m)\left(x^2+a^2\right)$. The point (x_e, y_e) can be a positive equilibrium point (equilibrium at interior of the first quadrant) or cannot exist there. So, the abscise x_e satisfies the equation

$$P(x) = x^4 - (K+m-Knq)x^3 + (a^2+Km+Kbnq)x^2 - a^2(K+m)x + Ka^2m = 0$$

In order to simplify the calculus we follow the methodology used in [18, 21], making a change of variable and a time rescaling; we have

Proposition 1 *System* (1) *is topologically equivalent to*

$$U_\eta : \left\{ \begin{array}{rcl} \frac{du}{d\tau} = & \left((1-u)(u-M)\left(u^2 + A^2\right) - Quv(u+B)\right)u^2 \\ \frac{dv}{d\tau} = & S(u-v)(u+B)\left(u^2 + A^2\right)v \end{array} \right. , \tag{3}$$

defined in $\bar{\Omega} = \{(u,v) \in \mathbb{R}^2 / \ u \geq 0, \ v \geq 0\}$, *where* $\eta = (A,B,Q,S,M) \in \Delta =]0,1[^2 \times \mathbb{R}_+^2 \times]-1,1[$, *with* $A = \frac{a}{K}$, $B = \frac{b}{K}$, $Q = \frac{nq}{r}$, $S = \frac{s}{r}$ *and* $M = \frac{m}{K}$.

Proof. Using the change of variables given by $x = Ku$ and $y = nKv$, replacing in (1), we have

$$V_\mu : \left\{ \begin{array}{rcl} \frac{du}{dt} & = & \left(r(1-u)\left(1-\frac{m+b}{Ku+b}\right) - \frac{q(Ku)(nKv)}{(Ku)^2+a^2}\right)u \\ \frac{dv}{dt} & = & s\left(1-\frac{nKv}{nKu}\right)v \, . \end{array} \right.$$

After simplification and factoring, the new vector field is

$$V_\mu : \left\{ \begin{array}{rcl} \frac{du}{dt} & = & r\left((1-u)\left(1-\frac{\frac{m}{K}+\frac{b}{K}}{u+\frac{b}{K}}\right) - \frac{qn}{r}\frac{uv}{u^2+\left(\frac{a}{K}\right)^2}\right)u \\ \frac{dv}{dt} & = & s\left(1-\frac{v}{u}\right)v \, . \end{array} \right.$$

By means of the time rescaling given by $t = \frac{1}{r}\left(u+\frac{b}{K}\right)u\left(u^2+\left(\frac{a}{K}\right)^2\right)\tau$ and by using the chain rule, it follows

$$Y_\mu : \left\{ \begin{array}{rcl} \frac{du}{dt} & = & \left((1-u)\left(u-\frac{m}{K}\right)\left(u^2+\left(\frac{a}{K}\right)^2\right) - \frac{qn}{r}uv\left(u+\frac{b}{K}\right)\right)u \\ \frac{dv}{dt} & = & \frac{s}{r}(u-v)\left(u+\frac{b}{K}\right)\left(u^2+\left(\frac{a}{K}\right)^2\right)v \end{array} \right.$$

Finally, replacing the new parameters A, B, Q, S, M, we obtain system (2).

Therefore, we have constructed the diffeomorphism [9] $\varphi : \bar{\Omega} \times \mathbb{R} \longrightarrow \Omega \times \mathbb{R}$,

so that

$\varphi(u,v,\tau) = \left(Ku, nKv, \frac{1}{r}\left(u+\frac{b}{K}\right)u\left(u^2+\left(\frac{a}{K}\right)^2\right)\tau\right) = (x,y,t)$

and we have that

$\det D\varphi(u,v,\tau) = \frac{Kn}{r}\left(u+\frac{b}{K}\right)u\left(u^2+\left(\frac{a}{K}\right)^2\right) > 0.$

Thus, φ is a diffeomorphism preserving the time orientation; thus, the vector field X_μ, is topologically equivalent to the vector field $U_\eta = \varphi \circ X_\mu$ with $U_\eta = P(u,v)\frac{\partial}{\partial u} +$

 ISBN: 978-84-617-8694-7

$Q(u,v)\ \frac{\partial}{\partial v}$and the associated differential equation system is given by the polynomial system of fourth degree. ■

The equilibrium points of system (3) or singularities of vector field U_η are $(0,0)$, $(M,0)$, $(1,0)$, and the points lie in the intersection of the isoclinic curves

$v = \frac{(1-u)(u-M)\left(u^2\ +\ A^2\right)}{Qu(u+B)}$ and $v = u$.

Then, the abscissa u is solution of the fourth degree equation:

$$p(u) = u^4 - (1+M-Q)u^3 + (A^2+M+BQ)u^2 - A^2(M+1)u + A^2M = 0 \qquad (4)$$

This equation can have up to four positive roots and different cases must be studied. Due to this algebraic complexities and because the dynamics of model depend on the parameter M, we will focused our study for the case $M = 0$.

The local stability of equilibrium points is determined by the Jacobian or community matrix [4] given by

$$DU_\eta\,(u,v) = \begin{pmatrix} DU_\eta\,(u,v)_{11} & -Q\,(u+B)\,u^3 \\ DU_\eta\,(u,v)_{21} & S\,(u-2v)\left(A^2+u^2\right)(u+B) \end{pmatrix}$$

where

$DU_\eta\,(u,v)_{11} = -u(6u^4 - 5\,(M+1)\,u^3 + 4\left(A^2+M+Qv\right)u^2 + 3\left(BQv - A^2 - A^2M\right)u + 2A^2M)$,

$DU_\eta\,(u,v)_{21} = Sv\left(4u^3 + 3\,(B-v)\,u^2 + 2\left(A^2 - Bv\right)u + A^2\,(B-v)\right)$.

3 MAIN RESULTS

For system (3) we have the following general properties:

Lemma 2 *1, The set* $\bar{\Gamma} = \left\{(u,v) \in \tilde{\Omega}/\ 0 \le u \le 1,\ v \ge 0\right\}$ *is an invariant region*

2. The solutions are bounded

Proof. 1. Clearly the $u-axis$ and the $v-axis$ are invariant sets because the system is of Kolmogorov type. If $u = 1$, we have

$\frac{du}{d\tau} = -Q\,(1+C)\,v < 0$

and whatever it is the sign of

$\frac{dv}{d\tau} = S\,(1+A)\,(\ 1 + C -\ v)\ v$

the trajectories enter and remain in the region $\tilde{\Gamma}$.

2. We use the Poincaré compactification [9, 13] given by the change of variables $u = \frac{w}{z}$ and $v = \frac{1}{z}$, to obtain a new system with a zero Jacobian matrix. To desingularize the origin we use the blowing-up method; then, we have that $(0,0)$ is a non-hyperbolic saddle point; hence, the point $(0,\infty)$ in the compactified system (3) is a non-hyperbolic saddle point. ■

 ISBN: 978-84-617-8694-7

3.1 Nature of equilibrium points over axis

Lemma 3 *For all* $\eta = (A, S, C, Q) \in]0, 1[\times\mathbb{R}^3_+$

1. *The singularity* $(1, 0)$ *is a hyperbolic saddle point.*
2. *The equilibrium* $(M, 0)$ *is a hyperbolic repellor.*

Proof. Evaluating the Jacobian matrix in each point is immediate that
1) $\det DY_\eta\,(1,0) = -S\,(A+1)^2\,(1+B)\,(1-M) < 0$.
Therefore, the equilibrium $(1, 0)$ is saddle point.
2) $\det DY_\eta\,(M,0) = SM^3\,(1-M)\left(A^2+M^2\right) > 0$ and
$\mathrm{tr}DY_\eta\,(M,0) = M(A^2+M^2)(M(1-M)+S(B+M)) > 0$.
Then, the equilibrium $(M, 0)$ is a repellor point. ■ $\bar{\Sigma}$

Lemma 4 *The point* $(0, 0)$ *of the vector field* U_η *has a hyperbolic and a parabolic sector [29], determined for the line* $v = \frac{M+BS}{BS}u$*, i.e., there exists a separatrix curve* $\bar{\Sigma}$*, inthephaseplanethatdividesthebel is then an attractor point for certain trajectories and a saddle point for others.*

Proof. As $DY_\eta\,(0,0)$ is the zero matrix, we use the horizontal blowing-up given by the function $W\,(p,q) = (p, pq) = (u, v)$.

In the new vector field U_η the singularities are $(0, 0)$ and $\left(0, \frac{M+BS}{BS}\right)$, which are a hyperbolic saddle point and an attractor point, respectively. Then, a separatrix straight line exists in the phase plane pq, determined by $v = \frac{M+BS}{BS}u$.

Then, using the blowing down, the point $(0, 0)$ is a saddle-node in the vector field U_η; thus, there exist a curve dividing the behavior of trajectories on the phase plane. ■

3.2 A Special Case of a Weak Allee Effect

When $M = 0$, a particular case of the weak Allee effect is described by the system:

$$U_\zeta : \begin{cases} \frac{du}{d\tau} &= ((1-u)(u^2+A^2) - Q(u+B)v)u^3 \\ \frac{dv}{d\tau} &= S(u-v)(u+B)(u^2+A^2)v, \end{cases} \tag{5}$$

where $\zeta = (A, B, Q, S) \in (]0, 1[)^2 \times \mathbb{R}^2_+$. In this case, there are only two equilibrium points on the axes, $(0, 0)$ and $(1, 0)$, since $(M, 0)$ coincides with the origin. Now, the polynomial (4) can be factored as $up^*\,(u)$, where

$$p^*\,(u) = u^3 - (1-Q)\,u^2(\left(A^2+BQ\right)u - A^2. \tag{6}$$

Using Descartes's rule of signs on the polynomial $p^*\,(u)$ we have that:

1. There exists a unique positive root, if and only if, $1 - Q \leq 0$.

2. There are three, two (one of multiplicity two) or one positive real roots, if and only if, $1 > Q$. In any case, we can assure that there is at least one positive real root denoted by H. Making synthetic division between $p^*\,(u)$ and $u - H$ we obtain:

 ISBN: 978-84-617-8694-7

$$p^*(u) = (u-H)\left(u^2 - (1-Q-H)u + BQ + A^2 - H(1-Q-H)\right),$$

and the condition

$$Q = \frac{(1-H)\left(A^2+H^2\right)}{H(B+H)}.$$

As $Q > 0$ then $H < 1$. So, the quadratic factor of p^* can be written as

$$q(u) = u^2 - \frac{(1-H)\left(BH-A^2\right)}{H(B+H)}u + \frac{A^2}{H}.$$

Again, using Descartes's rule of signs for the polynomial $q(u)$ we have that:

1. No positive roots exist, if and only if, $BH - A^2 \leq 0$.
2. Assuming, $BH - A^2 > 0$, we analyze the discriminant:

$$D_q = \left(\frac{(1-H)\left(BH-A^2\right)}{H(B+H)}\right)^2 - 4\frac{A^2}{H}.$$

Then,

2.1 There no exist positive roots, if and only if, $D_q < 0$.

2.2 There exists a unique positive root of multiplicity two, if and only if, $D_q = 0$. This root is given by

$H_0 = \frac{(1-H)\left(BH-A^2\right)}{2H(B+H)}$.

2.3 There exist two positive roots, if and only if, $D_q > 0$, which are given by

$H_{1,2} = \frac{1}{2}\left(\frac{(1-H)\left(BH-A^2\right)}{2H(B+H)} \pm \sqrt{D_q}\right)$.

Lemma 5 *For system* (5) *inside the region* $\bar{\Gamma}$ *we have:*

a. If $BH \leq A^2$ *or else* $A^2 < BH$ *and* $D_q < 0$*, then the system has a unique positive equilibrium point:* $P_H = (H, H)$.

b. If $A^2 < BH$ *and* $D_q = 0$*, then the system has two singularities:* (H, H) *and* (H_0, H_0).

c. If $A^2 < BH$ *and* $D_q > 0$*, then the system has three singularities:* (H, H), (H_1, H_1) *and* (H_2, H_2).

In this case, the Jacobian matrix of system (5) has the same components that the Jacobian matrix of system (3), except the first entry given by

$DU_\zeta(u,v)_{11} = -u^2\left(6u^3 - 5u^2 + 4\left(A^2+Qv\right)u + 3\left(BQv - A^2\right)\right)$.

We recall that, for all parameter values the equilibrium point $(1, 0)$ is a hyperbolic saddle point for all parameter values.

 ISBN: 978-84-617-8694-7

Lemma 6 *The equilibrium point* $(0,0)$ *of the vector field* U_ζ *has two hyperbolic sectors and one parabolic sector determined by the straight line* $v = u$*, i.e., there exists a separatrix curve* $\bar{\Sigma}_0$ *in the phase plane that divides the behavior of trajectories; the point* $(0,0)$ *is a point attractor for certain trajectories, a saddle point for others and a repellor point for others.*

Proof. The proof is similar to that of Lemma 4. The Jacobian matrix of the vector field U_ζ evaluated at $(0,0)$ is the zero matrix, then we use the horizontal blowing-up. The demonstration is in two parts with the understanding that in this case the origin represents the collapse of three points: two obtained in Lemma 4 and the other point $(M,0)$.

Based on the properties of the points $(0,0)$, $\left(0, \frac{M+BS}{BS}\right)$ and $(M,0)$ of system (3), we can see that there exists the separatrix curve $\bar{\Sigma}_0$ and the origin is an attractor point for certain trajectories, a saddle point for some and a repellor point for others. ■

The determinant of the Jacobian matrix evaluated in the equilibrium point (u,u) is
$\det DU_\zeta(u,u) = Su^3\left(A^2+u^2\right)(B+u)\left((1-Q)u^2 - 2\left(A^2+BQ\right)u + 3A^2\right)$;
then, the sign of $\det DU_\zeta(u,u)$ depends on the factor
$\mathrm{d}[u] = (1-Q)u^2 - 2\left(A^2+BQ\right)u + 3A^2$.
The trace of the Jacobian matrix is
$TrDU_\zeta(u,u) = -u\,(t\,[u])$
where the factor $t\,[u]$ is
$\mathrm{t}[u] = (1-2Q+S)u^3 - \left(2A^2+3BQ-BS\right)u^2 + A^2(S+3)u + A^2BS$.

Now, suppose $BH \leq A^2$ or $A^2 < BH$ and $D_q < 0$; then, the system has a unique positive equilibrium point (H,H), and we have that:

Theorem 7 *The singularity* (H,H) *is:*

1. *a stable equilibrium point, if and only if,*
$S > \frac{H^2\left(H^2-2H^3-A^2B-3BH^2+2BH-A^2\right)}{\left(A^2+H^2\right)(B+H)^2}$,
2. *an unstable singularity surrounding a stable limit cycle, if and only if,*
$S < \frac{H^2\left(H^2-2H^3-A^2B-3BH^2+2BH-A^2\right)}{\left(A^2+H^2\right)(B+H)^2}$.

Proof. At the point (H,H) we have that
$d[H] = \frac{1}{B+H}\left(\left(A^2+H^3\right)(B+H) - H(1-H)\left(BH-A^2\right)\right)$
In both cases when there is a unique positive equilibrium point we have that
$d\,[u] > 0$, then, $\det DU_\zeta(u,u) > 0$
and the nature of singularity (H,H) depends on the trace, that is, it depends of
$t\,[H] = \left(A^2+H^2\right)(B+H)S - \frac{H^2\left(-2H^3+(1-3B)H^2+2BH-A^2(B+1)\right)}{B+H}$
Clearly,

1. If $t\,[H] > 0$, then $TrDU_\zeta(u,u) < 0$, and the point (H,H) is a stable equilibrium point.

 ISBN: 978-84-617-8694-7

2. If $t[H] < 0$, then $TrDU_\zeta(u,u) > 0$, and the point (H,H) is an unstable equilibrium point. Moreover, verifying the transversality condition [9], we have

$\frac{\partial\left(traDU_\zeta(H,H)\right)}{\partial S} = \left(A^2 + H^2\right)(B+H) > 0.$

By Hopf Bifurcation Theorem a stable limit cycle is generated at this point. ■

Remark. The existence of more than a limit cycle in the system (9) must be demonstrated, since by simulations it is possible to show the existence of two limit cycles .

4 CONCLUSIONS

In this work we have studied the dynamics of a modified Leslie-Gower type predator-prey model, considering a Holling type III functional response and double Allee effect on prey. The particular case of a weak Allee effect was mainly analyzed where $M = 0$, due to the algebraic complexities to obtain equilibrium points in the general case.

The expressions for the coordinates of these equilibrium points when $M > 0$, correspond to the roots of a polynomial of the fourth degree, which are quite complex because the polynomial coefficients depend on the system parameters.

Another difficulty for the analysis is that the original system (1) describing our model it is not defined in the origin $(0,0)$. To solve this problem and to reduce the number of parameters, we made a reparameterization and a time rescaling, by using a diffeomorphism, obtaining a polynomial topologically equivalent system described for system (3).

For this new system (3), we determined the nature of singularities located over the axis, when $M > 0$, emphasizing the importance of the point $(0,0)$ on the global dynamics of the model. It has been shown that this point has a parabolic and a hyperbolic sectors [29].

Using the directional blowing-up method, we show the existence of a curve determined by the stable manifold of the origin, which divides the behavior of the trajectories, implying that trajectories near the curve are highly sensitive to initial conditions. This means that the paths above this separatrix curve have the point $(0,0)$ as its $\omega-limit$, while those trajectories under the separatrix may have different $\omega - limits$, could be an attractor equilibrium point or a stable limit cycle.

For $M = 0$ it is possible to obtain three possible dynamics of system according the amount of positive equilibrium points, (one, two or three). In this work, the local stability was analyzed with a unique positive equilibrium point, obtaining highly interesting results, in the sense that populations can coexist for a wide set of parameter values.

For example, when there is a single interior point, this can be stable or unstable, but is unstable when the appearance of the stable limit cycle, via Hopf bifurcation, prevents the global stability of the origin, which means that there is no extinction of both species. However, for certain parameter values, this limit cycle is broken and the origin $(0,0)$ becomes a global asymptotically stable equilibrium point, implying the extinction of both species.

Abstract

We have a good number of eighth-order iterative methods for simple zeros of nonlinear equations in the available literature. But, unfortunately, we don't have a single iterative method of eighth-order for multiple zeros with known or unknown multiplicity. Some scholars from the worldwide have tried to present optimal or non-optimal multipoint eighth-order iteration functions. But, unfortunately, none of them get success in this direction and attained maximum sixth-order convergence in the case of multiple zeros with known multiplicity m. Motivated and inspired by this fact, we propose an optimal scheme with eighth-order convergence based on weight function approach. In addition, an extensive convergence study is discussed in order to demonstrate the eighth-order convergence of the proposed scheme. The proposed scheme is optimal in the sense of Kung-Traub conjecture. Moreover, we also show the applicability of the proposed scheme on some real life as well as academic problems. These problems illustrate that our proposed iterative functions are more efficient among the available multiple root finding techniques.

Key words: Multiple zeros, iterative functions, Kung-Traub conjecture, Nonlinear equations, efficiency index

1 Introduction

Finding new higher-order multipoint iteration functions for the multiple zeros with known multiplicity m of univariate function of the form

$$f(x) = 0, \tag{1.1}$$

(where $f : \mathbb{C} \to \mathbb{C}$ is analytic function in a neighborhood of the required zero) is one of the most important and challenging task in the field of numerical analysis. The advantages of multipoint iterative methods over the one-point iterative methods can be seen in well-known standard text books Ostrowski [1], Traub [2] and Petković et al. [3].

In the past and recent years, several scholars given optimal fourth-order iteration functions for multiple zeros with known multiplicity m e.g. Li et al. [4] in (2009), Sharma and Sharma [5] and Li et al. [6] in (2010), Zhou et al. [7] in (2011), Sharifi et al. [8] in (2012), Soleymani et al. [9], Soleymani and Babajee [10], Liu and Zhou [11] and Zhou et al. [12] in (2013), Thukral [13] in (2014), Behl et al. [14] and Hueso et al. [15] in (2015) and Behl et al. [16] in (2016) . In addition, Li et al. [6] (expect two of them are optimal) and Neta [17] given non-optimal iterative functions of order four. Most of the above mentioned iteration functions are either the extension or modification of modified Newton's method (also known as Rall's method [2]) or Newton like method at the expense of additional functional evaluations or increase the substep of the original methods.

In 2013, Thukral [18] presented a multi-point iterative method with sixth-order convergence, which is given by

$$\begin{aligned} y_n =& x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n =& x_n - m\frac{f(x_n)}{f'(x_n)}\sum_{i=1}^{3} i\left(\frac{f(y_n)}{f(x_n)}\right)^{\frac{i}{m}}, \\ x_{n+1} =& z_n - m\frac{f(x_n)}{f'(x_n)}\left(\frac{f(z_n)}{f(x_n)}\right)^{\frac{1}{m}}\left[\sum_{i=1}^{3} i\left(\frac{f(y_n)}{f(x_n)}\right)^{\frac{i}{m}}\right]^2. \end{aligned} \tag{1.2}$$

Recently, Geum et al. in [19], presented a non-optimal family of two-point sixth-order methods to find multiple zeros, given as follows:

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \quad m > 1, \\ x_{n+1} &= y_n - Q(u_n, s_n)\frac{f(y_n)}{f'(y_n)}, \end{aligned} \tag{1.3}$$

where, $u_n = \sqrt[m]{\frac{f(y_n)}{f(x_n)}}$, $s_n = \sqrt[m-1]{\frac{f'(y_n)}{f'(x_n)}}$ and Q is an analytic function in a neighborhood of $(0, 0)$. The problem with this scheme is that it does not work for simple zeros ($m = 1$).

 ISBN: 978-84-617-8694-7

Very recently, another non-optimal family of three-point sixth-order methods for multiple zeros was proposed by Geum et al. [20], and it is given by

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \quad m \geq 1, \\ w_n &= y_n - mG(u_n)\frac{f(x_n)}{f'(x_n)}, \\ x_{n+1} &= w_n - mK(u_n, v_n)\frac{f(x_n)}{f'(x_n)}, \end{aligned} \tag{1.4}$$

where $u_n = \sqrt[m]{\frac{f(y_n)}{f(x_n)}}$ and $v_n = \sqrt[m]{\frac{f(w_n)}{f(x_n)}}$. The weight functions $G : \mathbb{C} \to \mathbb{C}$ and $K : \mathbb{C}^2 \to \mathbb{C}$ are analytic in a neighborhood of 0 and $(0, 0)$, respectively.

The above discussion illustrate that many scholars have tried to construct iteration functions for multiple zeros with optimal/non-optimal eighth-order convergence. But, none of them get success in this direction till date and the highest attained order is six. So, this means there is not a single research article where any scholar claims optimal eighth-order convergence is attained to this date, according to our knowledge. In addition, the optimal multipoint iterative functions have more importance than the non-optimal ones because of the higher efficiency index, timing and faster convergence.

Keeping all these points in our mind, we try to solve this problem which has been pending for several years. So, we propose an optimal scheme for multiple zeros with eighth-order convergence. Weight function approach is used in the construction of this scheme. In addition, our proposed methods not only give the faster convergence but also have smaller residual error and asymptotic error constants. Each member of the proposed scheme also satisfies the classical Kung-Traub conjecture [21]. So, all the members are optimal in the sense of Kung-Traub conjecture. We have demonstrated the usefulness of the presented iteration functions by performing several applied science problems for numerical tests. Finally, we concluded from the numerical results that our methods have far better numerical results, than the existing robust iterative schemes (in the regards of smaller asymptotic error constants, stable computational order of convergence and smaller residual errors).

2 Construction of the proposed scheme

In this section, we present the following new scheme

 ISBN: 978-84-617-8694-7

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - \frac{f(x_n)}{f'(x_n)} u_n G_f(u_n), \\ x_{n+1} &= z_n + \frac{f(x_n)}{f'(x_n)} \frac{w_n u_n}{1-w_n}\Big(H_f(u_n) + K_f(v_n)\Big), \end{aligned} \tag{2.1}$$

where the weight functions $G_f, H_f, K_f : \mathbb{C} \to \mathbb{C}$ are analytic functions in a neighborhood of (0) with $u_n = \left(\frac{f(y_n)}{f(x_n)}\right)^{\frac{1}{m}}$, $v_n = \left(\frac{f(z_n)}{f(x_n)}\right)^{\frac{1}{m}}$ $w_n = \left(\frac{f(z_n)}{f(y_n)}\right)^{\frac{1}{m}}$.

In the next Theorem 2.1, we demonstrate that the order of convergence of the proposed scheme will reach at eight without using any additional function evaluations. In addition, we will also discuss the conditions on weight functions in the following Theorem 2.1.

Theorem 2.1 *Let $x = \xi$ be a multiple zero with multiplicity m of an analytic function $f : \mathbb{C} \to \mathbb{C}$ in the region enclosing the multiple zero ξ. Then, the proposed scheme* (2.1) *attain eighth-order convergence when the weight functions G_f, H_f, K_f will satisfy the following conditions*

$$\begin{cases} G(0) = m, \quad G'(0) = 2m, \quad H(0) = -m - K(0), \quad H'(0) = -2m, \quad H''(0) = -G''(0) - 2m, \\ K'(0) = -2m, \quad H'''(0) = -\big(6G''(0) + G'''(0) - 24m\big). \end{cases} \tag{2.2}$$

Proof Let us assume that $e_n = x_n - \alpha$ be the error at nth step. We will obtain the following expressions by expanding $f(x_n)$ and $f'(x_n)$ about $x = \alpha$ with the help of Taylor's series

$$f(x_n) = \frac{f^{(m)}(\alpha)}{m!} e_n^m \Big(1 + c_1 e_n + c_2 e_n^2 + c_3 e_n^3 + c_4 e_n^4 + c_5 e_n^5 + c_6 e_n^6 + c_7 e_n^7 + c_8 e_n^8 + O(e_n^9)\Big), \tag{2.3}$$

and

$$\begin{aligned} f'(x_n) = &\frac{f^m(\alpha)}{(m)!} e_n^{m-1} \Big(m + c_1(m+1)e_n + c_2(m+2)e_n^2 + c_3(m+3)e_n^3 + c_4(m+4)e_n^4 \\ &+ c_5(m+5)e_n^5 + c_6(m+6)e_n^6 + c_7(m+7)e_n^7 + c_8(m+8)e_n^8 + O(e_n^9)\Big), \end{aligned} \tag{2.4}$$

respectively.
With the help of above expressions (2.3) and (2.4), we have

$$y_n - \alpha = \frac{c_1 e_n^2}{m} + \frac{2c_2 m - c_1^2(m+1)}{m^2} e_n^3 + \sum_{k=0}^{4} \xi_k e_n^{k+4} + O(e_n^9), \tag{2.5}$$

 ISBN: 978-84-617-8694-7

where $\xi_k = \xi_k(m, c_1, c_2, \ldots, c_8)$ are given in terms of $m, c_2, c_3, \ldots, c_8$ with explicitly written two coefficients $\xi_0 = \frac{1}{m^3}\{3c_3m^2 + c_1^3(m+1)^2 - c_2c_1m(3m+4)\}$ and $\xi_1 = \frac{1}{m^4}\{c_1^4(m+1)^3 - 2c_2c_1^2m(2m^2+5m+3) + 2c_3c_1m^2(2m+3) + 2m^2(c_2^2(m+2) - 2c_4m)\}$, etc.
Again by using Taylor Series expansion, we further yield

$$f(y_n) = f^{(m)}(\alpha)e_n^{2m}\Bigg[\frac{\left(\frac{c_1}{m}\right)^m}{m!} + \frac{(2c_2m - c_1^2(m+1))\left(\frac{c_1}{m}\right)^m e_n}{c_1m!} + \left(\frac{c_1}{m}\right)^{1+m}\frac{1}{2m!c_1^3}\Big\{(3+3m+3m^2 + m^3)c_1^4 - 2m(2+3m+2m^2)c_1^2c_2 + 4(-1+m)m^2c_2^2 + 6m^2c_1c_3\Big\}e_n^2 + \sum_{k=0}^{5}\bar{\xi}_k e_n^{k+3} + O(e_n^9)\Bigg] \tag{2.6}$$

and

$$u_n = \frac{c_1e_n}{m} + \frac{(2c_2m - c_1^2(m+2))e_n^2}{m^2} + \frac{c_1^3(2m^2+7m+7) + 6c_3m^2 - 2c_2c_1m(3m+7)}{2m^3}e_n^3 + \lambda_0e_n^4 + \lambda_1e_n^5 + O(e_n^6), \tag{2.7}$$

where $\lambda_0 = -\frac{1}{6m^4}\big[c_1^4(6m^3+29m^2+51m+34) - 6c_2c_1^2m(4m^2+16m+17) + 12c_3c_1m^2(2m+5) + 12m^2(c_2^2(m+3) - 2c_4m)\big]$ and $\lambda_1 = \frac{1}{24m^5}\big[-24m^3(c_2c_3(5m+17) - 5c_5m) + 12c_3c_1^2m^2(10m^2 + 43m + 49) + 12c_1m^2\{c_2^2(10m^2+47m+53) - 2c_4m(5m+13)\} - 4c_2c_1^3m(30m^3+163m^2 + 306m + 209) + c_1^5(24m^4+146m^3+355m^2+418m+209)\big]$.
It is straightforward to say from the expression (2.7) that u_n is of order e_n. So, we can expand weight function $G_f(u_n)$ in the neighborhood of origin by Taylor series expansion up to fourth-order term for the eighth order convergence as follow:

$$G_f(u_n) = G(0) + G'(0)u_n + \frac{1}{2!}G''(0)u_n^2 + \frac{1}{3!}G'''(0)u_n^3 + \frac{1}{4!}G''''(0)u_n^4. \tag{2.8}$$

By inserting the expressions (2.3) – (2.8) in the second substep of the proposed scheme (2.1), we have

$$z_n - \alpha = \frac{(m - G(0))c_1}{m^2}e_n^2 + \frac{\big(3G - G'(0) - m + Gm - m^2\big)c_1^2 + 2m(-G+m)c_2}{m^3}e_n^3 + \sum_{k=1}^{5}\Omega_k e_n^{k+3} + O(e_n^9). \tag{2.9}$$

where $\Omega_k = \Omega_k(G(0), G'(0), G''(0), G'''(0), G''''(0), m, c_1, c_2, \ldots, c_8)$.
Fourth-order convergence can be attained, when the coefficient of e_n^2 and e_n^3 simultaneously are equaled to zero. That is possible only for the following particular values of $G(0)$ and $G'(0)$

$$G(0) = m, \quad G'(0) = 2m, \tag{2.10}$$

which can be obtained from the expression (2.9).
Insert the above expression (2.10), we obtain

$$z_n - \alpha = \frac{\big(-G''(0)+m(9+m)\big)c_1^3 - 2m^2c_1c_2}{2m^4}e_n^4 + \sum_{k=1}^{4}\bar{\Omega}_k e_n^{k+4} + O(e_n^9). \tag{2.11}$$

Now, again by using the Taylor series expansion, we have

$$f(z_n) = f^{(m)}(\alpha)e_n^{4m}\left[\frac{2^{-m}}{m!}\left(\frac{(m(9+m)-G''(0))c_1^3 - 2m^2c_1c_2}{m^4a_1^2}\right)^m + \sum_{k=1}^{5}\bar{\bar{\Omega}}_k e_n^k + O(e_n^6)\right], \tag{2.12}$$

$$v_n = \frac{\big((-G''(0)+m(9+m))c_1^3 - 2m^2c_1c_2\big)}{2m^4}e_n^3 + \beta_0 e_n^4 + \beta_1 e_n^5 + O(e_n^6), \tag{2.13}$$

and

$$w_n = \frac{(m(9+m)-G''(0))c_1^2 - 2m^2c_2}{2m^4}e_n^2 + \gamma_0 e_n^3 + \gamma_1 e_n^4 + O(e_n^5), \tag{2.14}$$

where $\beta_0 = -\frac{1}{6m^5}\Big[\big(G'''(0) - 3G''(0)(8+3m) + m(152+87m+7m^2)\big)c_1^4 - 6m\big(m(29+4m) - 3G''(0)\big)c_1^2c_2 + 12m^3c_2^2 + 12m^3c_1c_3\Big]$, $\beta_1 = \frac{1}{24m^6}\Big[\big(-G''''(0) + 2061m + 2246m^2 + 711m^3 + 46m^4 + 8G'''(0)(5+2m) - 12G''(0)(37+30m+6m^2)\big)c_1^5 - 4m\big(8G'''(0) - 9G''(0)(20+7m) + m(1123 + 624m + 53m^2)\big)c_1^3c_2 + 12m^2(-9G''(0) + m(87+13m))c_1^2c_3 - 168m^4c_2c_3 - 12m^2c_1\big((12G''(0) - m(121+17m))c_2^2 + 6m^2c_4\big)\Big]$, $\gamma_0 = -\frac{1}{6m^4}\Big[\big(G'''(0) + 98m + 54m^2 + 4m^3 - 6G''(0)(3+m)\big)c_1^3 + 12m(G''(0) - m(9+m))c_1c_2 + 12m^3c_3\Big]$, $\gamma_1 = \frac{1}{24m^5}\Big[\big(899m + 1002m^2 + 313m^3 + 18m^4 + 4G'''(0)(8+3m) - 6G''(0)(43+33m+6m^2) - G''''(0)\big)c_1^4 - 12m\big(2G'''(0) - G''(0)(33+10m) + m(167+87m+6m^2)\big)c_1^2c_2 + 24m^2(-3G''(0) + m(26+3m))c_1c_3 + 12m^2\big((-4G''(0) + m(35+3m))c_2^2 - 6m^2c_4\big)\Big]$.

We observed from the expressions namely, (2.7) and (2.14) that u_n and v_n are of order e_n and e_n^3, respectively. Therefore, we can expand both weight functions $H_f(u_n)$ and $K_f(v_n)$ in the neighborhood of origin (0) by Taylor series expansion up to fourth-order and third-order terms, respectively as follow:

$$H_f(u_n) = H(0) + H'(0)u_n + \frac{1}{2!}H''(0)u_n^2 + \frac{1}{3!}H'''(0)u_n^3 + \frac{1}{4!}H''''(0)u_n^4 \tag{2.15}$$

and

$$K_f(v_n) = K(0) + K'(0)v_n + \frac{1}{2!}K''(0)v_n^2 + \frac{1}{3!}K'''(0)v_n^3. \tag{2.16}$$

By using the expression (2.3) – (2.16), we have

$$e_{n+1} = \frac{(K(0)+H(0)+m)\big(m(9+m)-G''(0)\big)c_1^3 - 2m^2c_1c_2\big)}{2m^5}e_n^4 + \sum_{k=0}^{3}\phi_k e_n^{k+5} + O(e_n^9), \tag{2.17}$$

 ISBN: 978-84-617-8694-7

where $\phi_k = \phi_k(m, G''(0), G'''(0), G''''(0), H(0), H'(0), H''(0), H'''(0), H''''(0), K(0), K'(0), K''(0), K'''(0), c_1, c_2, \ldots, c_8)$.
We can easily obtain at least fifth-order convergence, when we choose the following value of $H(0)$

$$H(0) = -K(0) - m, \tag{2.18}$$

which is obtained from the expression (2.17).
In addition, by using this value $H(0) = -K(0) - m$ in $\phi_0 = 0$. Then, we have

$$H'(0) = -2m. \tag{2.19}$$

By inserting the expressions namely, (2.18) and (2.19) in $\phi_1 = 0$, we get

$$(G''(0) + H''(0) + 2m) = 0 \tag{2.20}$$

which further gives

$$H''(0) = -(G''(0) + 2m). \tag{2.21}$$

Now, with the help of expressions (2.18), (2.19) and (2.21) in $\phi_2 = 0$, we have

$$K1+2m = 0, \;\; 3G''(0)K'(0) - m\left(G'''(0) + H'''(0) + 27K'(0) + 30m + 3K'(0)m + 6m^2\right) = 0, \tag{2.22}$$

the above two independent expressions which leads us

$$K'(0) = -2m \quad H'''(0) = -(6G''(0) + G'''(0) - 24m). \tag{2.23}$$

Finally, we will use the expressions (2.18), (2.19), (2.21) and (2.23) in the expression (2.17), in order to obtain final asymptotic error constant term. Then, we obtain

$$e_{n+1} = \frac{c_1^2\big((m(9+m) - G''(0))c_1^2 - 2m^2c_2\big)}{48m^9}\Big[\big(8G'''(0) - 36G''(0) + G''''(0) + H''''(0) + 268m + 84m^2 + 8m^3\big)c_1^3 - 24m^2(7+m)c_1c_2 + 24m^3c_3\Big]e_n^8 + O(e_n^9), \tag{2.24}$$

where $G''(0), G'''(0), G'''(0), H''(0), K(0), K''(0)$ and $K'''(0)$ are finite real/complex parameters.
The above asymptotic error constant term (2.24) reveals that the proposed scheme (2.1) attain eighth-order convergence by using only four functional evaluations (viz. $f(x_n)\, f'(x_n)\, f(y_n)$ and $f(z_n)$) per iteration. So, it is optimal in the sense of classical Kung-Traub conjecture. This completes the proof. □

Remark 2.2 *It is worthy to note that the weight functions G_f, H_f and K_f play an important role in the construction of the proposed scheme with desired convergence order. However, only terms namely, $G''(0), G'''(0), G''''(0)$ and $H''''(0)$ are involve in the asymptotic error constant term* (2.24)*. On the other hand, other terms namely $K''(0)$ and $K'''(0)$ do not effect the asymptotic error constant term* (2.24) *at all. So, we can say that these are dummy parameters. However, we can't leave them in the beginning.*

2.1 Special cases of the proposed family

In this section, we will discuss some special cases of our proposed class (2.1) by assigning different weight functions Q_f and G_f.

1. Let us consider the following weight functions which are chosen directly from the proposed Theorem 2.1. Then, we get a new optimal class of order eight as follows:

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - \frac{f(x_n)}{f'(x_n)}u_n\left[m + 2mu_n + \frac{G''(0)u_n^2}{2} + \frac{G'''(0)u_n^3}{6} + \frac{G''''(0)u_n^4}{24}\right], \\ x_{n+1} &= z_n + \frac{f(x_n)}{f'(x_n)}\frac{w_n u_n}{1-w_n}\Big[-m - 2mu_n - \frac{(G''(0)+2m)}{2}u_n^2 + \frac{1}{6}(24m - 6G''(0) - G'''(0))u_n^3 \\ &\quad + \frac{H''''(0)u_n^4}{24} - 2mv + \frac{K''(0)v^2}{2} + \frac{K'''(0)v^3}{6}\Big], \end{aligned} \tag{2.25}$$

where $G''(0), G'''(0), G''''(0)$, $K''(0), K'''(0)$ and $H''''(0)$ are free disposable parameters.
Sub cases of the given scheme (2.25):

(a) Let us consider $G''(0) = -2m, K''(0) = K'''(0) = G'''(0) = G''''(0) = 0, H''''(0) = -4m(85 + 21m + 2m^2)$ in expression (2.25), we obtain

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - m\frac{f(x_n)}{f'(x_n)}u_n(1 + 2u_n - u_n^2), \\ x_{n+1} &= z_n + m\frac{f(x_n)}{f'(x_n)}\frac{w_n u_n}{1-w_n}\Big[-1 - 2u_n + 6u_n^3 - \frac{1}{6}(85 + 21m + 2m^2)u_n^4 - 2v\Big]. \end{aligned} \tag{2.26}$$

(b) For $G''(0) = K''(0) = K'''(0) = G''(0) = G''''(0) = H''''(0) = 0$, in expression (2.25), we have

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - m\frac{f(x_n)}{f'(x_n)}u_n(1 + 2u_n), \\ x_{n+1} &= z_n + m\frac{f(x_n)}{f'(x_n)}\frac{w_n u_n}{1-w_n}\Big[-1 - 2u_n - u_n^2 + 4u_n^3 - 2v_n\Big]. \end{aligned} \tag{2.27}$$

 ISBN: 978-84-617-8694-7

2. Another choice of weight functions gives the following family of eighth-order methods

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - m\frac{f(x_n)}{f'(x_n)}u_n(1+2u_n), \\ x_{n+1} &= z_n - m\frac{f(x_n)}{f'(x_n)}\frac{w_n u_n}{1-w_n}\Big[\frac{1+9u_n^2+2v_n+u_n(6+8v_n)}{1+4u_n}\Big]. \end{aligned} \tag{2.28}$$

3. By considering one more weight functions of the following form, we will obtain one more optimal family of eighth-order iteration function

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)}, \\ z_n &= y_n - m\frac{f(x_n)}{f'(x_n)}u_n\left[\frac{m}{1-2u_n}\right], \\ x_{n+1} &= z_n + m\frac{f(x_n)}{f'(x_n)}\frac{w_n u_n}{1-w_n}\Big[\frac{5+u_n^2+10v_n-2u_n(1+12v_n)}{-5+12u_n}\Big]. \end{aligned} \tag{2.29}$$

In the similar fashion by arbitrary choice of assumed weight functions $G_f(u_n)$, $H_f(u_n)$ and $K_f(v_n)$ (provided the conditions on them in the above Theorem 2.1 should be satisfied), we can obtain several new optimal methods of eighth-order for multiple zeros.

3 Numerical experiments

In this section, we will check the efficiency and convergence behavior of our proposed iteration functions namely, expression (2.26), expression (2.27) expression (2.28) and expression (2.29) denoted by $PM1, PM2, PM3$ and $PM4$, respectively. In this regards, we consider a total number of three test problems: first two are real life problems; third one is a standard test problem, which are mentioned in Examples 3.1 to 3.3.

Unfortunately, we don't have any optimal eighth-order iteration function for multiple zeros for the comparison. So, we consider the highest-order methods of order six (multiple zeros) for comparison which is available in the literature. Now, we compare our proposed methods with family of two-point sixth-order method which were given by Geum et al. in [19], out of them we choose the following expression:

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)},\ m>1, \\ x_{n+1} &= y_n - m\left[1+2(m-1)(u_n-s_n)-4u_n s_n+s_n^2\right]\frac{f(y_n)}{f'(y_n)}, \end{aligned} \tag{3.1}$$

 ISBN: 978-84-617-8694-7

called $GM1$.

Finally, we compare them with the non optimal family of sixth-order methods based on weight function approach presented by the same authors Geum et al. [20], out of them we consider the following expression (11)

$$\begin{aligned} y_n &= x_n - m\frac{f(x_n)}{f'(x_n)},\ m \geq 1, \\ w_n &= x_n - m\left[1 + u_n + 2u_n^2\right]\frac{f(x_n)}{f'(x_n)}, \\ x_{n+1} &= x_n - m\left[1 + u_n + 2u_n^2 + (1+2u_n)v_n\right]\frac{f(x_n)}{f'(x_n)}, \end{aligned} \tag{3.2}$$

denoted by $GM2$.

In the numerical tests presented in Tables 1 to 3, we have compared our methods with the known ones on the basis of approximated zeros, residual error of the involved functions, difference between the two consecutive iterations, asymptotic error constants. In Tables 1 – 3, we display the number of iteration indices (n), approximated zeros (x_n), absolute residual error of the corresponding function ($|f(x_n)|$), error in the consecutive iterations $|x_{n+1} - x_n|$, computational order of convergence $\left(\rho = \frac{\log|(x_{n+1}-x_n)/(x_n-x_{n-1})|}{\log|(x_n-x_{n-1})/(x_{n-1}-x_{n-2})|},\ n = 2, 3\right)$ (the details of this formula can be seen in Cordero and Torregrosa [22]), $\left|\frac{x_{n+1}-x_n}{(x_n-x_{n-1})^p}\right|$ (where p is either 6 or 8 corresponding to the considered iteration function), the estimation of asymptotic error constant $\eta \approx \lim_{n\to\infty}\left|\frac{x_{n+1}-x_n}{(x_n-x_{n-1})^p}\right|$ at the last iteration. We make our calculations with several number of significant digits (minimum 3000 significant digits) to minimize the roundoff error.

As we mentioned in the above paragraph, we calculate the values of all the constants and functional residuals up to several number of significant digits but we display the value of x_n up to 25 significant digits. In addition, we also display $\left|\frac{x_{n+1}-x_n}{(x_n-x_{n-1})^p}\right|$ and η up to 10 significant digits. Moreover, absolute residual error in the function $|f(x_n)|$ and error in the consecutive iterations $|x_{n+1} - x_n|$ are displayed up to 2 significant digits with exponent power which are mentioned in Tables 1 – 3. Finally, computational order of convergence is up to 5 significant digits. Furthermore, the approximated zeros up to 25 significant digits are also displayed in the Examples 3.1– 3.3 although minimum 3000 significant digits are available with us.

For these numerical tests, all computations have been performed using the programming package $Mathematica$ 11 with multiple precision arithmetic. Further, the meaning of $a(\pm b)$ is $a \times 10^{(\pm b)}$ in Tables 1–3.

 ISBN: 978-84-617-8694-7

Example 3.1 Population growth problem:
Law of population growth is defined as follows:

$$\frac{dN(t)}{dt} = \gamma N(t) + \eta, \tag{3.3}$$

where N(t) = population at time t, η= fixed/constant immigration rate and γ = fixed/constant birth rate of population. We can easily obtain the following solution of the above differential equation (3.3)

$$N(t) = N_0 e^{\gamma t} + \frac{\eta}{\gamma}(e^{\gamma t - 1}), \tag{3.4}$$

where N_0 is initial population.
For a particular case study, the problem is given as: Suppose a certain population contains 1000000 individuals initially, that 300000 individuals immigrate into the community in the first year and that 1365000 individuals are present at the end of one year. Find birth rate (γ) of this population.
To determine the birth rate, we must solve the equation

$$f_1(x) = 1365 - 1000e^x - \frac{300}{x}(e^x - 1). \tag{3.5}$$

wherein $x = \gamma$ and our desired zero of the above function f_1 is 0.055046224513351778274834 21.

Example 3.2 Van der Waals equation of state

$$\left(P + \frac{a_1 n^2}{V^2}\right)(V - na_2) = nRT,$$

explains the behavior of a real gas by introducing in the ideal gas equations two parameters, α_1 and α_2, specific for each gas. The determination of the volume V of the gas in terms of the remaining parameters requires the solution of a nonlinear equation in V

$$PV^3 - (na_2P + nRT)V^2 + \alpha_1 n^2 V - \alpha_1\alpha_2 n^2 = 0.$$

Given the constants α_1 and α_2 of a particular gas, one can find values for n, P and T, such that this equation has a three simple roots. By using the particular values, we obtain the following nonlinear function

$$f_2(x) = x^3 - 5.22x^2 + 9.0825x - 5.2675.$$

have three zeros and out of them one is a multiple zero $\alpha = 1.75$ of multiplicity of order two and other one simple zero $\alpha = 1.72$. However, our desired root is $\alpha = 1.75$.

 ISBN: 978-84-617-8694-7

Example 3.3 Let us consider the following standard nonlinear test function from Behl et al. [16]

$$f_3(x) = \left(-\sqrt{1-x^2} + x + \cos\left(\frac{\pi x}{2}\right) + 1\right)^3 \tag{3.6}$$

The above function has a multiple zero at $\xi = -0.72858404644482671671233310 2423$ of multiplicity 3.

4 Conclusions

In this study, we proposed an optimal scheme for multiple zeros with known multiplicity $m \geq 1$ having eighth-order convergence, for the first time according to our best knowledge. A detail convergence analysis is presented which demonstrate that the proposed scheme has attained eighth-order convergence theoretically. In addition, the proposed scheme also satisfy the classical Kung-Traub conjecture. So, each member of the scheme is optimal. The main advantage of the proposed iteration functions is that they have not only minimum residual errors and smaller absolute errors difference between two consecutive iterations corresponding to the listed test functions. But, they also show the stable computational order of convergence as compared to the other listed methods. Further, the computational efficiency index of the proposed scheme is $E = \sqrt[4]{8} \approx 1.682$ which is better than the efficiency index of Newton's method $E = \sqrt[2]{2} \approx 1.414$ and also the schemes proposed by Thukral [18] and Guem et al. [19, 20], $E = \sqrt[4]{6} \approx 1.565$. Moreover, we can easily develop many new interesting and optimal iteration functions having eighth-order convergence with the different choices of weight functions. Finally, we can claim on the basis of obtained numerical results that our proposed iteration functions are highly efficient and perform better than the existing robust methods.

Abstract

Sound source localization is an important topic in the field of audio signal processing, with multiple applications such as automatic camera steering systems, humanmachine interaction, video gaming and audio surveillance. The Steered Response Power with Phase Transform (SRP-PHAT) algorithm is a well-known method for sound source localization due to its robust performance in noisy and reverberant environments. SPR-PHAT implementations require to handle a high number of signals coming from a microphone array and a huge search grid that influences the localization accuracy of the system. In this context, high performance in the localization process can only be achieved using massively parallel computational resources. Different types of multi-core machines based on either multiple CPUs or GPUs are commonly employed in diverse fields of science for accelerating a number of applications. In this work, we evaluate and analyze OpenCL-based and OpenMP-based implementations on two different parallel platforms. Our results show that the proposed implementations achieve close-to-peak speedup on multi-CPU platforms. Furthermore, the OpenCL solution offers higher performance on GPU than on CPU.

Key words: Sound source localization, Audio processing, Microphone arrays, multi-core platforms, many-core platforms.

ISBN: 978-84-617-8694-7

1 Introduction

The localization of sound sources in acoustic environments with noise and reverberation is a challenging task for applications arising in a wide range of areas. Applications such as acoustic-based surveillance, gaming, spatial sound and virtual reality can be highly improved under a location-aware system [1].

In order to locate a sound source, it is necessary to process the input signals captured by a set of microphones in real time. The microphones can be arranged either in a distributed configuration or by following a specific geometry. The processing is usually based on the computation of the *Generalized Cross-Correlation* (GCC) functions [2, 3] of all the microphone pairs in the system. GCCs are usually obtained from the inverse Fourier transform of the cross-power spectral density of the microphone signals, multiplied by a proper spectral weighting function. A well-known algorithm that makes use of GCCs is the *Steered Response Power - Phase Transform* (SRP-PHAT). Indeed, this is the preferred choice due to its robustness in noisy and reverberant environments. Moreover, the SRP-PHAT method exhibits massive fine-grain parallelism, that is, the same operations are performed over different sets of data. Usually, these different data sets correspond to the audio samples of the different audio channels involved in the system. Basically, the SRP-PHAT algorithm evaluates a functional over a fine spatial grid and identifies its maximum value as the most likely source position.

The fact that current processors are composed of multiple cores and general-purpose GPUs has allowed to accelerate multiple applications in distinct fields, including audio signal processing [8]. In fact, there exists a high variety of hardware, CPUs and GPUs, and programming technologies, OpenMP [4] and OpenCL [5], that can be used for this purpose. However, deciding which is the most suitable option is not straightforward. To this end, in this work we propose an OpenCL-based implementation that runs on a multi-core CPU and a GPU, and an OpenMP-based implementation that is executed on the multi-core CPU.

In the next section, we describe briefly the SRP-PHAT algorithm. Section 3 is devoted to implementation issues and the performance analysis. Finally, Section 4 provides some conclusion remarks.

2 The SRP-PHAT Algorithm

Consider the output from a microphone l, $m_l(t)$, in a system composed of S microphones. Then, the SRP at the spatial point $\mathbf{x} = [x, y, z]^T$ for a time frame n of length T is defined as

$$P_n(\mathbf{x}) \equiv \int_{nT}^{(n+1)T} \left| \sum_{l=1}^{S} w_l m_l \left(t - \tau(\mathbf{x}, l)\right) \right|^2 dt, \tag{1}$$

 ISBN: 978-84-617-8694-7

where w_l is a weight and $\tau(\mathbf{x}, l)$ is the direct time of travel from location $\mathbf{x}$ to microphone l. DiBiase [6] showed that the SRP can be computed by summing up the GCCs for all possible pairs of the set of microphones in the system. In particular, the GCC for a microphone pair (k, l) is computed as

$$R_{m_k m_l}(\tau) = \int_{-\infty}^{\infty} \Phi_{kl}(\omega) M_k(\omega) M_l^*(\omega) e^{j\omega\tau} d\omega, \tag{2}$$

where τ is the time lag, * denotes complex conjugation, $M_l(\omega)$ is the Fourier transform of the microphone signal $m_l(t)$, and $\Phi_{kl}(\omega)$ is a combined weighting function in the frequency domain. The Phase Transform (PHAT) [2] has been demonstrated to be a suitable GCC weighting for time delay estimation in reverberant environments:

$$\Phi_{kl}(\omega) \equiv \frac{1}{|M_k(\omega) M_l^*(\omega)|}. \tag{3}$$

Taking into account the symmetries involved in the computation of Eq. (1), and removing some fixed energy terms [6], the part of $P_n(\mathbf{x})$ that changes with $\mathbf{x}$ is isolated as

$$P'_n(\mathbf{x}) = \sum_{k=1}^{S} \sum_{l=k+1}^{S} R_{m_k m_l}\left(\tau_{kl}(\mathbf{x})\right), \tag{4}$$

where $\tau_{kl}(\mathbf{x})$ is the *Inter-Microphone Time-Delay Function* (IMTDF). This function is very important, since it represents the theoretical direct path delay for the microphone pair (k, l) resulting from a point source located at $\mathbf{x}$. The IMTDF is mathematically expressed as [7]

$$\tau_{kl}(\mathbf{x}) = \frac{\|\mathbf{x} - \mathbf{x}_k\| - \|\mathbf{x} - \mathbf{x}_l\|}{c}, \tag{5}$$

where c is the speed of sound, and $\mathbf{x}_k$ and $\mathbf{x}_l$ are the microphone location vectors.

All in all, the SRP-PHAT algorithm consists in evaluating the functional $P'_n(\mathbf{x})$ on a fine grid G with the aim of finding the point-source location $\mathbf{x}_s$ that provides the maximum value:

$$\hat{\mathbf{x}}_s = \arg\max_{\mathbf{x} \in G} P'_n(\mathbf{x}). \tag{6}$$

Figure 1(a) shows schematically the intuition behind SRP-PHAT localization. In this figure, an anechoic environment is assumed so that the GCC for each microphone pair is a delta function located at the real TDOA (Time Difference of Arrival). Each TDOA defines a half-hyperboloid of potential source locations. The intersection resulting from all the half-hyperboloids matches the point of the grid having the largest accumulated value.

 ISBN: 978-84-617-8694-7

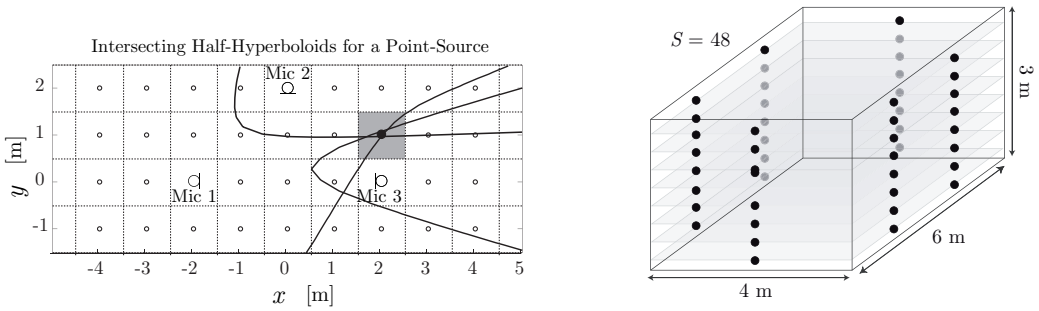

Figure 1: (a) Intersecting half-hyperboloids for $M = 3$ microphones. Each half-hyperboloid corresponds to a TDOA peak in the GCC. (b) Microphone set-up for 48 microphones.

2.1 Basic implementation of the SRP-PHAT

The SRP-PHAT algorithm is usually implemented on a grid by carrying out the following steps:

1. A spatial grid G is defined with a given spatial resolution r. The theoretical delays from each point of the grid to each microphone pair are pre-computed using Eq. (5).
2. For each analysis frame, the GCC of each microphone pair using Eq. (2).
3. For each position of the grid $\mathbf{x} \in G$, the contribution of the different cross-correlations are accumulated (using delays pre-computed in step 1), as in Eq. (4).
4. Finally, the position with the maximum score is selected as in Eq. (6).

Taking into account the above steps, we have implemented several parallel versions of the algorithm using two different parallel programming technologies, namely, OpenCL an OpenMP.

3 Performance on a GPU and a Multi-core CPU

All the CPU experiments have been performed on an Intel Xeon processor E5-2695 v3 at 2.3 GB with 28 cores and 64 GB of RAM. The GPU experiments have been executed on a NVIDIA GTX1080 GPU that implements Pascal architecture. This GPU has a clock frequency of 1.771 MHz and includes 8 GB of global memory. It provides 20 OpenCL compute units and allows a maximum work-group size of 1024 work-items.

Figure 2 shows the speedups obtained with the OpenMP version of the algorithm on the 28 cores of the CPU with respect to the sequential version of the algorithm executed on

one core. The left-hand side figure shows the results using 24 microphones and varying the grid resolution. We can observe that the performance improves as we increase the resolution and, therefore, the amount of parallel computations to perform. The right-hand side plot in the same figure, obtained with the maximum resolution ($r = 0.005$), shows that we obtain very good speedups for any number of microphones.

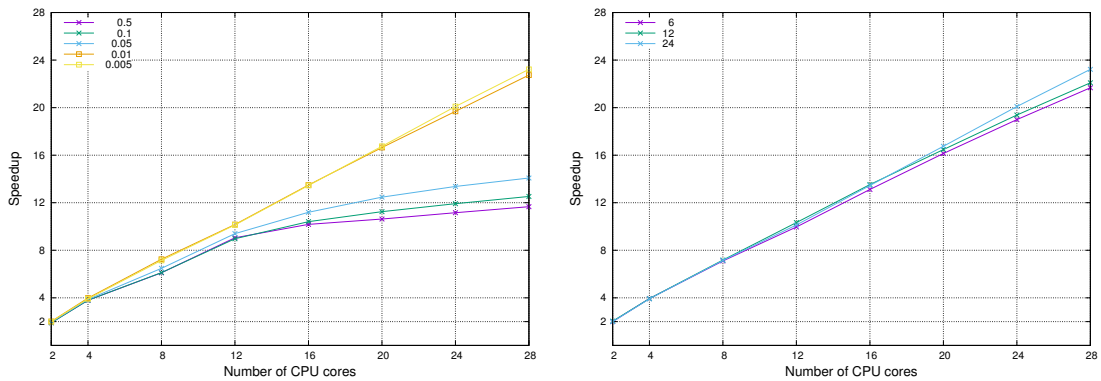

Figure 2: Speedups obtained with the OpenMP algorithm on the CPU.

We have evaluated the OpenCL implementation of the algorithm both on the CPU and the GPU. Figure 3 shows the runtime of this version of the algorithm using the 28 cores of the CPU and 24 microphones. We can observe that, for relatively small resolutions ($r < 0.005$), the cost of the algorithm only depends on the number of microphones. In this case most of the cost is due to the Fourier transforms and the computation of the GCC matrix, both of which depend only on the number of microphones, S, and the length of the audio frame, T. However, for larger resolutions, almost all the cost is due to the computation of the SRP matrix and so it grows very quickly with the resolution that defines the grid size. Figure 3 also shows that we can achieve real time performance even with 24 microphones and very fine resolutions (see black line in Figure 3).

Finally, we compare the speedups obtained with both versions of the algorithm (OpenMP and OpenCL) and using both parallel platforms (CPU and GPU) (in Figure 4). The speedups have been obtained with respect to the sequential algorithm executed on one of the cores of the CPU. In this experiment, we can observe that the OpenCL algorithm executed on the GTX1080 GPU obtains much higher speedups than the same version of the algorithm executed on the CPU. This clearly proves that an state-of-the art many-core GPU is better suited to run massive data-parallel algorithms even when compared with an up-to-date multi-core CPU with 28 cores.

On the other hand, if we compare the two versions of the algorithm on the 28 cores of the CPU, we can appreciate that the OpenCL version clearly outperforms the OpenMP

 ISBN: 978-84-617-8694-7

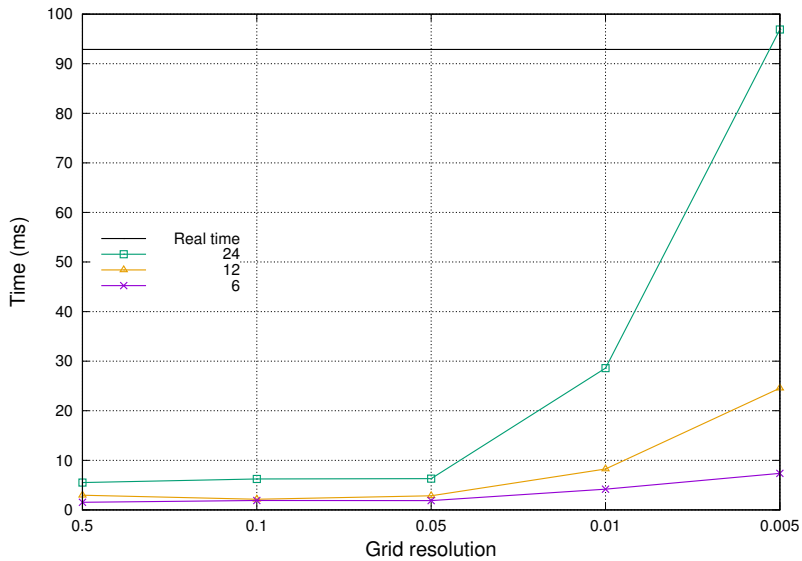

Figure 3: Time in milliseconds using the OpenCL algorithm on the CPU with a resolution r=0.005 and varying the number of microphones. The horizontal line represents the time threshold that allows to perform the localization process in real time.

version. The first version can obtain speedups much higher than the number of cores. For example, the OpenCL algorithm obtains an speedup of 45 with a grid resolution of 0.005. The OpenMP version of the algorithm delivers speedups close to the number of cores when running as many threads as cores, but is slower if we use more threads. However the OpenCL is able to run several work-items per core in parallel overlapping computations with accesses to the memory and so it reaches speedup rates that exceed the number of cores.

4 Conclusion

New emerging multi-core and many-core architectures help to overcome different computational problems in acoustic signal processing. This paper analyzed the specific case of sound source localization, where using very fine spatial resolutions or having a high number of microphones have a deep impact on the performance of real-time applications.

Currently, there are different techniques to exploit the parallel resources of the multi-core and many-core processors. In this work, we have compared performances on a 28-core CPU and a modern GPU with NVIDIA's Pascal architecture. Our results show that

 ISBN: 978-84-617-8694-7

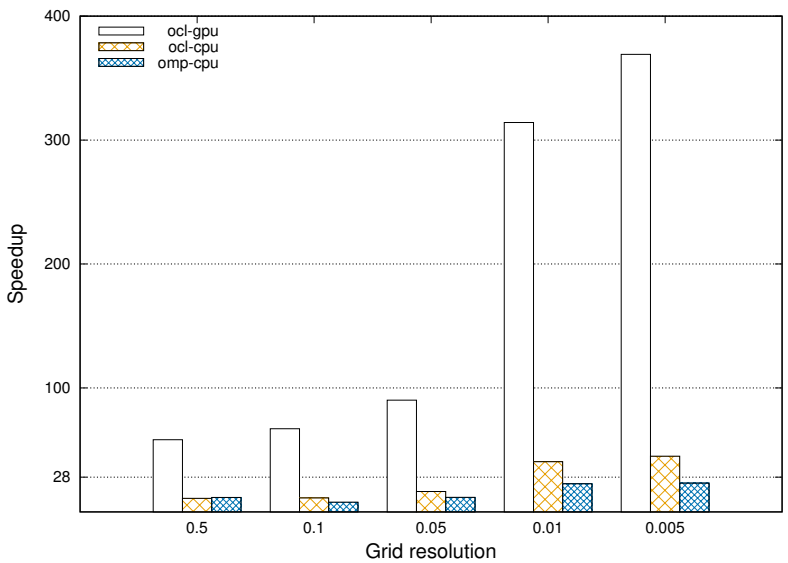

Figure 4: Comparison of the speedups of the different parallel versions of the algorithm using both platforms (GPU and GPU) and both programming technologies (OpenMP and OpenCL). We use 24 microphones and vary the grid resolution.

OpenCL on GPU clearly overcomes the implementation on CPU both using OpenCL and OpenMP. Regarding the CPU, the OpenMP-based implementation attains speedups close to the number of cores. However, this performance is clearly improved by the OpenCL version of the algorithm which is able to perform several tasks per core in parallel.

Abstract

Closed sets are the basis for the development of the concept lattice, a key issue in formal concept analysis. The enumeration of all the closed sets is a complex problem, having an exponential cost. In addition to the closed set, it is very useful for applications to add the information of all the minimal generators for each closed set. In this work we explain how to approach this problem from a complete set of implication by means of a sound and complete logic.

Key words: Formal concept analysis, closed sets, minimal generator, logic.

1 Introduction

Formal concept analysis (FCA) is a theoretical and practical framework to store information and manage them [GW99]. Data is stored in a table, representing a binary relation between a set of objects and attributes. The success of FCA relies on its solid theoretical framework and a wide set of methods and techniques to extract the knowledge from this data and manipulate it. One outstanding representation of the knowledge is the concept lattice, built over the closed sets, considering the subset relation as the order relation. Such representation depict a overall view of the information with a very strong formalism, opening the door to use the lattice theory as a metatheory to manage the information [BDVG17].

If-then rules have been introduced in several areas, dressed with different clothes. Thus, in relational databases [Cod71] they are named Functional Dependencies, in FCA they are named Implications and in Logic Programming (fuzzy logic) [BV06a] they are named if-then rules. All this notions captures a very intuitive idea: when the premise occurs, then the conclusion holds. Nevertheless, their semantics are very different and they further use are

 ISBN: 978-84-617-8694-7

also distinct. In this work we consider implications as elements to describe the information and we design a method to enumerate all closed sets and their minimal generators.

The proposed method is an evolution of [CEMO12], where the authors introduce a logic-based method based on $\mathbf{SL}_{FD}$, a sound and complete logic for implications. That method works by traversing the set of implications and applying a set of inference rules, following a tree paradigm in its execution. In that method, an exhaustive search was developed, producing the intended result but with an improvable performance. Here, we propose the design of several pruning strategies to improve such performance. These strategies are motivated by the idea of avoiding the opening of full branches in the tree or reducing the size of the information in their nodes.

The rest of the work is organized as follows: in the following section we present $\mathbf{SL}_{FD}$ and the axiomatic system which constitutes the basis of the MinGen algorithm. In Section 3 we present the algorithm to enumerate the closed sets and minimal generators and summarize the strategies to improve its execution in practice. The work ends with a brief conclusion.

2 Logic for implications

First, the main notions related formal concept analysis needed in this work are presented.

A **formal context** is a triple $\mathbf{K} := (G, M, I)$ where G is a set of objects, M is a set of attributes and $I \subseteq G \times M$ is a binary relation between G and M such that, for $o \in G$ and $a \in M$, $o\ I\ a$ means that the object o has the attribute a. Then, two mappings are defined $(\ )' \colon 2^G \to 2^M$ defined for all $A \subseteq G$ as $A' = \{m \in M \mid g\ I\ m \text{ for all } g \in A\}$, and $(\ )' \colon 2^M \to 2^G$ defined for all $B \subseteq M$ as $B' = \{g \in G \mid g\ I\ m \text{ for all } m \in B\}$. We use the same symbol since no confusion arises. This pair of mappings is a Galois connection.

The composition of the intent and the extent mappings, and vice versa, introduces two closure operators $(\ )'' \colon 2^G \to 2^G$ and $(\ )'' \colon 2^M \to 2^M$. The notion of closed set (as a fixpoint of a closure operator) is defined as follows:

Definition 1 *A **formal concept** is a pair (A, B) such that $A \subseteq G$, $B \subseteq M$, $A' = B$ and $B' = A$. Consequently, A and B are closed sets of objects and attributes, respectively called extent and intent.*

In this work we focus on the attributes closed sets. A key point in this work is the notion of the minimal generator (mingen) [GW99], which provides a minimal representation for each closed set, and is defined as follows:

Definition 2 *Let $\mathbf{K} = (G, M, I)$ be a formal context and $A \subseteq M$. The set of attributes A is said to be a minimal generator (**mingen**) if, for all set of attributes $X \subseteq A$ if $X'' = A''$ then $X = A$.*

 ISBN: 978-84-617-8694-7

Remark that the above definition allows to characterize each closed set by means of a minimal subset to provide a canonical representation of the closed sets. Moreover, we would like to remark that such representation is not unique, since a given closed sets can have several minimal generators.

The notion of minimal generator can also be defined from the point of view of implications. They are expressions $A \to B$ where A and B are attribute sets. A context satisfies the implication $A \to B$ if every object that has all the attributes from A also has all the attributes from B.

Definition 3 *An (attribute) implication of a formal context* $\mathbf{K} = (G, M, I)$ *is defined as a pair* (A, B)*, written* $A \to B$*, where* $A, B \subseteq M$ *and* $A \cap B = \varnothing$*. Implication* $A \to B$ *holds (is valid) in* $\mathbf{K}$ *if* $A' \subseteq B'$*.*

The set of all valid implications in a context satisfies the well-known Armstrong's axioms [Arm74], which constitutes the pioneer logic to manage implications. The author introduces a sound a complete axiomatic system to infer new implications holding in a context from a given set of implications. Moreover, this logic constitutes a proposal to solve the attribute closure, i.e. to find the maximal set of attributes A^+ such that the implication $A \to A^+$ holds. As we mentioned, this maximal set is a closed set as defined before and this closure operator $()^+$ allows us to guide the automatization the search for closed sets. Thus, we introduce a new logic suitable for this goal.

The introduction of the Simplification Logic [MECF12], named $\mathbf{SL}_{FD}$, opened the door to the development of automated reasoning methods directly based on its novel axiomatic system. $\mathbf{SL}_{FD}$ considers reflexivity as axiom scheme

$$\texttt{[Ref]} \quad \frac{}{A \to A}$$

together with the following inference rules called Fragmentation, Composition and Simplification respectively.

$$\texttt{[Frag]} \ \frac{A \to BC}{A \to B} \qquad \texttt{[Comp]} \ \frac{A \to B,\ C \to D}{AC \to BD} \qquad \texttt{[Simp]} \ \frac{A \to B,\ C \to D}{A(C \setminus B) \to D}$$

Similarly to the dual vision of closed set (in terms of Galois connection and implications), a dual definition of minimal generator can be done in terms of implications:

Definition 4 *Let* $\mathbf{K} = (G, M, I)$ *be a formal context and* $A \subseteq M$*. The set of attributes* A *is said to be a minimal generator (**mingen**) if, for all set of attributes* $X \subseteq A$ *if* $X \to A^+$ *then* $X = A$*.*

In the following section we introduce the algorithm to enumerate the minimal generator based on $\mathbf{SL}_{FD}$ and describe the strategies to improve its performance.

 ISBN: 978-84-617-8694-7

3 An algorithm to enumerate all closed sets and their minimal generators

Simplification logic has allowed us to design several executable methods to manage implications. Thus in [MECF12] we developed a novel method to compute attribute closure strongly based on $\mathbf{SL}_{FD}$ inference rules. This method has been showed to have a better performance than the classical methods based on indirect techniques. One outstanding characteristics of $\mathbf{SL}_{FD}$ closure is the output it renders: given a set of attributes $X \subseteq M$ and a set of implications Γ, it renders its closure X^+ and a new set of implications Γ' which describes the remaining knowledge in the set $M \setminus X^+$.

This logic-based closure method is the basis of another method, named MinGen, to compute the set of all minimal generators from a set of implicant set presented in [CEMO12]. The algorithm works by applying the $\mathbf{SL}_{FD}$Closure algorithm to each implication in the set, opening a new branch. This application provides a new candidate to be added to mingen and a smaller implications set which guides us in the search of new sets of attributes to be added to mingens, producing a tree-like execution.

In summary, the input of this algorithm is a set of attributes M and a set of implications Γ over the attributes in M. The output is the set of closed sets endowed with all the minimal generators, i.e. $\{\langle C, mg(C)\rangle : C \text{ is a closed set of attributes}\}$ where $mg(C) = \{D : D \text{ is a mingen and } D^+ = C\}$. In this work we only consider non-trivial minimal generators, i.e. pairs of closed set and minimal generator $\langle X, Y\rangle$ where $Y \subsetneq X$.

For example, if $M = \{a, b, c, d, e, f\}$ and $\Gamma = \{a{\to}b, bc{\to}d, de{\to}f, ace{\to}f\}$ the output is the set $\{\langle abcdef, \{ace\}\rangle, \langle abdef, \{ade\}\rangle, \langle abcde, \{ac\}\rangle, \langle bcdef, \{bce\}\rangle, \langle bcd, \{bc\}\rangle, \langle def, \{de\}\rangle, \langle ab, \{a\}\rangle, \langle c, \{c\}\rangle, \langle \varnothing, \{\varnothing\}\rangle\}$. The execution of the method is depicted in Figure 1. We refer the reader to [CEMO12] for a detailed description of the method and its theoretical results.

In this work, we propose two pruning strategies to improve MinGen method. We briefly describe them as follows:

- The first strategy characterizes the branches that can be considered a superfluous one because all their nodes explore closed sets and minimal generators already considered in another branches. To implement this strategy we will consider a subset test on the branches of the same level and in the same branch.

- The second strategy is to expedite the execution of the method by including the closure method in each node in two steps, so that in the first one the closure set is computed and, in the second one, the resulting set of implications is computed taking into account this closed set. In this way, the resulting set of implications will be a smaller one and the method will have a better performance.

4 Conclusion and future works

In this work we have studied the state of the art in the enumeration of closed sets and minimal generators based on logic. We have considered the MinGen method based on Simplification Logic as the target of our work and we propose to improve it by means of several prunes to improve its performance.

In a future work, we propose to establish the theoretical results to state these strategies and to develop an exhaustive practical experiment to show its benefits.

Abstract

In this work we approximate the solution of the second order mixed nonlinear two-dimensional Volterra-Fredholm integral equation, by means of a new method based on the Fixed Point Theorem and making use of Schauder bases.

Key words: Two dimensional integral equations, Schauder bases, Banach spaces, Fixed Point Theorem, numerical methods.
MSC 2000: AMS 45A05, 45L05, 45N05,65R20.

1 Introduction

Several problems in engineering and physics can be modeled using nonlinear mixed two-dimensional Volterra-Fredholm integral equations of the second kind. On many occasions it is non possible to find an exact solution to these equations. Therefore, it is necessary use numerical methods for solving this type of equations. In recent years several numerical approaches have been proposed, deserving to be mentioned here, among others: the two-dimensional radial basis functions (see [1]), the Haar wavelet collocation method (see [2]), the discrete time collocation method of Brunner with a formulation of Kumar and Sloan (see [10]), the bivariate Chebyshev collocation method (see [11]), a meshless method using a radial basis function collocation scheme (see [12]), the piecewise constant two-dimensional block-pulse functions and their operational matrices (see [13]), the two-dimensional orthogonal triangular functions (see [14]), the homotopy perturbation method (see [15]), the He's variational iteration method (see [16])...

 ISBN: 978-84-617-8694-7

2 The problem and the method

In this work we develop an effective method for approximating the solution of the nonlinear mixed two–dimensional Volterra-Fredholm integral equation:

$$f(s,t) = g(s,t) + \int_{\gamma}^{t} \int_{\alpha}^{\alpha+\beta} K(s,t,x,y,f(x,y))\ dxdy \tag{1}$$

where $\alpha, \gamma \in \mathbb{R}$, $\beta, \delta \in \mathbb{R}^+$, $\Omega = [\alpha, \alpha+\beta] \times [\gamma, \gamma+\delta]$, $f \in C(\Omega)$ is the solution to be approximated, and g and K are given real-valued continuous functions defined, respectively, on Ω and $\Omega^2 \times \mathbb{R}$.

The numerical method to solve the equation (1) is based in two analytical techniques: the Banach fixed point theorem and Schauder bases in appropriate Banach spaces of continuous functions. Such tools have been used successfully in the study of certain types of one–dimensional integral and integro-differential equations (see [3], [4], [5]). We have also developed these analytical tools using the Geometric Series theorem with Schauder bases to solve numerically the linear two-dimensional Volterra integral equation (see [6]). The study of convergence and error are also described. Finally we illustrate the theoretical results with some numerical examples confirming the validity of the method employed.

Abstract

Using a version of the Banach fixed-point theorem and biorthogonal systems in adequate Banach spaces, we propose an interesting method for approximating the solution of an important type of two-dimensional nonlinear integral equation.

Key words: Two dimensional integral equations, Schauder bases, Banach spaces, Fixed Point Theorem, numerical methods.
MSC 2000: AMS 45A05, 45L05, 45N05,65R20.

1 Introduction

The numerical solution of the nonlinear two-dimensional integral equations (NTDIEs) has been a subject of considerable interest. This equations arises in various physical, engineering and biological problems. In fact, few numerical methods have been known for approximating the solution of NTDIEs. For example, in [1] the authors present the definition and operation of both two-dimensional differential transformation method and their reduced form, for finding the numerical solution of two-dimensional Volterra integral equations. A method for approximating the solution of a two-dimensional second kind integral equation with a smooth kernel using a bivariate quadratic spline quasi-interpolant defined on a uniform criss-cross triangulation of a bounded rectangle is presented in [2]. In [12], the two-dimensional linear Fredholm integral equations of the second kind are solved by using two-dimensional modification of hat functions and operational matrix of integration.

In order to solve two-dimensional Volterra-Fredholm integral equations, the two-dimensional orthogonal triangular functions are used in [3], in [9] the authors presented a

 ISBN: 978-84-617-8694-7

method based on approximating unknown funcion with Berstein polynomials and in [13] the approximate solution is expressed as expansion of two-dimensional delta basis functions.

The aim of this work is to introduce a new numerical method in order to approximate the solution of the nonlinear two–dimensional integral equations of the form:

$$f(s,t) = g(s,t) + \int_{\gamma}^{t}\int_{\alpha}^{s} K(s,t,x,y,f(x,y))\ dxdy + \int_{\gamma}^{\gamma+\delta}\int_{\alpha}^{\alpha+\beta} H(s,t,x,y,f(x,y))\ dxdy \tag{1}$$

where $\alpha, \gamma \in \mathbb{R}$, $\beta, \delta \in \mathbb{R}^+$, $f(s,t)$ is an unknown continuous function to be approximated defined on $\Omega = [\alpha, \alpha+\beta]\times[\gamma, \gamma+\delta]$, $g(s,t)$ and $K(s,t,x,y,z)$ are given real-valued continuous functions defined, respectively, on Ω and $\Omega^2 \times \mathbb{R}$.

2 The numerical method and examples

Using fixed-point techniques and biorthogonal systems in adequate Banach spaces, we present a interesting numerical method for solving integral equation (1). Such tools have been used successfully in the study of certain types of one–dimensional integral and integro-differential equations (see [4], [5], [6]). Using the Geometric Series theorem and the Schauder bases we have also study the linear two-dimensional Volterra integral equation (see [7]). The study of the convergence and error will be done. Numerical examples of the performance of the method are provided, confirming its reliability and precision.

Abstract

We propose a spectral preconditioner to accelerate the iterative solution of the correction equation i.e. the indefinite linear system to be solved at each step of the Jacobi-Davidson (JD) method fot the computation of the leftmost eigenpairs of large and sparse symmetric positive definite matrices. To construct the spectral preconditioner we use eigeninformation obtained by running the JD method itself at a low accuracy. The spectral preconditioner produces a clustering of the eigenvalues of the preconditioned correction equation thus speeding up the JD algorithm. Preliminary numerical tests accounts for the improving provided by the proposed approach.

Key words: eigenpairs, Jacobi-Davidson, spectral preconditioners

Extended abstract

The computation of $m \ll n$ eigenvalues of a symmetric positive definite (SPD) matrix A is a common task in many scientific applications. We will denote as $\lambda_1 < \lambda_2 < \cdots < \lambda_m < \ldots < \lambda_n$ the eigenvalues of A and $\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_m, \ldots, \boldsymbol{v}_n$ the corresponding (normalized) eigenvectors. Recently in [2] a new preconditioning strategy is developed for accelerating the second stage of the DACG-Newton method [1]. The idea is to use eigenvector approximation to construct a spectral preconditioner for the efficient solution of the correction equation:

$$\begin{aligned} J_k \boldsymbol{u}_k &= -\boldsymbol{r}_k, \qquad \text{where} \\ J_k &= (I - \boldsymbol{u}_k \boldsymbol{u}_k^\top)(A - \theta_k I)(I - \boldsymbol{u}_k \boldsymbol{u}_k^\top), \quad r = -(A\boldsymbol{u}_k - \theta_k \boldsymbol{u}_k), \quad \theta_k = \frac{\boldsymbol{u}_k^\top A \boldsymbol{u}_k}{\boldsymbol{u}_k^\top \boldsymbol{u}_k} \end{aligned} \tag{1}$$

 ISBN: 978-84-617-8694-7

to be solved at each step of this projected Newton method. As the preconditioner for equation (1) a tuned preconditioner $\mathcal{P}$ is employed ([3]) i.e. a preconditioner satisfying $\mathcal{P}AV_m = V_m$, where V_m is a rectangular matrix containing an approximation of the m leftmost eigenvectors of A as columns.

In this paper we propose to use a spectral preconditioner to accelerate the correction equation (1) within the Jacobi-Davidson method. For the details of this method we refer to the original paper [5], as well as to successive works (see e.g. [4]) which analyze JD both theoretically and experimentally. Our approach is based on a twofold run of the JD solver. Namely, we first run JD to evaluate a number of (inaccurate) leftmost eigenpairs which will bw the columns of V_m. We then run a second time the JD method up to the final accuracy, using V_m both as the initial search subspace for JD and to construct the spectral preconditionerm as a low-rank update of a given inverse approximation of matrix A.

PCG solution of the correction equation

As a Krylov subspace solver for the correction equation we chose the Preconditioned Conjugate gradient (PCG) method since the Jacobian J_k has been shown to be SPD in the subspace orthogonal to $\boldsymbol{u}_k$. Regarding the implementation of PCG, we mainly refer to the work [4], where the author shows that it is possible to solve the linear system in the subspace orthogonal to $\boldsymbol{u}_k$ and hence the projection step needed in the application of J_k can be skipped. Moreover, we adopted the exit strategy for the linear system solution described in the above paper, which allows for stopping the PCG iteration, in addition to the classical exit test, whenever the l-th PCG iterate satisfies an eigenresidual test $\|\boldsymbol{r}_{k,l}\| < \tau$ or when the decrease of $\|\boldsymbol{r}_{k,l}\|$ is slower than the decrease of the residual of the linear system at step l because in this case further iterating does not improve the accuracy of the eigenvector.

Acceleration by spectral preconditioners

A class of spectral preconditioners is defined in [2] based on a very rough approximation of the sought eigenpairs. Denoted as P_0 an initial approximate inverse of A, we assume that the JD method has provided the m leftmost eigenpairs (to a low relative accuracy specified by parameter τ_0) satisfying

$$A\tilde{\boldsymbol{v}}_j = \lambda_j \tilde{\boldsymbol{v}}_j + \mathbf{res}_j, \qquad \|\mathbf{res}_j\| \leq \tau_0 \lambda_j, \ j = 1, \ldots, m, \tag{2}$$

Then, for a generic eigenvalue λ_j ($j < m$) we define the following tuned preconditioner, which will be kept constant throughout the second JD iterations to accurately compute the j-th eigenpair:

$$P_j = P_0 - W \left(W^\top A V_j \right)^{-1} W^\top, \qquad \text{with} \qquad W = P_0 A V_j - V_j \tag{3}$$

where

$$V_j = [\tilde{\boldsymbol{v}}_{j+1}, \ldots, \tilde{\boldsymbol{v}}_m] \qquad \text{and} \qquad \Lambda_j = \mathrm{diag}(\lambda_{j+1}, \ldots, \lambda_m). \tag{4}$$

 ISBN: 978-84-617-8694-7

A direct computation shows that P_j is a tuned preconditioner i.e. satisfies: $P_j A V_j = V_j$, irrespective of the error introduced by the computation of V_j. The previous relation implies that the preconditioned matrix $P_j A$ has the eigenvalue 1 with at least multiplicity $m - j$. When P_j is used to accelerate the Newton iteration, it must be projected in the space orthogonal to the previous computed eigenpairs as described in [5] (we will call $\widehat{P}_j$ the projected preconditioner).

Theorem 1 (whose proof is given in [2]) will characterize the eigenvalues of the preconditioned matrix $\widehat{P}_j J_k^{(j)}$, where index k identifies the JD iteration number in computing eigenpairs $(\lambda_j, \boldsymbol{v}_j)$.

Theorem 1 *Let matrix V_j be defined as in (4), P_j a tuned preconditioner, then each column of V_j i.e. $\tilde{\boldsymbol{v}}_s, s = j+1, \ldots, m$, is an approximate eigenvector of $P_j J_k^{(j)}$ corresponding to the approximate eigenvalue $1 - \dfrac{\theta}{\lambda_s} \approx 1 - \dfrac{\lambda_j}{\lambda_s}$. In particular the following relation holds:*

$$\widehat{P}_j J_k^{(j)} \tilde{\boldsymbol{v}}_s = \left(1 - \frac{\theta}{\lambda_s}\right) \tilde{\boldsymbol{v}}_s + \mathbf{err} \tag{5}$$

with $\|\mathbf{err}\| \leq \tau_0 \, C$, and $C \equiv C(\tau_0, \|P_j\|, \lambda_j, \lambda_{j+1})$.

Implementation

1. Limited memory implementation. We fix the maximum column size of matrix V_j, parameter $l_{\max}$.
2. Enlarging matrix V_m. A second variant consists in computing an additional number of approximated eigenpairs in the first JD stage to avoid matrix V_m to be empty when computing the $m-$th eigenpair. We introduce a further parameter, win, which counts these extra eigenpairs.

Taking into account these variants, in the computation of the j-th eigenpair we will use $V_j = [\tilde{\boldsymbol{v}}_{j+1}, \ldots, \ \tilde{\boldsymbol{v}}_{j_{end}}]$ with $j_{end} = \min\{m + \text{win}, l_{\max} + j\}$ in formula (3), namely

$$P_j = P_0 - W \left(W^\top A V_j\right)^{-1} W^\top, \qquad \text{with} \qquad W = P_0 A V_j - V_j \tag{6}$$

being $P_0 = (LL^T)^{-1}$ and $L = IC(\texttt{droptol}, A)$ an incomplete triangular Cholesky factor of A, with parameter `droptol` the threshold for dropping small elements in the factorization.

Preliminary numerical results

The preconditioned two-stage JD algorithm is tried for different values of the parameters on a model problem. We used the *MatLAB* JDQR package which can be found at the webpage: `http://www.staff.science.uu.nl/~sleij101/index.html`. This package has

 ISBN: 978-84-617-8694-7

been modified in order to allow the solution of indefinite shifted linear systems by the PCG method as described in [4] accelerated by the spectral preconditioner described so far.

We tested the proposed algorithm in the computation of the 20 smallest eigenpairs of the Laplacian matrix of order 300. The exit test is $\|A\boldsymbol{u} - q(\boldsymbol{u})\boldsymbol{u}\| \leq \tau$, with a tolerance $\tau = \tau_0 = 10^{-2}$ for the first and $\tau = \tau_1 = 10^{-12}$ for the second JD run.

Table 1: Computation of the 20 smallest eigenvalues of the Laplacian(300) with different win and l_{max} values. The initial IC preconditioner is computed using `droptol` $= 0.1$.

win	$l_{\max}$	PCG its.			JD its.		
		1st JD	2nd JD	total	1st JD	2nd JD	total
5	5	1740	3608	5348	79	155	234
5	10	1740	3535	5275	79	162	241
5	15	1740	3464	5204	79	153	232
5	20	1740	3269	5009	79	144	223
10	10	2360	3437	5797	102	166	268
10	15	2360	3544	5904	102	171	273
10	20	2360	3107	5467	102	141	243
IC precond.				8017			204

From these initial results we obtain in all cases an improvement in the total number of PCG iterations with respect to using the Incomplete Cholesky preconditioner alone. Moreover the low-rank update seems effective even when the number of eigenvectors used for updating the preconditioner is small (see Table 1 for win $= 5, l_{\max} = 5$).

Efficient Parallel Stream Compaction on a Extremely Low-Cost SDC Cluster

Gregorio Bernabé[1] and Manuel E. Acacio[1]

[1] *Computer Engineering, University of Murcia*

emails: gbernabe@ditec.um.es, meacacio@ditec.um.es

Abstract

Many highly parallel algorithms usually generate large volumes of data containing both valid and invalid elements, and high-performance solutions to the stream compaction problem reveal extremely important in such scenarios. Although parallel stream compaction has been extensively studied in GPU-based platforms, and more recently, in the Intel Xeon Phi platform, no study has considered yet its parallelization using a low-cost computing cluster, even when general-purpose single-board computing devices are gaining popularity among the scientific community due to their high performance per $ and watt. In this work, we consider the case of an extremely low-cost cluster composed by four Odroid C2 single-board computers (SDCs), showing that stream compaction can also benefit–important speed-ups can be obtained–from this kind of platforms. To do so, we derive two parallel implementations for the stream compaction problem using MPI. Then, we evaluate them considering varying number of processes and/or SDCs, as well as different input sizes. In general, we see that unless the number of elements in the stream is too small, the best results are obtained when eight MPI processes are distributed among the four SDCs that conform the cluster.

Key words: General-purpose single-board computing (SDC); Odroid C2; Fast parallel stream compaction; Parallelization strategies; MPI; Speed-up

1 Introduction

Continuous improvements in the technologies used to build computers have recently made possible the fabrication of extremely low-cost general-purpose single-board computing devices. Nowadays, one can buy one of these *tiny* computers for a few dollars and make it run Windows 10 or Ubuntu-Linux operating systems [8]. Among the variety of vendors

providing these single-board computers (SBC), maybe the most renowned ones are Raspberry Pi and Odroid. Although the initial aim of these devices was to promote the teaching of basic computer science in schools [4] and developing countries [5], recent appearance of single-board computers with multicore CPU chips and several gigabytes of main memory have attracted interest of a multitude of projects trying to take advantage of their very low cost-performance ratio (i.e. for scientific computing [1]).

Whereas Raspberry Pi SBCs seem to have put the focus more on a "stand-alone" scenario, Odroid devices provide increased processor frequency, more main memory and higher bandwidth Ethernet capabilities. Particularly, the Raspberry Pi 3 model B that was launched in February 2016, features a 1.2 GHz, 4-core ARM Cortex-A53 CPU chip, 1 GB main memory and a 10/100 Ethernet port. Compared with its predecessor, the Raspberry Pi 2 model B released in February 2015, it adds wireless connectivity (2.4 GHz WiFi 802.11n and Bluetooth 4.1). On the contrary, the Odroid C2 sacrifices wireless connectivity in favor of higher clock frequencies (1.5 GHz, 4-core ARM Cortex-A53 CPU chip), larger main memory (2 GB) and Gigabit Ethernet connection. These characteristics make these particular devices more appropriate at building high-performance low-cost clusters able to meet the demands of some scientific applications.

On the other hand, a common characteristic found in many highly parallel algorithms is that they usually generate large volumes of data containing both valid and invalid elements. In these scenarios, high-performance solutions to the data reduction problem reveal extremely important. Stream compaction (also known as stream reduction) has been proposed to "compact" an input stream mixed with both valid and invalid elements to a subset with only the valid elements [12]. This way, stream compaction is found in many applications, that go from data mining and machine learning (in order to prune invalid nodes after each parallel breadth-first tree traversal step [11]) to deferred shading (to obtain the subset of pixels whose rays intersect, which allows for better workload balancing among the participating threads [6]).

Formally, given a list of elements $i_1, i_2, ..., i_n$ belonging to the set I and a predicate function $F : I \rightarrow \{true, false\}$, stream compaction divides I in valid and invalid elements (ones that satisfy the predicate F and others that do not), and keeps the relative order for all the valid elements in the output (O) [6]. As shown in Algorithm 1, the Serial stream compaction of I under the predicate function F is $O = \{i \epsilon I | F(i) = true\}$. Therefore, the output O simply contains all valid elements copied from the input I. An example of the execution of Algorithm 1 can be observed in Figure 1. The list of input elements is composed by numbers between 0 and 4. The Serial stream compaction selects all elements that are not zero (assuming that zero represents the invalid value), based on the predicate function F, as shown in the low part of Figure 1. Although Algorithm 1 is simple, the parallelization is not trivial because the output position of each valid element cannot be obtained until all its preceding elements have been discovered [10].

5:     end if
6: end for
```

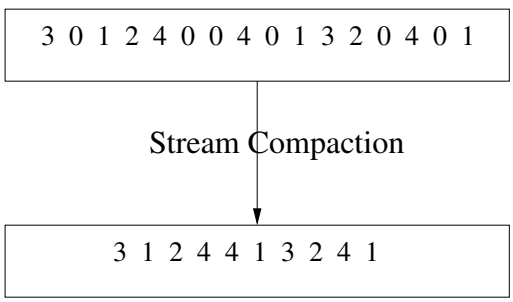

Figure 1: Example of serial stream compaction (Zero value is used to represent the invalid elements)

Parallel stream compaction has been extensively studied in GPU-based platforms [7, 12, 6, 10], and more recently parallel implementations for the Intel Xeon Phi processor have also been proposed [13]. In this work, we consider the case of an extremely low-cost cluster composed by four Odroid C2 single-board computers (SDCs), showing that stream compaction can also benefit–important speed-ups can be obtained–from this kind of platforms. To do so, we derive two parallel implementations for the stream compaction problem using MPI. Then, we evaluate them considering varying number of processes and/or SDCs, as well as different input sizes. In general, we see that unless the number of elements in the stream is too small, the best results are obtained when 8 MPI processes are distributed among the 4 SDCs that conform the cluster.

The rest of the paper is organized as follows. The parallelization strategies that we have implemented and evaluated in this work are explained in Section 2. In Section 3 we give the details of the cluster of Odroid C2 SDCs used for the evaluation, and then, we present the results. Finally, Section 4 concludes the paper and draws some lines of future work.

2 Parallelization on a cluster of Odroid C2s

In this Section we present the two parallelization strategies that we have considered in this work. In both cases, we have implemented them using MPI [3].

2.1 Parallel Stream Compaction

Algorithm 2 Parallel stream compaction

We have based on the implementation proposed in the Thrust library [9] to develop the Parallel stream compaction scheme shown in Algorithm 2. A vector of a particular length, the predicate function, the number of processes and the pid of each process are the inputs. We have divided Algorithm 2 in four phases namely: *Validation* phase (lines 4-8), *Scan* phase (lines 9-12), *Communication* phase (lines 13-21) and *Scatter* phase (lines 22-26). During the *Validation* phase, the input vector (I) is examined in parallel, and taking into consideration the predicate function, each process annotates the validity of each of its assigned elements in array *temp* (representing 1 a valid element and 0 an invalid one). The parallel *Scan* phase needs an additional array (*scan*) to compute the so called prefix-sum [2], where each element is the addition of all its preceding elements excluding itself. So, each process obtains in parallel the number of valid elements (*nvalid*) in its portion of the stream. Following this, in the *Communication* phase each process, identified by a pid, sends the number of valid elements that it has found to all the processes with higher pids. All the processes, except the first one, receive the number of valid elements and compute the position (*pos*) of the first of their valid elements. Finally, during the *Scatter* phase, based on the *scan* and *temp* arrays, all valid elements are transferred from the input array to the output one (I and O, respectively), preserving the order in which these elements appear in

 ISBN: 978-84-617-8694-7

the input array.

Figure 2 shows an example of an execution with four MPI processes for a list of input elements composed by numbers ranging between 0 and 4. In this case the predicate function F selects all elements that are not zero. Now, the input vector of length 16 positions is divided among the four MPI processes (*P0, P1, P2 and P3*). All the processes carry out the *Validation* and *Scan* phases in parallel. The position (*pos*) computed by each process is shown below the vector *scan*. Finally, the output O is built taking into account the *temp* and *scan* vectors, as well as the *pos*, previously computed.

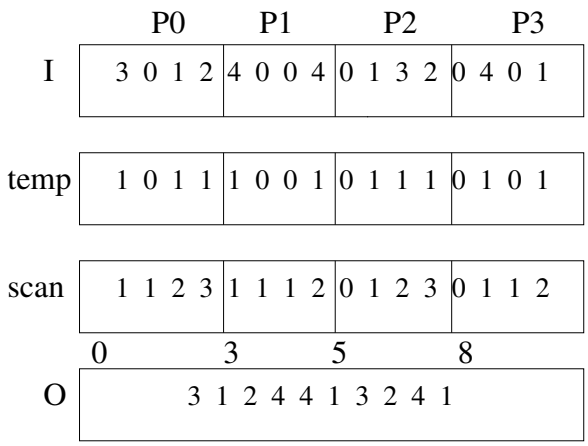

Figure 2: Example of Parallel stream compaction

2.2 Parallel Work-Efficient Stream Compaction

In [13], it is presented a work-efficient stream compaction algorithm aimed at improving the computing complexity of the Parallel stream compaction that was shown in Algorithm 2. Again, using MPI, we have developed the parallel version of this work-efficient stream compaction and we show it in Algorithm 3. Now, during the *Validation* phase (lines 5-10), each process saves the validity of each element on the array *scan* and stores the number of valid elements on the vector V. Therefore, the additional array of integers (*temp*) needed in Algorithm 2 is no longer necessary. In the *Communication* phase (lines 11-26), all processes except the first one send the number of valid elements to the first process (that with pid 0), which executes the inclusive prefix-sum on vector V [2], where each element is the addition of all its preceding elements including itself. Then, each position of the array V is sent back to the corresponding process. Following this, each process executes the *Scan* phase (lines 27-30) on its own segment independently, based on the shifting value received previously. Finally, in the *Scatter* phase (lines 31-35) the validity of each element is re-checked by

evaluating two consecutive positions of the *scan* array, obtaining the output array (O) with the valid elements from the input array (I).

Figure 3 illustrates an example for a list of elements ranging between 0 and 4 and the predicate function F that selects all elements that are not zero for an execution of four MPI processes. As in the previous example, 4 input elements are assigned to each MPI process and the *Validation* phase is applied producing directly the validity of each element on vector *scan* together with the number of valid elements that each process finds out. The latter is stored on vector V. Then, the process $P0$ executes the inclusive prefix-sum on vector V and sends back the output to the rest of the processes as is indicated by the arrows in Figure 3. Finally, each process enters the *Scan* and *Scatter* phases taking into account the corresponding shifting value calculated by $P0$.

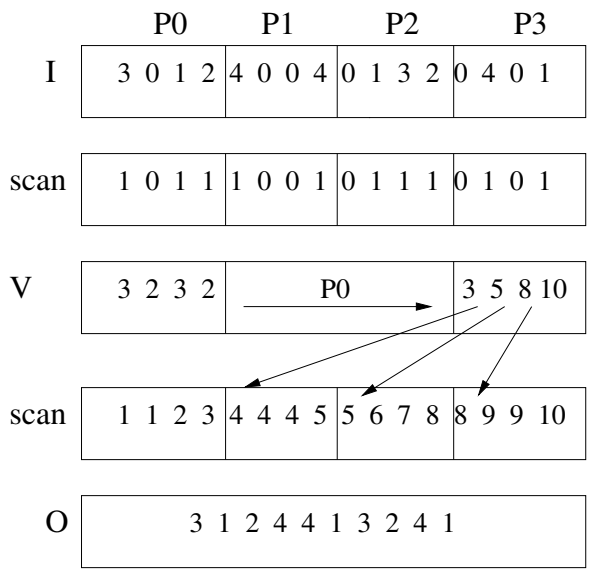

Figure 3: Example of Parallel work-efficient stream compaction

3 Experiments

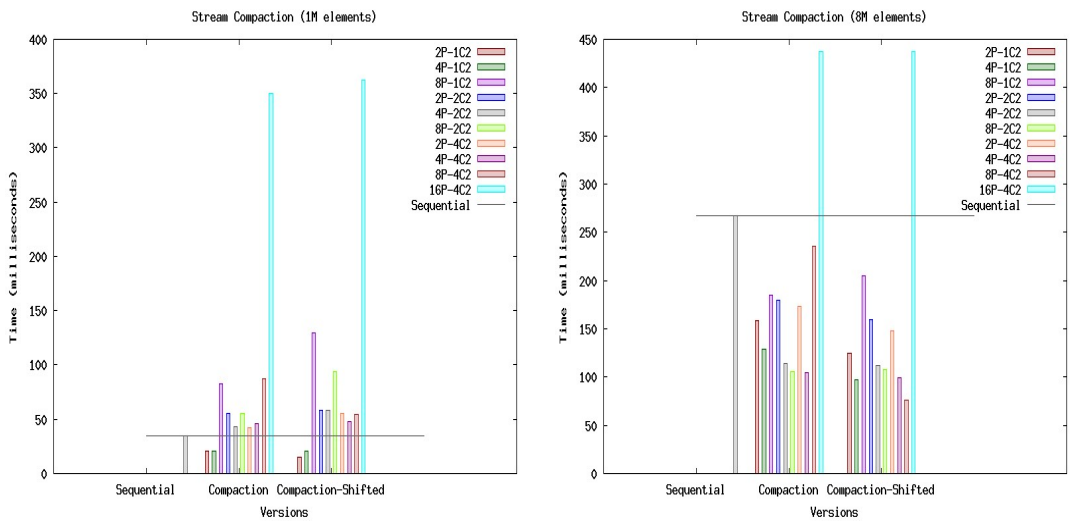
We have built a cluster which is composed by four Odroid C2 nodes. Each node contains a 1.5 GHz quad-core 64-bit ARM Cortex-A53 CPU and 2 GBytes of RAM memory. All the nodes are interconnected through a Gigabit Ethernet switch. The operating system installed on each node is Ubuntu 16.04.02 LTS. In this cluster we have installed MPICH (v3.2) as the MPI library implementation.

We have executed and measured the two parallelization strategies for stream compaction

 ISBN: 978-84-617-8694-7

presented in Section 2 on this cluster. The baseline for all the comparisons is the sequential version of Algorithm 2 without the *Communication* phase. Moreover, we have configured different parallel execution scenarios for the two parallel versions of the stream compaction problem explained before. We consider parallel executions with 2, 4, 8 and 16 MPI processes, running on the same Odroid C2 board or different boards (up to 4). We have chosen several input data sizes for our tests. In particular, we consider input arrays with $1M$, $8M$, $32M$ and $64M$ integer elements ranging between 0 and 4. The predicate function in all cases determines as valid all numbers that are not zero.

Figure 4a, Figure 4b, Figure 5a and Figure 5b show the execution times (in milliseconds) that are observed for input data sizes of $1M$, $8M$, $32M$ and $64M$ elements, respectively. For all these figures, from left to right, we first present the result obtained for the sequential version (`Sequential`), then we show the results for the Parallel stream compaction (`Compaction`) and Parallel work-efficient stream compaction (`Compaction-Shifted`) parallelization strategies respectively. For each one of them, we consider 2, 4 and 8 MPI processes running on one Odroid C2 board (`2P-1C2`, `4P-1C2` and `8P-1C2` respectively), and on 2 Odroid C2 boards, having 1, 2 and 4 MPI processes per board in each case (`2P-2C2`, `4P-2C2` and `8P-2C2` respectively), and finally 2, 4, 8 and 16 MPI processes running on 4 Odroid C2 boards, having 1, 2 or 4 processes per board as appropriate (`2P-4C2`, `4P-4C2` `8P-4C2` and `16P-4C2` respectively).



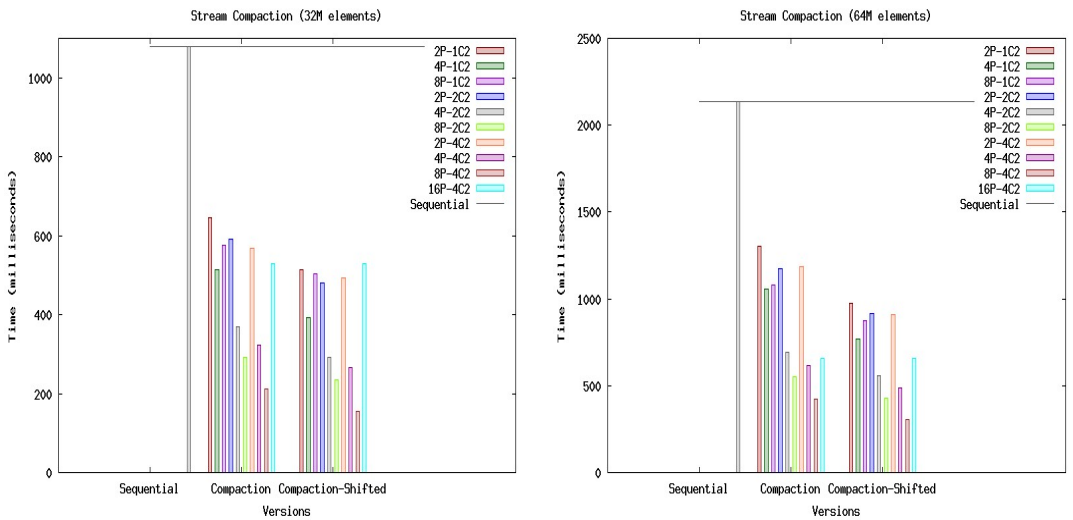
(a) (b)

Figure 4: Execution times (milliseconds) for stream compaction

From Figure 4a, we can see that the two proposed parallelization strategies for the

 ISBN: 978-84-617-8694-7

stream compaction problem obtain noticeable speed-ups when they are executed on a single Odroid C2 board with 2 or 4 MPI processes with regard to the sequential version. However, the executions on different Odroid C2 boards show negative outcomes from the performance point of view when the size of the input array is excessively small (1M elements). What makes the differences is that in the first case all communications take place on the same board, and therefore, can be performed with low latency. Contrarily what happens when communications involve several Odroid C2 boards. In this case, the time required for communication does not compensate the small processing time that is needed to obtain the stream compaction for such a small number of elements. Moreover, the executions on a single Odroid C2 SDC with 8 MPI processes (2 MPI processes per core) also show negative speed-ups revealing (as expected) that a configuration with more than one MPI process per core increments the communications and potentially slows computations.



(a) (b)

Figure 5: Execution times (milliseconds) for stream compaction

Taking a closer look at the results for one Odroid C2 board and 1M input size, we see that the speed-ups of the Parallel stream compaction strategy for 2 and 4 MPI processes are 1.68 and 1.64 respectively. Similarly, the work-efficient stream compaction parallelization strategy obtains speed-ups of 2.25 and 1.63 for 2 and 4 MPI processes respectively. Therefore, in both cases, fewer MPI processes, and therefore, less amount of communications among several processes brings the best results. These two parallel versions do not scale due to the small computation/communication ratio that they exhibit, which decreases as the number of processes grows.

In general, from Figures 4b, 5a and 5b, we can see that as the input data size increases, so it does the speed-ups obtained by the two parallelization strategies analyzed in this work when more cores are involved. The exception is the configuration with 16 processes running on 4 Odroid C2 boards (4 processes per board), which reaches lower speed-ups than that with 8 processes running on 4 Odroid C2 boards (2 processes per board).

More specifically, Figure 4b shows the results seen for 8M elements. In this case the two proposed parallelization strategies obtain significant speed-ups when executed on a single Odroid C2 board with 2, 4 or 8 MPI processes with regard to the sequential version. Additionally, the scalability is good for 2 and 4 MPI processes obtaining 1.69 and 2.06 for the Parallel stream compaction strategy and 2.14 and 2.74 for the Parallel work-efficient stream compaction approach. Therefore, for medium input data sizes the computation/communication ratio is appropriate. Although the two parallelization strategies also achieve gains for the configuration ($8P-1C2$) with 2 processes per core on a single Odroid C2 (speed-ups of 1.44 and 1.31, respectively), these speed-ups are (as expected) lower than those of the ($4P-1C2$) case. It is clear that the fact that there are twice the number of MPI processes than the total number of cores available introduces extra scheduling overhead and causes worse use of cores' resources (such as caches). On the other hand, the executions on different Odroid C2 SDCs (except for $8P-4C2$ and $16P-4C2$) present important speed-ups and good scalability for 2, 4 and 8 MPI processes for the two proposed parallelization strategies. Thus, the increment in the number of processes per Odroid C2 implies a suitable operation of the Odroid C2 cluster, where the communication latency among the different boards of the cluster does not ballast performance. In the $8P-4C2$ case is where the performance differences between the two parallelization strategies start appearing. Whereas the most efficient strategy (namely Compaction-Shifted) achieves the highest speed-up for this configuration, the other one cannot improve over the results reached by $4P-4C2$ demonstrating its more limited scalability for medium-sized workloads. Finally, the large number of processes involved in $16P-4C2$ results into excessively small computation/communication ratios, which is the reason for the negative outcomes observed in both cases.

As we can observe in Figures 5a and 5b, having higher input data sizes for the two parallel stream compaction strategies results into significant gains in all the configurations. For both input data sizes both Compaction and Compaction-Shifted obtain speed-ups that are close to that observed for the $8M$ elements case when executed on a single Odroid C2 SDC with 2, 4 or 8 MPI processes. However, the resulting speed-ups become even more important as the number of involved cores grows. Moreover, they scale nicely for 2, 4 and 8 MPI processes, achieving their highest values for 8 MPI processes running on 4 Odroid C2 SDCs (5.10 and 5.06 for the parallel stream compaction and input data sizes of $32M$ and $64M$, respectively; and 6.96 and 7.04 for the parallel work-efficient stream compaction and input data sizes of $32M$ and $64M$, respectively). It is also worth noting that even for these

 ISBN: 978-84-617-8694-7

large input sizes, the results reached for the $16P - 4C2$ configuration are worse than those of the $8P - 4C2$ in both cases. Now this the differences between them becomes narrower as input data sizes increase.

4 Conclusions

In this work, we have studied the parallelization of the stream compaction problem on a low-cost cluster of single-board computers. Particularly, we have configured the low-cost cluster from 4 Odroid C2 SDCs which are interconnected using a typical Gigabit Ethernet switch. We have implemented two parallel versions for the stream compaction problem using MPI. Then, we evaluate them considering varying number of processes and/or SDCs, as well as different input sizes. In general, we see that when the number of elements in the stream is too small, the most important benefits are observed when all participating processes are in the same Odroid board. In this case the low computation/communication ratio for small number of input elements cannot make up for the overhead entailed by the inter-SDC communications. As the number of elements in the input stream increases, so it does the number of processes that can participate in parallel executions, and important speed-ups are reached. Overall, the best results are reached when eight MPI processes are distributed among the four SDCs that conform the cluster. In this case, speed-ups of 6.96 and 7.04 are obtained for the Compaction and Compaction-Shifted strategies respectively, for the larger problem size considered in this work (input data size of $64M$).

Quasi-monogenic functions

Swanhild Bernstein[1]

[1] *Department of Mathematics and Informatics, TU Bergakademie Freiberg*

emails: swanhild.bernstein@math.tu-freiberg.de

Abstract

We define quasi-monogenic functions based on a generalized Riesz-Hilbert operator. An application of this theory is the linear Riesz transform which commutes (up to a constant) with shears.

Key words: quasi-monogenic, monogenic functions, Riesz transforms, Hardy space decomposition

1 Introduction

Quaternionic and Clifford analysis are a refinement of classical harmonic analysis. Similar to the analytic signal that is based on classical function theory, the monogenic signal [2] is an important tool in higher dimensional signal analysis. The analytic signal is based on the Hilbert transform whereas the monogenic signal is based on the Riesz transforms. Using quaternions, the Riesz transforms build a higher dimensional analog of the Hilbert transform. More on applications of monogenic signals can be found in [1]. All Hilbert transform are related to Dirac and Cauchy-Riemann operators and Hardy spaces as spaces of boundary values of monogenic functions in upper/lower half spaces.
The Hilbert and Riesz transforms are the most important singular integrals and had been investigated in detail in [8]. Because they are also operators of convolution type, they can be studied in Fourier domain. That was done in [7] and extended to more general operators in [5]. The Riesz transforms can be used to construct monogenic wavelets [4] and can be applied to signal processing. Shearlets are similar to wavelets, but they are invariant under shears and not under rotations. Unfortunately, the Riesz transforms does not correspond to shear operations. But the in [3] introduced linearized Riesz transforms do. Therefore, quasi-monogenic shearlets are constructed by the aid of the linearized Riesz transforms.

The aim of this paper to construct Dirac operator D_L in $\mathbb{R}^2$ and Cauchy-Riemann operators in $\mathbb{R}^3$ which are generated by Riesz transforms $\mathcal{H}_L$. That will prove that the quasi-monogenic Riesz transforms generate an essentially equivalent function theory even though the operators can only be described by their Fourier multipliers.
Examples of quasi-monogenic Riesz transforms are the classical Riesz transforms, and the linearized Riesz transforms defined in [3].

2 Preliminaries

Let $\mathbb{H}$ the algebra of complex quaternions. The algebra consists of the basic elements e_0, e_1, e_2, e_3 which fulfill

$$e_0^2 = 1, \quad e_0 e_j = e_j e_0, \quad e_j^2 = -1, \quad e_i e_j = -e_j e_i, \ i, j = 1, 2, 3,$$

$$e_1 e_2 = e_3, \quad e_2 e_3 = e_1, \quad e_3 e_1 = e_2.$$

Because e_0 is the unit element of the algebra we identify e_0 with 1.

Definition 1 *Given u in the Schwartz space $\mathcal{S}(\mathbb{R}^2)$ we define the Fourier transform $\mathcal{F}(u) = \hat{u}$ of f as*

$$\widehat{u}(\underline{\omega}) := \frac{1}{2\pi} \int_{\mathbb{R}^2} u(\underline{x})\, e^{-i\underline{\omega}\cdot\underline{x}}\, d\underline{x}.$$

The inverse Fourier transform $\mathcal{F}^{-1}(u) = u^{\vee}$ is given by

$$u^{\vee}(\underline{x}) = \frac{1}{2\pi} \int_{\mathbb{R}^2} u(\underline{\omega})\, e^{i\underline{x}\cdot\underline{\omega}}\, d\underline{\omega}.$$

Theorem 2 (Hörmander-Mikhlin Mulitplier theorem) *Let $m(\underline{\omega})$ be a complex-valued bounded function on $\mathbb{R}^n\backslash\{0\}$ that satisfies either*

(a) Mikhlin's condition

$$|\partial_{\underline{\omega}}^{\alpha} m(\underline{\omega})| \leq A|\underline{\omega}|^{-|\alpha|}$$

for all multi-indices $|\alpha| \leq \left[\frac{n}{2}\right] + 1$,

(b) Hörmander's condition

$$\sup_{R>0} R^{-n+2|\alpha|} \int_{R<|\underline{\omega}|<2R} |\partial_{\underline{\omega}}^{\alpha} m(\underline{\omega})|\, d\underline{\omega} \leq A^2 < \infty$$

for all multi-indices $|\alpha| \leq \left[\frac{n}{2}\right] + 1$.

Then for all $1 < p < \infty$ m is an $L^p(\mathbb{R}^n)$ mulitplier and moreover, the operator $f \mapsto \mathcal{F}^{(-1)}(\mathcal{F}(f)m)$ maps $L^1(\mathbb{R}^n)$ to $L^{1,\infty}(\mathbb{R}^n)$, it suffices to prove that the distribution W coincides with a function K on $\mathbb{R}^n\backslash\{0\}$ that satisfies Hörmander's condition.

 ISBN: 978-84-617-8694-7

3 Quasi-monogenic functions

We consider a generalization of the theory of [6]. Let be

$$\mathcal{H}_L u = \mathcal{F}^{(-1)}(\mathcal{F}(u)h_L),$$

where h_L is an $L^p(\mathbb{R}^n)$ mulitplier and $h_L^2(\underline{\omega}) = 1$ and

$$P_L^{\pm} u = \frac{1}{2}\left(1 \pm \mathcal{H}_L\right) u.$$

The operator $|D|$, defined by $(|D|u)^\wedge(\underline{\omega}) = |\underline{\omega}|\widehat{u}(\underline{\omega})$, is a closed unbounded operator in $L^2(\mathbb{R}^2)$ with domain $\mathcal{D}(|D|) = \mathcal{D}(D) = H^1(\mathbb{R}^2)$, the Sobolev space $H^1(\mathbb{R}^2) = \{u \in L^2(\mathbb{R}^2 : \frac{\partial u}{\partial x_j} \in L^2(\mathbb{R}^2),\ 1 \le j \le 2\}$.

Definition 3 *The operator $D_L : H^1(\mathbb{R}^2) \to L^2(\mathbb{R}^2)$ is defined as*

$$D_L = -|D|\mathrm{sgn}(D_L) = -|D|\mathcal{H}_L.$$

Further,

$$|D| = |D_L| = -\mathrm{sgn}\{D_L\}D_L \quad \text{where} \quad \mathrm{sgn}\{D_L\} = P_L^+ - P_L^-,$$

is a bounded linear operator on $L^2(\mathbb{R}^2)$ satisfying $(\mathrm{sgn}\{D_L\})^2 = I$ and the operator D_L is self-adjoint and factorizes the Laplacian $D_L\overline{D_L} = -D_L D_L = \Delta$ on $\mathbb{R}^2$.

Given $u \in L^2(\mathbb{R}^2)$ and $t > 0$, define $u_+(t) \in L^2(\mathbb{R}^2)$ by

$$u_+(t) = e^{-t\{D_L\}}P_L^+ u = e^{-t|D|}P_L^+ u.$$

Definition 4 *A function u is left or right **quasi-monogenic** in $\mathbb{R}^3$ if*

$$(\partial_{x_0} + D_L)u = 0 \quad or \quad u(\partial_{x_0} + D_L) = 0.$$

Theorem 5 *Let $u \in L^2(\mathbb{R}^2)$, define functions U_+ on $\mathbb{R}^3_+$ and U_- on $\mathbb{R}^3_-$ by*

$$U_+(x_0 e_0 + \underline{x}) = u_+(x_0)(\underline{x}), \quad x_0 > 0, \underline{x} \in \mathbb{R}^2,$$
$$U_-(x_0 e_0 + \underline{x}) = u_-(x_0)(\underline{x}), \quad x_0 < 0, \underline{x} \in \mathbb{R}^2,$$

then

(1) $\dfrac{\partial U_\pm}{\partial x_0}(x_0 e_0 + \underline{x}) + D_L U_\pm(x_0 e_0 + \underline{x}) = 0, \quad x_0 e_0 + \underline{x} \in \mathbb{R}^3_\pm$, *or in other words, that the functions $U_\pm$ are left **quasi-monogenic** on their respective half-spaces.*

(2) $\lim\limits_{x_0 \to 0\pm} U_\pm(x_0 e_0 + \underline{x}) = P_L^\pm U(\underline{x})$ *for almost all* $\underline{x} \in \mathbb{R}^2$.
(Plemelj-Sochotzki formulae)

 ISBN: 978-84-617-8694-7

(3) $\lim_{x_0 \to \pm\infty} U_{\pm}(x_0 e_0 + \underline{x}) = 0$ *for all* $\underline{x} \in \mathbb{R}^2$.

Examples of quasi-monogenic Riesz transforms are the classical Riesz-Hilbert transform in Clifford analysis and the linearized Riesz transforms.

Definition 6 (Linearized Riesz transforms) *The linearized Riesz transforms* $\mathcal{R}_1$, $\mathcal{R}_2$, $L^2(\mathbb{R}^2) \to L^2(\mathbb{R}^2)$ *are defined by*

$$\mathcal{R}_1 u(\underline{x}) := \mathcal{F}^{-1}(-i\cos(\theta_L(\underline{\omega}))\widehat{u}(\underline{\omega})), \quad \mathcal{R}_2 u(\underline{x}) := \mathcal{F}^{-1}(-i\sin(\theta_L(\underline{\omega}))\widehat{u}(\underline{\omega})),$$

where $\theta(\underline{\omega}) = \arctan2(\underline{\omega}) = \arctan2\left(\frac{\omega_2}{\omega_1}\right)$ *and* $\mathcal{H} = e_1\mathcal{R}_1 + e_2\mathcal{R}_2$.

The linearized Riesz transforms are invariant under shears $S_s := \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix}, s \in \mathbb{R}$, ([3]).

Abstract

We review some existence results in the linear elastodynamics of quasicrystals with and without nonlinear phason inertia, and prove in the latter case the existence of a weak attractor.

Key words: Continuum mechanics, quasicrystals, gyroscopic phason inertia, existence theorems, weak attractors
MSC 2000: Primary 74A30; Secondary 74A60, 35A01

1 Introduction

The results of 1982 experiments by D. Shechtman, published in 1984 [20], showed atomic arrangements with icosahedral symmetry in aluminum-based synthetic alloys, and pentagonal symmetry in thin films of the same materials, not determined by twinned atomic structures. Natural quasi-periodic alloys have been found since then in meteorites. In a 1991 the International Union of Crystallography changed the definition of crystals including the possibility of quasi-periodic atomic arrangements [9].

In fact, a quasi-periodic atomic arrangement in a m-dimensional space can be viewed as the orthogonal projection of a portion of a periodic lattice, in a $2m$-dimensional space, onto an appropriate (incommensurate) subspace [5]. If we move orthogonally to itself the subspace in the lattice in an appropriate way, we recognize the need of atomic shifts to assure quasi-periodicity. They are commonly called **phason** defects. The hyperspace construction, however, is just an ideal geometric representation of what the nature is. Indeed, we can

 ISBN: 978-84-617-8694-7

consider phasons as *inner* degrees of freedom exploited locally by the atoms to assure quasi-periodicity, compatibly with the boundary conditions imposed to a quasi-crystalline body by the interaction with the external environment. As inner degrees of freedom, they are invariant with respect to rigid translations of the whole body.

In building up a continuum representation of quasicrystal mechanics, the geometric constructions above have suggested at a first glance of thinking just of a higher dimensional replica of traditional crystal elasticity or viscoelasticity (see, e.g., for the first proposals [11], [6] and also [10], [17], [8]). Researchers have then focused attention primarily on its linear version, having in this way the concrete advantage of a format where we can easily reproduce systematically, all the standard results of traditional linear elasticity. However, the circumstance that phasons are insensitive to global rigid translations of a body, as they are inner degrees of freedom, implies the existence of a self-action (see Theorem 2.1 below) rendering the description of the mechanics of quasicrystals more complicated than the mere reproduction of standard elasticity, in a space with dimension higher than the one of the physical ambient. A phason self-action has been already *assumed* to exist in [17] but just to have dissipative nature and to drive phason diffusion. A first proof of the existence of a possibly nonzero phason self-action with both conservative and dissipative nature appeared first in [13], and in [16].

Here, we consider the dynamics of quasicrystals with nonlinear rotational phason inertia and phason diffusion. We summarize the results obtained in [2] an a theorem in the same reference determining the appropriate balance equations. Then, we show new results concerning the existence of weak attractors.

2 Continuum mechanics of quasicrystals

2.1 Deformation and phason field

We write $\mathcal{B}$ for the macroscopic **reference** shape of a quasicrystalline body, assumed to be a bounded arcwise connected open region in the three-dimensional point space $\mathcal{E}^3$, coinciding with the interior of its closure and endowed with surface-like boundary uniquely oriented everywhere to within a finite number of corners and cusps. In an space isomorphic to $\mathcal{E}^3$, indicated by $\tilde{\mathcal{E}}^3$, we record shapes of the body that we consider **deformed** with respect to $\mathcal{B}$, reached by means of one-to-one, differentiable, orientation preserving maps $x \longmapsto y := \tilde{y}(x) \in \tilde{\mathcal{E}}^3$.

A field $\tilde{\nu}$ taking values in a three-dimensional real vector space $\mathcal{V}^3$, accounts point-by-point at the continuum scale for the atomic flips, which allow to match quasi-periodicity. This is the so-called **phason field** in Lagrangian representation, i.e., considered as a field over the reference place. We endow $\tilde{\mathcal{E}}^3$, $\mathcal{E}^3$ and $\mathcal{V}^3$ with Cartesian frames.

 ISBN: 978-84-617-8694-7

Motions are (in generalized sense) pairs

$$(x,t) \longmapsto y := \tilde{y}\,(x,t) \in \tilde{\mathcal{E}}^3, \quad (x,t) \longmapsto \nu := \tilde{\nu}\,(x,t) \in \mathcal{V}^3,$$

assumed to be sufficiently differentiable in time.

We will write F and N for the **deformation gradient** and the **phason field gradient**, evaluated at x and t. The assumption that the deformation preserves the local orientation of triples of linearly independent vectors implies $\det F > 0$. We define another vector field, the **displacement** as $(x,t) \longmapsto u := \tilde{u}\,(x,t) := \tilde{y}\,(x,t) - i\,(x)$, also called the **phonon field** in the jargon of the physics of quasicrystals. Consequently, we have $\nabla u := \nabla \tilde{u}\,(x,t) = F + I$, where I is the second-rank unit tensor. As a matter of notation, we will write u_t, u_{tt}, and ν_t for the values $\dot{u} := \frac{d\tilde{u}(x,t)}{dt}$, $\ddot{u} := \frac{d^2\tilde{u}(x,t)}{dt^2}$, and $\dot{\nu} := \frac{d\tilde{\nu}(x,t)}{dt}$, respectively, the latter chosen for the sake of notational uniformity. The velocity in the physical space and the phason time rate just listed are expressed in Lagrangian representation, i.e., as fields over the reference place and the time scale. We can have an Eulerian representation of such fields, i.e. we can consider them defined over the actual shape $\mathcal{B}_a = \tilde{y}(\mathcal{B},t)$. In this case we write $\mathrm{v}(y,t)$ and $\upsilon(y,t)$. Since at x and t, the vector $\dot{y}(x,t) = \dot{u}(x,t)$ is tangent to $\mathcal{B}_a$ at the point $y := \tilde{y}(x,t)$, we have the standard identity $\dot{y}(x,t) = \mathrm{v}(y,t)$. An analogous relation *does not hold* between $\upsilon(y,t)$ and $\dot{\nu}(x,t)$. The lack of identity depends on the circumstance that υ is the time rate of the Eulerian representation of the phason field, which is a map $\tilde{\nu}_a$ defined by $\tilde{\nu}_a := \tilde{\nu} \circ \tilde{y}^{-1}$, a definition possible for $\tilde{y}$ is one-to-one. The subscript a means *actual*, i.e. *referred to the deformed configuration*, here and in what follows. The condition $|\nabla u| \ll 1$ defines the **small strain regime**, in which we develop the analyses presented in Sections 3 and 4. In this setting we can 'confuse' $\mathcal{B}$ with $\mathcal{B}_a$ and ν with $\nu_a := \tilde{\nu_a}(y,t)$.

2.2 Changes in observers

According to the definition proposed explicitly in [13] and in [14], we define **observer** *a collection of frames of reference assigned on all spaces necessary to describe the shape of a body and its motion*. Here, an observer is then (1) a frame in $\tilde{\mathcal{E}}^3$, (2) one in $\mathcal{E}^3$, (3) a frame in $\mathcal{V}^3$ and (4) a time scale. We consider time-varying synchronous changes in observers leaving invariant the reference space and changing the frame(s) in $\tilde{\mathcal{E}}^3$ by a rigid body motion. Precisely, let us write $\mathcal{O}$ and $\mathcal{O}'$ for these two observers. Let v and v' the velocities recorded by $\mathcal{O}$ and $\mathcal{O}'$, respectively. Write v^* for the pull-back of v' into the frame of reference $\mathcal{O}$. For v^* we get

$$\mathrm{v}^* := c\,(t) + q\,(t) \times (y - y_0) + \mathrm{v},$$

where $c(t)$ and $q(t)$ are translational and rotational components of the rigid velocity of $\mathcal{O}'$ with respect to $\mathcal{O}$, as measured by $\mathcal{O}$. The distinction between the ambient space $\tilde{\mathcal{E}}^3$ and the phason one $\mathcal{V}^3$ is just matter of modeling. Atomic flips occur in the physical space. Also,

 ISBN: 978-84-617-8694-7

the notion of observer is just a formal representation of the concrete action of recording a phenomenon. Hence, when we rotate an observer in space we should perceive rotated the atomic flips. They are not affected by rigid translations in space for they are internal degrees of freedom. Consequently, in Eulerian representation of the phason rate we get

$$\upsilon^* = \upsilon + q \times \nu_a.$$

2.3 External power, invariance and balance

We derive balance equations from the invariance of power over a generic *part* of the body (see [12] for general complex materials as quasicrystals are). The word **part** indicates here a subset $\mathfrak{b}_a$ of $\mathcal{B}_a = \tilde{y}(\mathcal{B}, t)$ with non-null volume and the same geometric regularity of $\mathcal{B}_a$. Given a generic $\mathfrak{b}_a$, we divide as usual all actions exerted on $\mathfrak{b}_a$ by the environment and the rest of the body into bulk and contact families, the latter intended to be exerted through the boundary of $\mathfrak{b}_a$. Each family is also subdivided into standard and phason components, all defined by the expression of the power that the external actions must perform over $\mathfrak{b}_a$ to change its state of motion with velocity v in the physical space and phason rate υ. For this reason we call such a power **external**, indicating it by $\mathcal{P}^{ext}_{\mathfrak{b}}$ and defining it in Eulerian representation by

$$\mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}, \upsilon) := \int_{\mathfrak{b}_a} \left(b^{\ddagger}_a \cdot \mathrm{v} + \beta^{\ddagger}_a \cdot \upsilon \right) \, d\mu(y) + \int_{\partial \mathfrak{b}_a} (\mathfrak{t} \cdot \mathrm{v} + \tau \cdot \upsilon) \, d\mathcal{H}^2, \tag{1}$$

where $d\mathcal{H}^2$ is the surface measure along $\partial \mathfrak{b}_a$ and $d\mu(y)$ the volume measure in $\mathcal{B}_a$; $b^{\ddagger}_a$ and $\beta^{\ddagger}_a$ are standard and phason bulk actions respectively, while $\mathfrak{t}$ and τ are the contact ones.

At $y \in \partial \mathfrak{b}_a$, where $\partial \mathfrak{b}_a$ is oriented by the normal n, the standard traction $\mathfrak{t}$ is $\mathfrak{t} := \tilde{\mathfrak{t}}(y, n)$ (Cauchy's assumption). Here we impose also $\tau := \tilde{\tau}(y, n)$. We leave unexpressed the dependence on time for the sake of conciseness of some formulas below.

We subordinate $\mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}, \upsilon)$ to an axiom of invariance by following a view adopted in the general model-building framework of the mechanics of complex materials (see [12] for it).

Axiom 2.1. *$\mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}, \upsilon)$ is invariant under rigid-body-based changes in observers, i.e., $\mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}^*, \upsilon^*) = \mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}, \upsilon)$ for any choice of c, q, and $\mathfrak{b}_a$.*

Theorem 2.1. *The axiom of invariance implies the following list of assertions:*

*(a) If the fields $y \longmapsto b^{\ddagger}_a$, $y \longmapsto \nu \times \beta^{\ddagger}$, $y \longmapsto \mathfrak{t}$ and $y \longmapsto \tau$ are integrable over $\mathcal{B}_a$, the following integral balances hold for **any** part $\mathfrak{b}_a$ of $\mathcal{B}_a$ and for $\mathcal{B}_a$ itself:*

$$\int_{\mathfrak{b}_a} b^{\ddagger}_a \, d\mu(y) + \int_{\partial \mathfrak{b}_a} \mathfrak{t} \, d\mathcal{H}^2 = 0, \tag{2}$$

$$\int_{\mathfrak{b}_a} \left((y - y_0) \times b^{\ddagger}_a + \nu \times \beta^{\ddagger}_a \right) \, d\mu(y) + \int_{\partial \mathfrak{b}_a} ((y - y_0) \times \mathfrak{t} + \nu_a \times \tau) \, d\mathcal{H}^2 = 0. \tag{3}$$

 ISBN: 978-84-617-8694-7

(b) If the standard traction is continuous in y and the standard bulk action is bounded over $\mathcal{B}_a$ at every instant, $\mathfrak{t}$ satisfies the action-reaction principle $\mathfrak{t}(y,n) = -\mathfrak{t}(y,-n)$.

(c) In the same continuity conditions, a second-rank tensor σ independent of n exists and is such that $\mathfrak{t}(y,n) = \sigma(y)n(y)$.

(d) If the phason traction is continuous with respect to y and the field $y \longmapsto \nu \times \beta^{\ddagger}$ is bounded over $\mathcal{B}_a$ at every instant, τ satisfies a non-standard action-reaction principle, i.e., $\nu_a(y) \times (\tau(y,n) - \tau(y,-n)) = 0$.

(e) In the same regularity conditions above, a second-rank tensor $\mathcal{S}_a$ independent of n exists and is such that $\tau(y,n) = \mathcal{S}_a(y)n(y)$, a tensor that we call ***phason stress****.*

(f) If the field $y \longmapsto \sigma(y)$ is C^1 over $\mathcal{B}_a$ and just continuous over its boundary, equation (2) implies the validity of the standard pointwise balance of forces

$$b_a^{\ddagger} + \mathrm{div}\sigma = 0. \tag{4}$$

(g) If, in addition, the field $y \longmapsto \mathcal{S}_a(y)$ is C^1 over $\mathcal{B}_a$ and just continuous over its boundary, equation (3) implies the existence of a vector z_a such that

$$\mathrm{div}\mathcal{S}_a + \beta_a^{\ddagger} - z_a = 0, \tag{5}$$

and

$$\mathrm{Skw}\sigma = \mathrm{Skw}(\nu_a \otimes z_a + \nabla_y \nu_a)\mathcal{S}_a^T), \tag{6}$$

where the apex T means transposition, e *is Ricci's alternating symbol, and ∇_y is the gradient with respect to y.*

(h) The external power satisfies the following relation:

$$\mathcal{P}^{ext}_{\mathfrak{b}_a}(\mathrm{v}, \upsilon) = \int_{\mathfrak{b}_a} (\sigma \cdot \nabla_y \mathrm{v} + z_a \cdot \upsilon + \mathcal{S}_a \cdot \nabla_y \upsilon)\, d\mu(y), \tag{7}$$

for any choice of the rates involved. The right-hand side term takes the name of ***inner power****.*

Here, $b_a^{\ddagger}$ is the sum of inertial, (b_a^{in}), and non-inertial, (b_a), components. Since we do not know bulk forces acting directly over the phason field, we attribute to $\beta_a^{\ddagger}$ just inertial character. We identify b_a^{in} and $\beta_a^{\ddagger}$ by assuming that their power over $\mathfrak{b}_a$ equals the negative of the kinetic energy time rate, assumed to be the standard quadratic function of v, because experiments do no indicate peculiar phason inertia. By assumption the identity holds true for any velocity involved. Such arbitrariness and the assumed conservation of mass imply $b_a^{in} = -\rho a$, with $a := \dot{\mathrm{v}}$ the acceleration, and $\beta_a^{\ddagger} \cdot \upsilon = 0$. The latter identity may imply $\beta_a^{\ddagger} = -\ell\, \mathrm{curl}\, \mathrm{v} \times \upsilon$, with ℓ a positive constant, as showed in [16].

 ISBN: 978-84-617-8694-7

2.4 Constitutive structures

Clausius-Duhem inequality (combination of the first and the second law of thermodynamics) written in isothermal setting, imposes restrictions to the possible constitutive relations. It states that the rate of the free energy on any part of the body minus the external power developed by all actions on that part is lesser or equal to zero for any choice of the time rates involved in the inequality. When we presume that **free energy density** ψ, the stresses σ and $\mathcal{S}_a$, and the self-action z_a depend on F, ν, and N, we get

$$\sigma = (\det F)^{-1}\frac{\partial \psi}{\partial F}F^{\mathrm{T}},\ \ \mathcal{S}_a = (\det F)^{-1}\frac{\partial \psi}{\partial N}F^{\mathrm{T}},\ \ z_a = (\det F)^{-1}\frac{\partial \psi}{\partial \nu}.$$

These relations characterize the elastic setting of quasicrystals. By fixing ν and N, a standard argument shows that objectivity for ψ, i.e., invariance under the action of $SO(3)$ on the physical space, and convexity of ψ with respect to F are physically incompatible. Consequently, we commonly accept a polyconvex dependence of ψ on F. With respect to N, the free energy can be quadratic in the so-called *phason locked phase*, and ψ may admit a decomposed Ginzburg-Landau-type structure. In this case the existence of ground states (minimizers of the energy) has been found in [15] as a special case of a more general result presented there, further generalized in [7].

In small strain regime the dependence of the energy can be quadratic. With reference to the homogeneous and isotropic case, with $\varepsilon := \mathrm{Sym}\nabla u$ the small strain tensor and I the second-rank unit tensor, a rather general expression of the energy has been derived in [16]; it reads

$$\begin{aligned}\psi =& \frac{1}{2}\lambda\left(\varepsilon\cdot I\right)^2 + \mu\varepsilon\cdot\varepsilon + \frac{1}{2}k_1\left(N\cdot I\right)^2 + k_2\mathrm{Sym}N\cdot\mathrm{Sym}N + k_2'\mathrm{Skw}N\cdot\mathrm{Skw}N\\ &+ k_3\left(\varepsilon\cdot I\right)\left(N\cdot I\right) + k_3'\mathrm{Sym}N\cdot\varepsilon + \frac{1}{2}k_0\left|\nu\right|^2\end{aligned} \tag{8}$$

from which we get

$$\sigma = \lambda\left(\mathrm{tr}\varepsilon\right)I + 2\mu\varepsilon + k_3\left(\mathrm{tr}N\right)I + k_3'\mathrm{Sym}N, \tag{9}$$

$$z_a = k_0\nu, \tag{10}$$

$$\mathcal{S}_a = k_1\left(\mathrm{tr}N\right)I + 2k_2\mathrm{Sym}N + 2k_2'\mathrm{Skw}N + k_3\left(\mathrm{tr}\varepsilon\right)I + k_3'\varepsilon. \tag{11}$$

λ and μ are standard Lamé constants. k_0, k_1, k_2, k_2', k_3 are elastic constants related with the phason field.

Phason diffusion has dissipative character and may even determine viscous-like effects. To account for them, maintaining compatibility with the mechanical dissipative inequality, we presume additive decompositions of σ, $\mathcal{S}_a$ an z_a into energetic $(\sigma^e, \mathcal{S}_a^e, z_a^e)$ and dissipative $(\sigma^d, \mathcal{S}_a^d, z_a^d)$ components, the former depending on strain, phason filed and its gradient, the

 ISBN: 978-84-617-8694-7

latter being functions of the same variables and their first time rates. We declare the dissipative nature of σ^d, $\mathcal{S}_a^d$, and z_a^d, by imposing

$$\sigma^d \cdot \nabla\nu \geq 0, \quad \mathcal{S}_a^d \cdot \nabla\upsilon \geq 0, \quad z_a^d \cdot \upsilon \geq 0,$$

for any choice of $\nabla\nu$, $\nabla\upsilon$, and υ; the equality to zero occurs when the time rates vanish. These inequalities may imply that $\sigma^d = \epsilon\nabla\nu$, $\mathcal{S}_a^d = \delta\nabla\upsilon$, and $z_a^d = \varsigma\upsilon$, with ϵ, δ, and ς positive constants. In small strain regime $\nu \cong \dot{u} = u_t$, $\upsilon \cong \dot{\nu}_a = \dot{\nu} = \nu_t$, so that we write

$$\sigma^d = \epsilon\nabla u_t, \quad \mathcal{S}_a^d = \delta\nabla\nu_t, \quad z_a^d = \varsigma\nu_t.$$

Consequently, the constitutive equations (9), (10) and (11) become

$$\sigma = \lambda\,(\mathrm{tr}\varepsilon)\,I + 2\mu\varepsilon + k_3\,(\mathrm{tr}N)\,I + k_3'\mathrm{Sym}N + \epsilon\nabla u_t, \tag{12}$$

$$z_a = k_0\nu + \varsigma\nu_t, \tag{13}$$

$$\mathcal{S}_a = k_1\,(\mathrm{tr}N)\,I + 2k_2\mathrm{Sym}N + 2k_2'\mathrm{Skw}N + k_3\,(\mathrm{tr}\varepsilon)\,I + k_3'\varepsilon + \delta\nabla\nu_t. \tag{14}$$

3 Existence results

3.1 Dynamics with phason diffusion and absence of gyroscopic effects

In small strain regime and under the validity of the linear constitutive structures (9), (11) and (13), in absence of non-inertial body forces and gyroscopic-type phason inertia, by imposing u and ν along $\partial\mathcal{B}$ (Dirichlet boundary conditions) and their values together with those of the velocity u_t over $\mathcal{B}$ as initial conditions, the balance equations read

$$\begin{aligned}
&\rho u_{tt} = \mu\Delta u + \xi\nabla\,\mathrm{div}\,u + \kappa\Delta\nu + \bar{\xi}\nabla\,\mathrm{div}\,\nu && \text{in } (0,T)\times\mathcal{B},\\
&\varsigma\nu_t = \zeta\Delta\nu + \gamma\nabla\,\mathrm{div}\,\nu + \kappa\Delta u + \bar{\xi}\nabla\,\mathrm{div}\,u - \kappa_0\nu && \text{in } (0,T)\times\mathcal{B},\\
&u(t,x) = \bar{u}(x),\ \nu(t,x) = \bar{\nu}(x), && \text{on } (0,T)\times\partial\mathcal{B},\\
&u|_{t=0} = u_0,\ u_t|_{t=0} = \dot{u}_0,\ \nu|_{t=0} = \nu_0, && \text{on } \mathcal{B},
\end{aligned} \tag{15}$$

where u_0, $\dot{u}_0$ and ν_0 are the initial data, and the constitutive parameters are constants and satisfy the following relations: $\xi = \lambda + \mu$, $\bar{\xi} = k_3 + \frac{1}{2}k_3'$, $\zeta = k_2 + k_2'$, $\gamma = k_1 + k_2 - k_2'$, $\kappa = \frac{1}{2}k_3'$, and λ, μ, k_i, k_i', $i = 1,2,3$, and ρ is the mass density.

Definition 3.1. *We say that a pair (u,ν) is a **weak solution** of the system (15) if, for a given $T > 0$, the conditions listed below hold true.*

 ISBN: 978-84-617-8694-7

(1) Regularity:

$$\begin{aligned} &u \in L^\infty(0,T;\mathcal{H}^1) \cap C([0,T];L^2(\mathcal{B})) \cap C_{weak}([0,T];\mathcal{H}^1), \\ &\nu \in L^2(0,T;\mathcal{H}^1) \cap C([0,T];L^2(\mathcal{B})), \end{aligned} \tag{16}$$

$$\begin{aligned} &u_t \in L^\infty(0,T;L^2(\mathcal{B})) \cap C_{weak}([0,T];L^2(\mathcal{B})),\ u_{tt} \in L^2(0,T;\mathcal{H}^{-1}), \\ &\nu_t \in L^2(0,T;L^2(\mathcal{B})). \end{aligned} \tag{17}$$

(2) Weak formulation: For all $(w,h) \in C_0^\infty(0,T;\mathcal{H}^1) \times C_0^\infty(0,T;\mathcal{H}^1)$,

$$\begin{aligned} &\rho \int_0^T \int_{\mathcal{B}} u_{tt} \cdot w + \mu \int_0^T \int_{\mathcal{B}} \nabla u \cdot \nabla w + \kappa \int_0^T \int_{\mathcal{B}} \nabla \nu \cdot \nabla w \\ &= \int_0^T \int_{\partial\mathcal{B}} w \cdot \Big(\mu \frac{\partial u}{\partial n} + \kappa \frac{\partial \nu}{\partial n}\Big) + \xi \int_0^T \int_{\mathcal{B}} \nabla(\operatorname{div} u) \cdot w + \bar{\xi} \int_0^T \int_{\mathcal{B}} \nabla(\operatorname{div} \nu) \cdot w \end{aligned} \tag{18}$$

$$\begin{aligned} &\int_0^T \int_{\mathcal{B}} (\varsigma \nu_t + \kappa_0 \nu) \cdot h + \zeta \int_0^T \int_{\mathcal{B}} \nabla \nu \cdot \nabla h + \kappa \int_0^T \int_{\mathcal{B}} \nabla u \cdot \nabla h \\ &= \int_0^T \int_{\partial\mathcal{B}} h \cdot \Big(\kappa \frac{\partial u}{\partial n} + \zeta \frac{\partial \nu}{\partial n}\Big) + \gamma \int_0^T \int_{\mathcal{B}} \nabla(\operatorname{div} \nu) \cdot h + \bar{\xi} \int_0^T \int_{\mathcal{B}} \nabla(\operatorname{div} u) \cdot h, \end{aligned} \tag{19}$$

where, for the sake of conciseness, we have erased all volume, surface and time measures from the space-time integrals above, as we do below. An adapted Galerkin's approximation procedure, combined with a compactness argument (the Aubin-Lions lemma) and suitable a priori estimates, implies a first result.

Theorem 3.1. *[2] Assume* $\mu > -\lambda$, $\kappa > 0$, $\bar{\xi} > 0$, $\mu, \zeta > 2\kappa$, *and* $\xi, \gamma > 2\bar{\xi}$. *Assume also* $u_0, \nu_0 \in W^{1,2}(\mathcal{B})$ *so that* $\nabla u(0,x) = \nabla u_0$ *and* $\nabla \nu(0,x) = \nabla \nu_0(x)$ *on* $\mathcal{B}$ *and* $\bar{u}, \bar{\nu} \in L^2(\partial\mathcal{B})$. *Then, a unique regular weak solution to the problem* (15) *exists.*

3.2 Dynamics with phason diffusion and non-linear gyroscopic phason inertia

In the presence of gyroscopic-type phason inertia, previous problem becomes

$$\begin{aligned} &\rho u_{tt} = \mu \Delta u + \xi \nabla \operatorname{div} u + \kappa \Delta \nu + \bar{\xi} \nabla \operatorname{div} \nu && \text{in } \mathcal{B}_T, \\ &\varsigma \nu_t + \ell(\operatorname{curl} u_t) \times \nu_t = \zeta \Delta \nu + \gamma \nabla \operatorname{div} \nu + \kappa \Delta u + \bar{\xi} \nabla \operatorname{div} u - \kappa_0 \nu && \text{in } \mathcal{B}_T, \\ &u(t,x) = \bar{u}(x),\ \nu(t,x) = \bar{\nu}(x), && \text{on } \partial\mathcal{B}_T, \\ &u|_{t=0} = u_0,\ u_t|_{t=0} = \dot{u}_0,\ \nu|_{t=0} = \nu_0, && \text{on } \mathcal{B}. \end{aligned} \tag{20}$$

Definition 3.2 (Weak solution)**.** *We say that a pair* (u,ν) *is a* ***weak solution*** *to the system* (20) *if, for a given* $T > 0$, *the conditions defined below hold true.*

$$\begin{aligned} &u_t \in C([0,T];L^2(\mathcal{B})) \cap L^2(0,T;W^{1,2}(\mathcal{B})),\ u_{tt} \in L^2(0,T;\mathcal{H}^{-1}),\\ &\nu_t \in L^2(0,T;W^{1,2}(\mathcal{B})). \end{aligned} \tag{22}$$

(2) Weak formulation: For all $(w,h) \in C_0^\infty([0,T[\times\mathcal{B}) \times C_0^\infty([0,T[\times\mathcal{B})$,

$$\begin{aligned} &\rho\int_0^T\int_{\mathcal{B}} u_{tt}\cdot w + \mu\int_0^T\int_{\mathcal{B}} \nabla u\cdot\nabla w + \kappa\int_0^T\int_{\mathcal{B}} \nabla\nu\cdot\nabla w\\ &= \int_0^T\int_{\partial\mathcal{B}} w\cdot\Big(\mu\frac{\partial u}{\partial n} + \kappa\frac{\partial\nu}{\partial n}\Big) + \xi\int_0^T\int_{\mathcal{B}} \nabla(\operatorname{div} u)\cdot w + \bar\xi\int_0^T\int_{\mathcal{B}} \nabla(\operatorname{div}\nu)\cdot w, \end{aligned} \tag{23}$$

$$\begin{aligned} &\int_0^T\int_{\mathcal{B}} (\varsigma\nu_t + \kappa_0\nu)\cdot h + \ell\int_0^T\int_{\mathcal{B}} (\operatorname{curl} u_t)\times\nu_t\cdot h + \int_0^T\int_{\mathcal{B}} (\zeta\nabla\nu + \kappa\nabla u)\cdot\nabla h\\ &= \int_0^T\int_{\partial\mathcal{B}} h\cdot\Big(\kappa\frac{\partial u}{\partial n} + \zeta\frac{\partial\nu}{\partial n}\Big) + \gamma\int_0^T\int_{\mathcal{B}} \nabla(\operatorname{div}\nu)\cdot h + \bar\xi\int_0^T\int_{\mathcal{B}} \nabla(\operatorname{div} u)\cdot h. \end{aligned} \tag{24}$$

Boundary terms vanish because we have selected test functions in C_0^∞. We analyze the regularized counterpart of problem (20), obtained by introducing dissipative components of the stresses, at fixed the parameters $\epsilon > 0$ and $\delta > 0$:

$$\begin{aligned} &\rho u_{tt} - \epsilon\Delta u_t = \mu\Delta u + \xi\nabla\operatorname{div} u + \kappa\Delta\nu + \bar\xi\nabla\operatorname{div}\nu && \text{in } \mathcal{B}_T,\\ &\varsigma\nu_t - \delta\Delta\nu_t + \ell(\operatorname{curl} u_t)\times\nu_t = \zeta\Delta\nu + \gamma\nabla\operatorname{div}\nu + \kappa\Delta u + \bar\xi\nabla\operatorname{div} u - \kappa_0\nu && \text{in } \mathcal{B}_T,\\ &u(t,x) = \bar u(x),\ \nu(t,x) = \bar\nu(x), && \text{on } \partial\mathcal{B}_T,\\ &u|_{t=0} = u_0,\ u_t|_{t=0} = \dot u_0,\ \nu|_{t=0} = \nu_0, && \text{on } \mathcal{B}. \end{aligned} \tag{25}$$

Theorem 3.2 (see Theorem 4.1 in [2])**.** *Assume* $\mu > -\lambda$, $\kappa > 0$, $\bar\xi > 0$, $\mu,\zeta > 2\kappa$, *and* $\xi,\gamma > 2\bar\xi$. *Assume also* $u_0,\nu_0 \in W^{1,2}(\mathcal{B})$, $\dot u_0 \in W^{1,2}(\mathcal{B})$, *such that* $\ell\|\dot u_0\|_{1,2} < \varsigma/2$ *and that* $\bar u,\bar\nu \in L^2(\partial\mathcal{B})$. *Then, the system* (20) *admits a weak solution.*

4 Weak global attractor for the time-shift semiflow

Let (W,d) be a metric space. A *semigroup* on (W,d) is a family of operators $\big(S(t)\big)_{t\geq 0}$, $S(t)\colon W \to W$, that satisfies $S(0)w = w$ and $S(s)S(t)w = S(t+s)w$ for each $w \in W$ and for every $s,t \geq 0$. A *semiflow* on (W,d) is a mapping $\sigma\colon [0,+\infty)\times W \to W$ defined by $\sigma(t,w) = S(t)w$, where $\big(S(t)\big)_{t\geq 0}$ is a semigroup, and such that the restriction $\sigma\colon]0,+\infty)\times W \to W$ is continuous. A bounded subset $\mathfrak{B} \subset W$ is called an *absorbing set* if for any bounded set B of W, there exists $t_1 = t_1(B)$ such that $S(t)B \subseteq \mathfrak{B}$ for all $t \geq t_1$. A semiflow is said to

 ISBN: 978-84-617-8694-7

be *compact* if, for every bounded set $B \subset W$ and for every $t > 0$, $S(t)B$ lies in compact subset of W.

We have the following result [18, 19, 21] (see also [1]).

Theorem 4.1. *Let $S(t)$ define a compact semiflow admitting an absorbing set $\mathfrak{B}$ on a complete metric space W. Then $S(t)$ has a global attractor $\mathcal{A}$ in W and coincides with the omega-limit set of $\mathfrak{B}$:*

$$\mathcal{A} = \bigcap_{\tau \geq 0} \overline{\bigcup_{t \geq \tau} S(t)\mathfrak{B}}\,,$$

where the closure is taken in W.

Starting from problem (25), we introduce a bulk force $f(x,t)$ in the balance of standard force and rewrite the whole system as

$$\begin{aligned}
&u_t = v && \text{in } \mathcal{B}_T,\\
&\rho v_t - \epsilon\Delta v = \mu\Delta u + \xi\nabla \operatorname{div} u + \kappa\Delta\nu + \bar{\xi}\nabla \operatorname{div}\nu + f(t,x) && \text{in } \mathcal{B}_T,\\
&\varsigma\nu_t - \delta\Delta\nu_t + \ell(\operatorname{curl} v)\times\nu_t = \zeta\Delta\nu + \gamma\nabla\operatorname{div}\nu + \kappa\Delta u + \bar{\xi}\nabla\operatorname{div} u - \kappa_0\nu && \text{in } \mathcal{B}_T,\\
&u(t,x) = 0,\ \nu(t,x) = 0, && \text{on } \partial\mathcal{B}_T,\\
&u|_{t=0} = u_0,\ v|_{t=0} = \dot{u}_0,\ \nu|_{t=0} = \nu_0, && \text{on } \mathcal{B},
\end{aligned} \tag{26}$$

with homogeneous Dirichlet boundary conditions. Although the forcing term f does not appear in the existence result ([2, Thereom 4.1]), the proof can be adapted to the present case, with very minor changes, by assuming that $f \in L^2(0,\infty;L^2(\mathcal{B}))$.

Let us write $\boldsymbol{w}(t) = (u(t),\nu(t);u_t(t)) = (u(t),\nu(t);v(t))$ for brevity, and denote by

$$\begin{aligned}
\boldsymbol{\mathcal{W}} = \big\{\boldsymbol{w} = (u,\nu;v) \in L^2_{\mathrm{loc}}[0,+\infty;W^{1,2}(\mathcal{B})^2)\times L^2_{\mathrm{loc}}[0,+\infty;L^2(\mathcal{B}))\mid v(t) = u_t(t)\\
\text{and } \boldsymbol{w} \text{ satisfying (21)-(22) and the weak formulation of (26) as in Def. 3.2}\big\}
\end{aligned} \tag{27}$$

the set of the weak solutions to (26). In the sequel, the role of W will be played by the set $\boldsymbol{\mathcal{W}}$ of the weak solutions to (26) in $L^2_{\mathrm{loc}}[0,\infty;W^{1,2}(\mathcal{B})^2)\times L^2_{\mathrm{loc}}[0,\infty;L^2(\mathcal{B}))$, with metric d defined by

$$d(\boldsymbol{w}_1,\boldsymbol{w}_2) = \sum_{n=0}^{\infty} 2^{-n}\min\big\{1,\ |||\boldsymbol{w}_1 - \boldsymbol{w}_2|||_{L^2(0,n)}\big\}. \tag{28}$$

where, given $\boldsymbol{w} = (u,v;\nu)$, with L^2-norm $\|\cdot\|$, we have that

$$|||\boldsymbol{w}|||^2_{L^2(a,b)} = \int_a^b |||\boldsymbol{w}(s)|||^2 ds \ \text{ and } |||\boldsymbol{w}(t)|||^2 = (\|u\|^2 + \|\nabla u\|^2 + \|\nu\|^2 + \|\nabla\nu\|^2 + \|v\|^2)(t).$$

 ISBN: 978-84-617-8694-7

We also recall that a set B in a linear topological space $\mathcal{Z}$ is called *bounded* if for every neighborhood U of the origin in $\mathcal{Z}$ there exists an $r > 0$ such that $B \subset \{ru\colon u \in U\}$. In the case of the space $\mathcal{Z} = L^2_{\rm loc}[0,\infty; W^{1,2}(\mathcal{B})^2) \times L^2_{\rm loc}[0,\infty; L^2(\mathcal{B}))$, this reduces to

$$\sup\left\{|||\boldsymbol{w}|||_{L^2(0,n)} \,|\, \boldsymbol{w} \in B\right\} < +\infty, \ \ \forall\, n = 0,1,2,\dots$$

Actually our aim would be to prove a proposition as follows:

Proposition 4.1. *The time-shift operator $S(t)$, associated with* (26)*, admits a unique global attractor $\boldsymbol{\mathcal{A}}$ in $\boldsymbol{\mathcal{W}}$.*

Due to the possible lack of uniqueness for the weak solutions of (26), we find convenient to follow the approach developed by Sell in [18], which is suitable for non-well-posed problems, and to perform our dynamical analysis on the phase space given by $\boldsymbol{\mathcal{W}}$, in which each point is a weak solution.

In order to prove Proposition 4.1, we need to show that the time-shift operator $S(t)$ verifies the hypotheses of Theorem 4.1. That $\sigma(t,\boldsymbol{w}) = S(t)(\boldsymbol{w})$, $(t,\boldsymbol{w}) \in]0,+\infty) \times \boldsymbol{\mathcal{W}}$ is a semiflow can be proven by following a lemma by Sell [18, Lemma 7].

Proposition 4.2. *The mapping $\sigma\colon]0,+\infty) \times \boldsymbol{\mathcal{W}} \to \boldsymbol{\mathcal{W}}$ given by $S(t)\boldsymbol{w} = \boldsymbol{w}(\cdot + t)$ is a semiflow.*

Consider the following map

$$z(t) = \int_{\mathcal{B}} \Big(\rho|u_t+\alpha u|^2+\alpha^2|u|^2+(\mu-\epsilon\alpha)|\nabla u|^2+(\kappa_0+\alpha\varsigma)|\nu|^2+(\zeta+\alpha\delta)|\nabla\nu|^2\Big)(t)\,\mathrm{d}x \approx |||\boldsymbol{w}(t)|||$$

where α is a positive parameter which appears in the next result, and $\mu - \epsilon\alpha > 0$ (for a possible similar situation, see also [4, Ch. VI, §4])

Lemma 4.1. *Taking $\alpha > 0$ sufficiently small, then the following relation holds true*

$$z(t) \le z(\tau)\exp\{-\tilde{\beta}(t-\tau)\} + \tilde{c}, \ \ \textit{with } t \ge \tau \ge 0, \tag{29}$$

where $\tilde{\beta}$ and $\tilde{c}$ are positive constants.

The proof of such a lemma and the ones of all statements in this section are in [3].

As a consequence we have the existence of an absorbing set.

Proposition 4.3. *There exists an absorbing set $\mathfrak{B} \subset \boldsymbol{\mathcal{W}}$ that is bounded in $\boldsymbol{\mathcal{W}}$.*

Thus, Proposition 4.1 would be a theorem, indeed, after proving the following conjecture.

Conjecture 4.1. *The semiflow defined by $S(t)$ on $\boldsymbol{\mathcal{W}}$ is compact, i.e for each bounded set B in $\boldsymbol{\mathcal{W}}$ and for each $t > 0$, then $S(t)B$ lies in a compact subset of $\boldsymbol{\mathcal{W}}$.*

Abstract

This paper is devoted to the construction of polynomial surfaces with Pythagorean normals (PN surfaces) interpolating given data subject to prescribed constraints on the surface area of the patch. This is a problem analogous to the interpolation with Pythagorean hodograph (PH) curves satisfying the condition on the arc length. The special structure of PN surfaces allows the surface-area condition to be expressed as algebraic constraints on the surfaces coefficients. We employ these shapes for solving the G^1 Hermite interpolation problem by triangular PN patches with prescribed surface area. The presented technique is based on interpolating points on the unit sphere and consequently on solving a system of several linear and one quadratic equations. We show that for generic input data there exist at most two quartic PN patches depending on the particular value of the prescribed surface area.

Key words: G^1 Hermite interpolation; PN surfaces; polynomial area element

1 Introduction

Rational surfaces with Pythagorean normals (PN surfaces) were introduced in [9] as a surface analogy to Pythagorean hodograph (PH) curves defined before in [4]. For a survey of shapes with Pythagorean property see e.g. [3] and references therein. It holds that PH curves in plane and PN surfaces in space share some common properties, e.g. they both yield rational offsets. Nevertheless there also exist significant differences between these classes of rational varieties. For instance, the curves with Pythagorean hodographs were introduced as planar *polynomial* shapes and a compact formula for their description based on Pythagorean triples

 ISBN: 978-84-617-8694-7

of polynomials was presented. On the other hand, a description of *rational* Pythagorean normal vector surfaces reflecting their dual description was revealed first in [9] and it is still not known how to gain the polynomial subclass from this formula. Nonetheless, new attempts to the investigation of PN surfaces have emerged recently, see [6, 8, 1].

The area element $\mathrm{d}A$, and thus also the surface area $A(u,v) = \iint \sqrt{EG - F^2}\,\mathrm{d}u\mathrm{d}v$ of a polynomial PN surface $\mathbf{x}(u,v)$ is polynomial, in general (which is not the case for their rational counterparts). This special algebraic structure of polynomial PN surfaces offers many useful computational advantages over "standard" polynomial parametric surfaces. In addition, this also underlines a prominent role of polynomial PN surfaces and relates them suitably with polynomial PH curves that possess polynomial length element. Unfortunately, there is not known very much about them. We recall at least the investigation of a family of cubic polynomial PN surfaces in [7] and a novel approach to polynomial PN surfaces based on bivariate polynomials with quaternion coefficients, presented recently in [6].

A new technique to the shape reconstruction is presented herein, based on the polynomial PN surfaces. We will continue in the most recent approach from [1], where the interpolation by polynomial PN surfaces is transformed to solving a system of linear equations. As an extra added value, we consider the conditions on the surface-area. The special structure of PN surfaces allows the surface-area condition to be expressed as algebraic constraints on the surfaces coefficients. This is a problem analogous to the interpolation with Pythagorean hodograph (PH) curves satisfying the condition on the arc length, see e.g. [5]. In more detail, we show that three points and three tangent vector can be interpolated by 1-parameter family of polynomial PN surfaces of degree four. These surfaces will be consequently used for constructing G^1 interpolants with the prescribed surface area. Moreover, for a generic data, the existence of 0, 1 or 2 quartic PN patches with prescribed surface area L depending on the particular value of L will be shown. Solving this problem can be useful everywhere where the surface area is important such as in CNC painting.

The remainder of this paper is organized as follows. Section 2 recalls some basic facts concerning polynomial PN surfaces and presents shortly the method from [1] for their generation. In Section 3, these results are applied to a practical problem of G^1 Hermite interpolation by polynomial PN triangular patches which will be used in Section 4 to compute interpolants with prescribed surface area. Finally, we conclude the paper in Section 5.

2 Polynomial PN surfaces

A parametric surface $\mathbf{x}(u,v)$ in $\mathbb{R}^3$ is called a surface with *Pythagorean normal vector field* (*a PN surface*) if there exists a rational function $\sigma(u,v)$ such that it is satisfied

$$\|\mathbf{n}(u,v)\|^2 = \sigma(u,v)^2, \tag{1}$$

 ISBN: 978-84-617-8694-7

where $\mathbf{n}(u,v) = \mathbf{x}_u(u,v) \times \mathbf{x}_v(u,v)$ is a normal vector field of $\mathbf{x}(u,v)$.Clearly, the distinguishing property of PN surfaces is the rationality of their two-sided δ-offset surfaces

$$\mathbf{x}_\delta = \mathbf{x} \pm \delta \frac{\mathbf{n}}{\|\mathbf{n}\|} = \mathbf{x} \pm \delta \, \frac{\mathbf{x}_u \times \mathbf{x}_u}{\sigma}. \tag{2}$$

Next, we recall that the squared *area element* of the parametric surface $\mathbf{x}(u,v)$ has the form

$$\mathrm{d}A^2 = \begin{vmatrix} \mathbf{x}_u \cdot \mathbf{x}_u & \mathbf{x}_u \cdot \mathbf{x}_v \\ \mathbf{x}_u \cdot \mathbf{x}_v & \mathbf{x}_v \cdot \mathbf{x}_v \end{vmatrix} \mathrm{d}u^2 \mathrm{d}v^2 = (EG - F^2)\, \mathrm{d}u^2 \mathrm{d}v^2, \tag{3}$$

where $E = \mathbf{x}_u \cdot \mathbf{x}_u$, $F = \mathbf{x}_u \cdot \mathbf{x}_v$, $G = \mathbf{x}_v \cdot \mathbf{x}_v$ are the coefficients of the first fundamental form. Moreover, as it holds

$$\|\mathbf{x}_u \times \mathbf{x}_v\|^2 = (EG - F^2), \tag{4}$$

the family of rational PN surfaces (i.e., rational offsets surfaces) coincides with the family of surfaces with rational area element. In addition, all polynomial PN surfaces possess polynomial surface area $A(u,v) = \iint \sqrt{EG - F^2}\, \mathrm{d}u\mathrm{d}v$. This offers many useful computational advantages compared to other surfaces (including rational PN surfaces).

However until recently, the construction of PN surfaces was based only on their dual representation, i.e., any rational PN surface is represented as the envelope of its tangent planes

$$\mathbf{n}(u,v) \cdot \mathbf{x} = h(u,v), \tag{5}$$

where $\mathbf{n}(u,v)$ is a polynomial normal vector field satisfying (1) and $h(u,v)$ is a rational function. Differentiating (5) with respect to u and v gives 3 linear equations in variables x_i

$$\mathbf{M}\,\mathbf{x} = \mathbf{h}, \qquad \text{where} \quad \mathbf{M} = (\mathbf{n}, \mathbf{n}_u, \mathbf{n}_v)^\top \ \text{ and } \ \mathbf{h} = (h, h_u, h_v)^\top. \tag{6}$$

Solving (6) we arrive at $\mathbf{x}(u,v) = \mathbf{M}^{-1}\,\mathbf{h}$, a description of non-developable PN surfaces, cf. [9]. Unfortunately this method is not suitable for computing parameterizations of *polynomial* PN surfaces. Nevertheless a novel direct approach based on solving a suitable system of linear equations was recently introduced in [1].

In more detail, when looking for some polynomial PN surface (i.e., polynomial surface with polynomial area element) we prescribe first a suitable polynomial normal vector field $\mathbf{n}(u,v)$ of degree k satisfying (1). Its parameterization can be easily gained for instance from polynomial Pythagorean quadruples, cf. [2]. Then we determine an associated polynomial PN parameterization of degree ℓ in a direct way, i.e., we find a suitable polynomial patch

$$\mathbf{x}(u,v) = \left(\sum_{i+j\le\ell} x_{1ij} u^i v^j, \sum_{i+j\le\ell} x_{2ij} u^i v^j, \sum_{i+j\le\ell} x_{3ij} u^i v^j \right)^\top, \tag{7}$$

 ISBN: 978-84-617-8694-7

such that it satisfies the following conditions:

$$\mathbf{x}_u(u,v)\cdot\mathbf{n}(u,v)\equiv 0 \qquad \text{and} \qquad \mathbf{x}_v(u,v)\cdot\mathbf{n}(u,v)\equiv 0. \tag{8}$$

Hence the problem is now transformed to solving a system of $\binom{k+\ell+1}{2}$ homogeneous linear equations with $3\binom{\ell+2}{2}$ unknowns $x_{1ij}, x_{2ij}, x_{3ij}$. This system is solvable in general for ℓ large enough. Nonetheless, we must emphasize that the method does not guarantee a polynomial surface $\mathbf{x}(u,v)$ for which $\mathbf{x}_u\times\mathbf{x}_v=\mathbf{n}(u,v)$. We arrive at a polynomial PN parameterization such that

$$\mathbf{x}_u(u,v)\times\mathbf{x}_v(u,v)=f(u,v)\,\mathbf{n}(u,v), \tag{9}$$

where $f(u,v)$ is a factor relating suitably the degrees of $\mathbf{n}(u,v)$ and $\mathbf{x}(u,v)$, see [1] for more details. Of course, the existence of a non-constant factor $f(u,v)$ does not abolish the polynomiality of the corresponding surface area $A(u,v)$.

3 Hermite interpolation with triangular PN patches

In this section we present a *direct* method for interpolating given data by triangular *polynomial* PN surfaces (surfaces with polynomial area elemnts).

Consider three points $\mathbf{p}_{ij}$, $i,j=0,1$ and $i+j<2$, and three associated tangent planes τ_{ij} determined by the unit normal vectors $\mathbf{N}_{ij}$. Following the ideas presented in the previous section, we can formulate the whole algorithm consisting of two subparts:

(i) We construct a normal vector field $\mathbf{n}(u,v)$ interpolating data $\mathbf{n}_{ij}=\lambda_{ij}\mathbf{N}_{ij}$, $\lambda_{ij}\in\mathbb{R}^+$, and having the polynomial norm.

(ii) We compute a polynomial patch interpolating the points $\mathbf{p}_{ij}$ and possessing the normal vector field $\mathbf{n}(u,v)$ via solving (8).

As concerns (i), we apply a well-known method based on using the stereographic projection. We choose a suitable center $\mathbf{w}$ of the stereographic projection (such that it is not contained in the the Gauss image of the interpolating surface) and project data $\mathbf{N}_{ij}\in\mathcal{S}^2$ to the plane $\mathbb{R}^2$, i.e.,

$$\widehat{\mathbf{N}}_{ij}=\pi_{\mathbf{w}}(\mathbf{N}_{ij})=\mathbf{w}+\frac{(\mathbf{N}_{ij}-\mathbf{w})}{1-\mathbf{w}\cdot\mathbf{N}_{ij}}. \tag{10}$$

Then, we construct the linear patch in $\mathbb{R}^2$ interpolating $\pi_{\mathbf{w}}(\mathbf{N}_{ij})$, i.e.,

$$\widehat{\mathbf{N}}(u,v)=\widehat{\mathbf{N}}_{10}\,u+\widehat{\mathbf{N}}_{01}\,v+\widehat{\mathbf{N}}_{00}\,(1-u-v)\quad u\in[0,1],\ v\in[0,1-u]. \tag{11}$$

Finally, employing the inverse stereographic projection and omitting the least common denominator, we arrive at the quadratic polynomial normal vector field

$$\mathbf{n}(u,v)=2\widehat{\mathbf{N}}(u,v)+\left(\widehat{\mathbf{N}}(u,v)\cdot\widehat{\mathbf{N}}(u,v)-1\right)\mathbf{w} \tag{12}$$

 ISBN: 978-84-617-8694-7

with the PN property

$$\|\mathbf{n}(u,v)\|^2 = \left(\widehat{\mathbf{N}}(u,v)\cdot\widehat{\mathbf{N}}(u,v)+1\right)^2 = \sigma(u,v)^2, \tag{13}$$

and satisfying the prescribed interpolation conditions

$$\mathbf{n}(i,j) = \lambda_{ij}\,\mathbf{N}_{ij}, \qquad \lambda_{ij} = \widehat{\mathbf{N}}_{ij}\cdot\widehat{\mathbf{N}}_{ij}+1 \in \mathbb{R}^+. \tag{14}$$

Once we have a quadratic vector field $\mathbf{n}(u,v)$ we can continue with part (ii). Our goal is to find a polynomial patch (7) of prescribed degree ℓ possessing $\mathbf{n}(u,v)$ as its associated normal vector field and interpolating given position data, i.e., it must hold (8) and

$$\mathbf{x}(i,j) = \mathbf{p}_{ij}. \tag{15}$$

To conclude the method, expressions (8) and (15) depend linearly on the coefficients $x_{1ij}, x_{2ij}, x_{3ij}$ of $\mathbf{x}(u,v)$ and therefore can be rewritten as a system of linear equations yielding always a solution. Hence we can formulate

Theorem 3.1 *For generic points $\mathbf{p}_{ij}$ and associated tangent planes τ_{ij}, solving the equations from systems* (8) *and* (15) *yields a* 1*-parameter set of quartic polynomial PN patches interpolating the points $\mathbf{p}_{ij}$ and touching the planes τ_{ij} at these points.*

Proof: Using computer algebra system Mathematica we have verified symbolically that the system of linear equation (8) and (15) is solvable and for quartic surface (7) the rank of its matrix is equal to 44 whereas the number of coefficients of (7) is 45. Moreover from (15) and the construction of the normal vector field $\mathbf{n}(u,v)$, the constructed surface interpolates the points $\mathbf{p}_{ij}$ and is tangent to the planes τ_{ij} at these points. □

4 Triangular PN patches with prescribed surface area

Now, we are able to design a simple algorithm for the construction of triangular quartic PN patches with the prescribed surface area.

Consider three points $\mathbf{p}_{ij}$, $i,j = 0,1$ and $i+j<2$, three associated unit normal vectors $\mathbf{N}_{ij}$ and in addition a value L, the prescribed surface area of the patch. First, employing the method described in more detail in the previous section, we construct a 1-parametric family of quartic triangular patches interpolating $\mathbf{p}_{ij}$ and $\mathbf{N}_{ij}$, i.e., we have

$$\mathbf{x}(u,v,\alpha) = \mathbf{x}_1(u,v) + \alpha\,\mathbf{x}_2(u,v). \tag{16}$$

Then

$$F(u,v,\alpha) = \|\mathbf{x}_u(u,v,\alpha)\times\mathbf{x}_v(u,v,\alpha)\| = f(u,v,\alpha)\,\sigma(u,v), \tag{17}$$

 ISBN: 978-84-617-8694-7

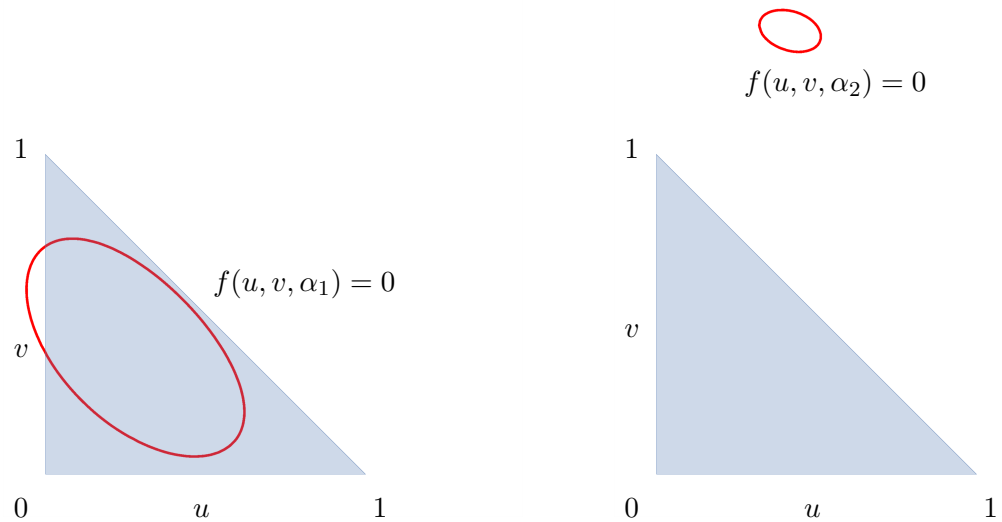

Figure 1: Curves in the parametr plane defined by the extra factors $f(u,v,\alpha_i)$ which correspond to singular curves on the resulting surfaces from Example 4.1.

where $\sigma(u,v)$ is given by (13) and $f(u,v,\alpha)$ is a quartic polynomial in u,v with coefficients quadratic in α. The corresponding surface area is then equal to

$$\int_0^1 \int_0^{1-u} F(u,v,\alpha)\,\mathrm{d}v\,\mathrm{d}u = A\alpha^2 + B\alpha + C = L, \quad A,B,C \in \mathbb{R}. \tag{18}$$

Hence for

$$L \geq \frac{4AC - B^2}{4A}, \tag{19}$$

we always obtain a solution, i.e, a quartic PN patch interpolating given data and subject to the surface-area constraint. In particular the interpolation problem has one solution in the case of equality and two solutions in the case of strong inequality in (19).

Example 4.1 Consider three points

$$\mathbf{p}_{00} = (0,0,0)^\top, \quad \mathbf{p}_{10} = (2,-1,1)^\top, \quad \mathbf{p}_{01} = (2,2,-1)^\top, \tag{20}$$

and the associated unit normal vectors

$$\mathbf{N}_{00} = (0,0,-1)^\top, \quad \mathbf{N}_{10} = \left(\frac{2}{3},-\frac{1}{3},-\frac{2}{3}\right)^\top, \quad \mathbf{N}_{01} = \left(-\frac{1}{3},-\frac{2}{3},-\frac{2}{3}\right)^\top. \tag{21}$$

Our goal is to construct a triangular PN patch interpolating the prescribed points and normals and possessing the surfaces area equal to $L = 4$.

 ISBN: 978-84-617-8694-7

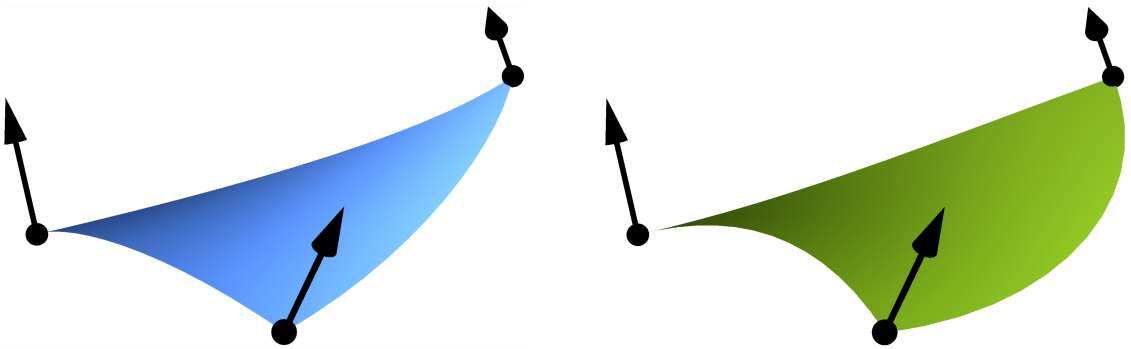

Figure 2: Quartic PN patch interpolating data (20) and (21) having areal element equal to 4 (left) and 4.5 (right) from Example 4.1.

We use the stereographic projection with $\mathbf{w} = (0, 0, 1)$, cf. (10), and construct the linear triangular planar patch (11), i.e.,

$$\widehat{\mathbf{N}}(u, v) = \left(\frac{1}{5}(2u - v), \frac{1}{5}(-u - 2v), 0\right)^{\top}. \tag{22}$$

Then lifting $\widehat{\mathbf{N}}$ back on the unit sphere $\mathcal{S}^2$ and omitting the denominator, cf. (12), yields the polynomial vector field

$$\mathbf{n}(u, v) = \left(\frac{2}{5}(2u - v), -\frac{2}{5}(u + 2v), \frac{1}{5}\left(u^2 + v^2 - 5\right)\right)^{\top} \tag{23}$$

fulfilling the PN condition

$$\|\mathbf{n}(u, v)\|^2 = \left[\frac{1}{5}\left(u^2 + v^2 + 5\right)\right]^2. \tag{24}$$

Then, we prescribe a polynomial parameterization (7) of degree four and solve the systems of linear equations (8) and (15) which yields 1-parametric solution (16). Finally computing the surface area (18) and solving

$$L = \frac{16001}{3686400}\alpha^2 + \frac{1219717}{6874560}\alpha + \frac{111456586}{26163225} = 4, \tag{25}$$

we arrive at the two values of the parameter $\alpha_1 \doteq -39.3537$ and $\alpha_2 \doteq -1.52238$ from which only α_2 corresponds to a patch without singularities – this can be verified by investigating the zeros of the extra factor $f(u, v, \alpha_i)$. In particular the curve defined by $f(u, v, \alpha) = 0$ in the parameter plane u, v corresponds to the singular curve on the corresponding patch,

hence our aim is to choose parameter α such that $f(u, v, \alpha)$ does not lie in the triangle $u \in [0, 1]$, $v \in [0, 1 - u]$. As mentioned before, this is satisfied only by α_2, see Fig. 1. In Fig. 2 two non-singular PN patches (with surface area equal to 4 and 4.5) interpolating points (20) and normals (21) are shown.

5 Conclusion

This paper was devoted to the construction of polynomial triangular PN patches interpolating given G^1 data and, in addition, possessing the prescribed surface area. We have shown that the first part (without considering the surface area constraint) is always possible by quartic surfaces. Moreover since the interpolation problem yields 1-parameter family of PN surfaces, the interpolation together with ensuring the prescribed area element gives 0, 1 or 2 solutions depending on the value of the particular are element. We also discussed that the resulting surfaces may contain the singular curve corresponding to the zeroes of the extra factor $f(u, v)$. Of course the good interpolants are those having $f(u, v) = 0$ outside the parameter domain. As far as we are aware of the literature, this paper is the first contribution solving for PN surfaces a problem analogous to the interpolation with PH curves satisfying the condition on the arc length. In our future work we would like to focus in more detail on ensuring the existence such interpolants and constructing piecewise PN surfaces with a prescribed continuity and subject to surface-area constraints.

Abstract

In this article a class of monogenic functions with (logarithmic) line singularities is presented. These functions have special properties with respect to the hypercomplex derivative (Appell property) and can be generated by a two step recurrence formula.

Key words: monogenic functions, line singularities, recurrence formulae
MSC 2000: 30G35, 33B30

1 Introduction

Nowadays, Clifford analysis is commonly understood as the higher dimensional counterpart to the complex function theory and has applications in many fields of mathematical physics. In the complex one-dimensional analysis, series expansions of holomorphic functions take a key role in solving applied as well as theoretical problems. In recent years there has been a lot of progress in finding higher dimensional analogs to the complex series expansions. In [2, 3], generalized Taylor- and Fourier series expansions and in [4] a generalized Laurent series expansion for quaternion-valued functions taking values in $\mathbb{R}^3$ were constructed. This approach was then unified in [5] for dimensions 2, 3 and 4. The construction of these series expansions was based on the use of complete orthogonal systems of inner and outer solid spherical monogenics which generalize all the essential properties of the holomorphic $\boldsymbol{z}$-monomials, such as orthogonality, Appell property, two step recurrence relations, to $\mathbb{R}^3$ and $\mathbb{R}^4$. Furthermore, these series expansions were successfully applied in solving three dimensional problems in linear elasticity theory by using recently developed higher dimensional generalizations of the Kolosov-Muskhelishvilli formulae [6, 9]. Recent results in this context indicate that the function systems and series expansions developed so far are not sufficient for solving more specific boundary value problems with point and line singularities, as for

example in the spatial fracture mechanics. In [7], a new set of monogenic functions with (logarithmic) line singularities was studied. Based on these results, a hypercomplex version of the fundamental solution in linear elasticity (Kelvin solution) was constructed, which describes the elastic displacements of a concentrated force acting at the origin of an infinite body. The Kelvin solution is of fundamental importance as one can also construct solutions for force groups or distributed forces by using the principle of superposition.

In this article a class of monogenic functions with (logarithmic) line singularities is studied which extends the results of [7]. These functions have special properties with respect to the hypercomplex derivative (Appell property) and can be generated by an associated two step recurrence formula.

2 Preliminaries

Let $\mathbb{H}$ be the algebra of real quaternions with the standard basis $\{\mathbf{e}_0, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ subjected to the multiplication rules

$$\begin{aligned} \mathbf{e}_i\mathbf{e}_j + \mathbf{e}_j\mathbf{e}_i &= -2\delta_{ij}\,\mathbf{e}_0,\ i,j=1,2,3, \\ \mathbf{e}_1\mathbf{e}_2 &= \mathbf{e}_3,\ \mathbf{e}_0\mathbf{e}_i = \mathbf{e}_i\mathbf{e}_0 = \mathbf{e}_i,\ i=0,1,2,3. \end{aligned}$$

The real vector space $\mathbb{R}^4$ will be embedded in $\mathbb{H}$ by identifying $\boldsymbol{a} = [a_0, a_1, a_2, a_3]^{\mathrm{T}} \in \mathbb{R}^4$ with the quaternion $\boldsymbol{a} = a_0 + a_1\mathbf{e}_1 + a_2\mathbf{e}_2 + a_3\mathbf{e}_3$, $a_i \in \mathbb{R}$, $i = 0, 1, 2, 3$, where $\mathbf{e}_0 = [1, 0, 0, 0]^{\mathrm{T}}$ is the multiplicative unit element of the algebra $\mathbb{H}$. Further, we denote by $\mathbf{Sc}(\boldsymbol{a}) = a_0$ the scalar part and by $\mathbf{Vec}(\boldsymbol{a}) = \underline{\boldsymbol{a}} = \sum_{i=1}^{3} a_i\mathbf{e}_i$ the vector part of $\boldsymbol{a}$. In addition, $\overline{\boldsymbol{a}} = a_0 - \underline{\boldsymbol{a}}$ denotes the conjugate and $|\boldsymbol{a}| = \sqrt{\boldsymbol{a}\,\overline{\boldsymbol{a}}}$ the norm of $\boldsymbol{a}$.

Now, let us consider the subset $\mathcal{A} := \mathrm{span}_{\mathbb{R}}\{1, \mathbf{e}_1, \mathbf{e}_2\}$ which is only a real vector space but not a sub-algebra of $\mathbb{H}$. The real vector space $\mathbb{R}^3$ will be embedded in $\mathcal{A}$ by the identification of $\boldsymbol{x} = [x_0, x_1, x_2]^{\mathrm{T}} \in \mathbb{R}^3$ with the *reduced quaternion*

$$\boldsymbol{x} = x_0 + \mathbf{e}_1\boldsymbol{\zeta} \in \mathcal{A} \quad \text{with} \quad \boldsymbol{\zeta} = x_1 - \mathbf{e}_3 x_2.$$

Let now Ω be an open subset of $\mathbb{R}^3$ with a piecewise smooth boundary. An $\mathbb{H}$-valued function is a mapping $\boldsymbol{f} : \Omega \longrightarrow \mathbb{H}$ such that $\boldsymbol{f}(\boldsymbol{x}) = \sum_{i=0}^{3} f^i(\boldsymbol{x})\,\mathbf{e}_i\,,\ \boldsymbol{x} \in \Omega$. The coordinates $f^i(\boldsymbol{x})$ are real-valued functions defined in Ω, i.e., $f^i(\boldsymbol{x}) : \Omega \longrightarrow \mathbb{R}\,, i = 0, 1, 2, 3$. Continuity, differentiability or integrability of $\boldsymbol{f}$ are defined coordinate-wise.

Furthermore, the *generalized Cauchy-Riemann operator* and the corresponding *adjoint generalized Cauchy-Riemann operator* are defined by

$$\overline{\boldsymbol{\partial}} := \frac{\partial}{\partial x_0} + 2\mathbf{e}_1\frac{\partial}{\partial\overline{\boldsymbol{\zeta}}} \quad \text{and} \quad \boldsymbol{\partial} := \frac{\partial}{\partial x_0} - 2\mathbf{e}_1\frac{\partial}{\partial\overline{\boldsymbol{\zeta}}} \quad \text{with} \quad \frac{\partial}{\partial\overline{\boldsymbol{\zeta}}} = \frac{1}{2}\left(\frac{\partial}{\partial x_1} - \mathbf{e}_3\frac{\partial}{\partial x_2}\right),$$

which leads to the following definitions:

 ISBN: 978-84-617-8694-7

Definition 1 *A function* $\boldsymbol{f} \in C^1(\Omega;\mathbb{H})$ *is called monogenic in* $\Omega \subset \mathbb{R}^3$ *if* $\overline{\boldsymbol{\partial}}\boldsymbol{f} = 0$ *in* Ω.

Definition 2 (Hypercomplex derivative [8]) *Let* $\boldsymbol{f} \in C^1(\Omega;\mathbb{H})$ *be a continuous, real-differentiable function and monogenic in* Ω. *The expression* $\boldsymbol{\partial_x f} := \frac{1}{2}\boldsymbol{\partial f}$ *is called hypercomplex derivative of* $\boldsymbol{f}$ *in* Ω.

3 Constructing monogenic functions with line singularities

Let us consider the *Legendre differential equation*

$$(1-t^2)\,\frac{\mathrm{d}^2 y}{\mathrm{d}t^2} - 2t\,\frac{\mathrm{d}y}{\mathrm{d}t} + n(n+1)y = 0, \quad n > 0,\ |t| < 1\,.$$

It is well known that the general solution of the second-order ordinary differential equation is given by

$$y = A\,P_n(t) + B\,Q_n(t),$$

where $P_n(t)$ and $Q_n(t)$ are the Legendre functions of the 1^{st} and 2^{nd} kind, respectively. In previous works [3, 4, 6] it was shown that the Legendre functions $P_n(t)$ as well as the associated Legendre functions $P_n^m(t)$ of the 1^{st} kind play a crucial role in defining orthogonal Appell basis of inner and outer spherical monogenics. Here, we will work with the Legendre functions $Q_n(t)$ of the 2^{nd} kind which can be defined, see for example [1], by the recurrence relation

$$(n+1)\,Q_{n+1}(t) = (2n+1)\,t\,Q_n(t) - n\,Q_{n-1}(t), \quad n \geq 1$$

with

$$Q_0(t) = \frac{1}{2}\ln\frac{1+t}{1-t} \qquad \text{and} \qquad Q_1(t) = t\,Q_0(t) - 1\,.$$

Due to the logarithmic term in $Q_0(t)$ the functions $Q_n(t)$ have infinite discontinuities at $t = \pm 1$. Therefore, we consider in the following the functions $Q_n(t)$ on the interval $|t| < 1$. Using the $Q_0(t)$, the *associated Legendre functions of the* 2^{nd} are defined by

$$Q_n^l(t) \;=\; (1-t^2)^{\frac{l}{2}}\,\frac{\mathrm{d}^l}{\mathrm{d}t^l}Q_n(t), \quad n, l \in \mathbb{N}_0,$$

which are solutions of the *associated Legendre differential equation* (see [1]). The main result of this section is stated in the following theorem.

Theorem 3 *For each* $n, l \in \mathbb{N}_0$, *the* $\mathbb{H}$*-valued functions*

$$\boldsymbol{W}_n^l(\boldsymbol{x}) = 2\,\boldsymbol{H}_n^l(\boldsymbol{x}) + \mathbf{e}_1\boldsymbol{H}_n^{l+1}(\boldsymbol{x})$$

composed of the harmonic functions

$$\boldsymbol{H}_n^l(\boldsymbol{x}) = \frac{2^{l-1}n!}{(n+l)!}\,|\boldsymbol{x}|^n\,Q_n^l(t)\left(\frac{\boldsymbol{\zeta}}{|\boldsymbol{\zeta}|}\right)^l \quad \textit{where} \quad t = \frac{x_0}{|\boldsymbol{x}|} \quad \textit{and} \quad \boldsymbol{\zeta} = x_1 - \mathbf{e}_3 x_2$$

are defined in $\Omega = \left\{\boldsymbol{x} \in \mathbb{R}^3 \;\middle|\; \boldsymbol{x} \neq x_0,\, x_0 \in \mathbb{R}\right\}$ *and have the following properties:*

 ISBN: 978-84-617-8694-7

(i) Monogenicity: $\overline{\boldsymbol{\partial}}\, \boldsymbol{W}_n^l(\boldsymbol{x}) = 0 \ \ \forall\, n, l \in \mathbb{N}_0$,

(ii) Generalized Appell property: $\boldsymbol{\partial_x}\, \boldsymbol{W}_{n+1}^l(\boldsymbol{x}) = (n+1)\, \boldsymbol{W}_n^l(\boldsymbol{x}) \ \ \forall\, n \in \mathbb{N}, l \in \mathbb{N}_0$,

(iii) Recurrence relation: For all $n \in \mathbb{N}, l \in \mathbb{N}_0$ *and* $n+1 \neq l$ *it holds*

$$\frac{2(n-l+1)(n+l+2)}{n+1}\, \boldsymbol{W}_{n+1}^l(\boldsymbol{x}) = \Big((2n+3)\boldsymbol{x}+(2n+1)\overline{\boldsymbol{x}}\Big)\boldsymbol{W}_n^l(\boldsymbol{x}) - 2n|\boldsymbol{x}|^2\, \boldsymbol{W}_{n-1}^l(\boldsymbol{x}).$$

Note, that the functions studied in [7] are obtained for the case $l = 0$.

Separate Node Ascending Derivatives Expansion (SNADE) on a Sequence of Nodes Alternating Between Two Values

Derya BODUR[1] and Metin DEMİRALP[1]

[1] *Informatics Institute, Computational Science and Engineering Program, İstanbul Technical University*

emails: deryabodur@itu.edu.tr, metin.demiralp@gmail.com

Abstract

This work focuses on a method called as Separate Node Ascending Derivatives Expansion (SNADE) which can be considered as a new Taylor Series Expansion. This method is distinguished from Taylor Series Expansion by its different node points using features. This paper investigates certain details of this issue. However a specific importance is given to the case where the SNADE nodal sequence is composed of elements alternating between two nodal values.

Key words: SNADE, Taylor Expansion, Integral Operator, Generating Functions
MSC 2000: 41A10, 41A58, 47G10

1 Introduction

There are various function representing methods whose structurings change depending on their number of independent variables. The multivariate function representation is out of the scope of this work. Hence we focus on only univariate function decomposition here. One very widely used method is to expand the considered function to the nonnegative powers of a first degree polynomial (a monomial minus a common constant which may be called the expansion point). This is the backbone of very well known Taylor series [1–10] and the obtained series converges in the complex-plane analyticity domain of the target function. As long as that domain is not empty the target function can be exactly represented by that power series even though its finite truncations are preferred to be used for practical purposes. The convergence is pointwise in analyticity domain, that is, the series uniformly converges at every interior point of the domain while the boundary points of the analyticity domain may give not uniform but conditional convergences.

Power series are not the only series representations. They are in fact very specific form of series representations as an infinite linear combination of a complete basis function set with constant coefficients such that the basis functions can be expressed as the natural number powers of the same first degree polynomial composed of a monomial of the independent variable minus a common constant. The orthogonal polynomial or function series are amongst these other much more general series. The convergence-in-the-mean is mostly encountered situation in these cases. Fourier series are perhaps the best examples to these groups. On the other hand, Taylor, Maclaurin and Laurent series are basically well-known power series even though the Laurent series contain polarly singular terms.

Taylor or Maclaurin series can be constructed by using an integral-of-derivative identity and includes a remainder term such that the convergence of the infinite series as the limit of the polynomial part depends on the vanishment of that remainder term when the polynomial part's degree grows unboundedly.

SNADE can be considered as a construction of a new Taylor series expansion. The method contains denumerable infinitely many nodes in contrast to Taylor series expansion. SNADE is based on the derivative integration formula[11–16]. The core topic of this work, "Separate Node Ascending Derivatives Expansion (SNADE)" is also based on the same identity. However, it uses infinitely many expansion points in each step of its repeated utilization.

This paper is organised as follows. The formulation about SNADE is given in the following section. In the third section, a special case of SNADE is considered such that there are two different nodal values which are used infinitely many times repeatedly and consecutively. Details will be given therein. A convergence investigating section follows this section. The convergence, in other words, the fact that the validity of infinite representation by this specific SNADE is proven in the following section while the last section finalizes the paper as usual.

2 Recalling SNADE

SNADE is based on the Integral-of-Derivative Identity which can be expressed as follows

$$f(x) = f(x_1) + \int_{x_1}^{x} d\xi f'(\xi), \quad x, x_1 \in [a, b] \tag{1}$$

The following equality can be obtained when the functions $f(x)$ and $f'(\xi)$ appearing in this identity are replaced with $f'(\xi)$ and $f''(\xi_1)$ respectively, the following equality can be obtained.

$$f'(\xi) = f'(x_2) + \int_{x_2}^{\xi} d\xi_1 f''(\xi_1) \tag{2}$$

 ISBN: 978-84-617-8694-7

If (1) and (2) are combined, the following equality can be achieved.

$$f(x) = f(x_1) + f'(x_2)(x - x_1) + \int_{x_1}^{x} d\xi_1 \int_{x_2}^{\xi_1} d\xi_2 f''(\xi_2) \tag{3}$$

Taylor series expansion has a single node and calculations are done at this point. But here function value at x_1 and function's derivative value at x_2 are used until now. If one more step is taken, the following equality can be obtained.

$$\begin{aligned} f(x) &= f(x_1) + f'(x_2)(x - x_1) + \frac{1}{2}(x - x_1)(x + x_1 - 2x_2) f''(x_3) \\ &+ \int_{x_1}^{x} d\xi_1 \int_{x_2}^{\xi_1} d\xi_2 \int_{x_3}^{\xi_2} d\xi_3 f'''(\xi_3) \end{aligned} \tag{4}$$

This structure can be written in symbolic form as follows

$$\begin{aligned} f(x) &= f(x_1)\mathcal{I}_0 1_f + f'(x_2)\mathcal{I}_1(x_1)1_f + f''(x_3)\mathcal{I}_2(x_1, x_2)1_f \\ &+ \mathcal{R}_2(x; x_1, x_2, x_3) \end{aligned} \tag{5}$$

where 1_f stands for the unit constant function and $\mathcal{I}$ is an integral operator which can be defined as

$$\begin{aligned} \mathcal{I}_m(x_1, \cdots, x_m)\, g(x) \equiv \int_{x_1}^{x} d\xi_1 \cdots \int_{x_m}^{\xi_{m-1}} d\xi_m g(\xi_m), \\ m = 1, 2, \cdots, \quad \mathcal{I}_0 g(x) \equiv g(x) \end{aligned} \tag{6}$$

where $g(x)$ is an arbitrary integrable function and x takes the role of nonexisting dummy variable ξ_0. The m-th order remainder term is obtained as follows

$$\mathcal{R}_m(x; x_1, \cdots, x_{m+1}) \equiv \mathcal{I}_{m+1}(x_1, \cdots, x_{m+1}) f^{(m+1)}(x), \qquad m = 0, 1, 2, \cdots \tag{7}$$

So, the formula given in (5) can be generalized as follows

$$f(x) = \sum_{i=0}^{m} f^{(i)}(x_{i+1})\mathcal{I}_i(x_1, \cdots, x_i)1_f + \mathcal{R}_{m+1}(x; x_1, \cdots, x_{m+1}), \qquad m = 0, 1, \cdots \tag{8}$$

Remainder term in the above formula tends to vanish when m grows unboundedly. So, the following equation can be written

$$f(x) = \sum_{i=0}^{\infty} f^{(i)}(x_{i+1})\mathcal{I}_i(x_1, \cdots, x_i)1_f \tag{9}$$

and is named as "Infinite Order SNADE".

 ISBN: 978-84-617-8694-7

3 SNADE on a Sequence of Nodes Alternating Between Two Values

We start this section with recalling SNADE formula as follows

$$\begin{aligned} f(x) &= \sum_{j=0}^{\infty} f^{(j)}(x_j) \int_{x_1}^{x} d\xi_1 \int_{x_2}^{\xi_1} d\xi_2 \cdots \int_{x_j}^{\xi_{j-1}} d\xi_j 1_f \\ &= \sum_{j=0}^{\infty} f^{(j)}(x_j) \widehat{\mathcal{I}}_j(x; x_1, ..., x_j) 1_f, \qquad \widehat{\mathcal{I}}_0 \equiv 1 \end{aligned} \tag{10}$$

The title of this section may imply that there are only two nodes in the approach here although the truth is different. There are in fact a denumerable infinite number of nodes here as expected. However, the values of nodes are alternated between two nodal values represented by x_1 and x_2. This means that the nodes are given through the sequence x_1, x_2, x_1,... In other words there is a pattern defined by $x_{2j-1} \equiv x_1, x_{2j} \equiv x_2$ which leads us to the definition of two-fold integral operator as follows

$$\widehat{\mathcal{J}}(x_1, x_2) g(x) \equiv \int_{x_1}^{x} d\xi_1 \int_{x_2}^{\xi_1} d\xi_2 g(\xi_2) \tag{11}$$

which urges us to define the following polynomials

$$P_{2k}(x; x_1, x_2) \equiv \widehat{\mathcal{J}}(x_1, x_2)^k 1_f, \qquad k = 0, 1, 2, ... \tag{12}$$

$$P_{2k+1}(x; x_1, x_2) \equiv \int_{x_1}^{x} d\xi P_{2k}(\xi; x_2, x_1), \qquad k = 0, 1, 2, ... \tag{13}$$

It is possible to show that the following recursions between these polynomials hold.

$$P_{2k}(x; x_1, x_2) = \widehat{\mathcal{J}}(x_1, x_2) P_{2k-2}(x; x_1, x_2) \quad k = 1, 2, 3, ..., \quad P_0 \equiv 1 \tag{14}$$

$$v \equiv x_1 - x_2, \qquad u \equiv (x - x_2)/v, \tag{15}$$

The impressions from these polynomial expressions bring us to the following structure

$$P_{2k}(x; x_1, x_2) = \frac{v^{2k}}{(2k)!} \sum_{j=0}^{k} p_{k,j} u^{2j} \qquad k = 1, 2, 3, ..., \qquad p_{0,0} \equiv 1 \tag{16}$$

To determine $p_{k,j}$ coefficients, the action of $\widehat{J}$ on u^k is studied and the following equality is obtained

$$\widehat{J}(x_1, x_2) u^k = \frac{v^2}{(k+1)(k+2)} \left(u^{k+2} - 1 \right), \qquad k = 0, 1, 2, ... \tag{17}$$

 ISBN: 978-84-617-8694-7

By using the action of $\widehat{J}$ on u^k and the recursion between P_{2k} and P_{2k-2}, the following equality can be obtained without explicitly showing the intermediate operations.

$$P_{2k}\left(x;x_1,x_2\right)=\frac{v^{2k}}{(2k)!}\sum_{j=1}^{k}\frac{(2k-1)2k}{(2j-1)2j}p_{k-1,j-1}\left(u^{2j}-1\right),\qquad k=1,2,3,... \tag{18}$$

When the right hand sides of the polynomial expressions in (18) and (16) are set equal to each other, the following coefficients of the polynomials can be obtained.

$$\begin{aligned} p_{k,j} &= \frac{2k(2k-1)}{2j(2j-1)}p_{k-1,j-1},\quad k=1,2,3,...;\quad j=1,2,...,k; \\ p_{k,0} &= -\sum_{j=1}^{k}\frac{2k(2k-1)}{2j(2j-1)}p_{k-1,j-1}=-\sum_{j=1}^{k}p_{k,j},\qquad k=1,2,3,... \end{aligned} \tag{19}$$

As can be noticed immediately in these polynomials, the sum of the coefficients of each polynomial except the constant one is zero. On the other hand, there is a recursion between the coefficients of two consecutive terms. The determination of $p_{k,k}$ is given as follows.

$$\begin{aligned} p_{k,k} &= p_{k-1,k-1},\qquad k=1,2,3,...; \\ p_{0,0} &= 1,\quad p_{k,k}=1,\qquad k=0,1,2,... \end{aligned} \tag{20}$$

$p_{k,k-j}$ coefficients are determined by consecutive examinations as we have done above. This gives

$$p_{k,k-j}=\binom{2k}{2j}p_{j,0},\qquad j=0,1,2,...\qquad k=j,j+1,j+2,... \tag{21}$$

4 Constitution of Generating Function

Now we focus on (19) to determine $p_{j,0}$ coefficients. For this purpose, $p_{k,k-j}$ expressions given by (21) can be used in (19) to get the following equation.

$$\sum_{j=0}^{k}\binom{2k}{2j}p_{j,0}=\delta_{k,0} \tag{22}$$

If both sides of this equality is multiplied by $z^{2k}/(2k)!$ and the resulting equality's both sides are separately sum over k from 0 to infinity then the right hand side becomes just 1 while the left hand side becomes the result of a Cauchy product between two power series. This gives

$$\sum_{k=0}^{\infty}\frac{z^{2k}}{(2k)!}\sum_{j=0}^{\infty}\frac{z^{2j}}{(2j)!}p_{j,0}=1 \tag{23}$$

 ISBN: 978-84-617-8694-7

which enables us to get

$$\sum_{j=0}^{\infty} \frac{z^{2j}}{(2j)!} p_{j,0} = \frac{1}{\cosh z} \tag{24}$$

This allows us to determine $p_{j,0}$ as follows

$$p_{j,0} = \left\{ \frac{d^{2j}}{dz^{2j}} \left(\frac{1}{\cosh z} \right) \right\}_{z=0}, \qquad j = 0, 1, 2, ... \tag{25}$$

Now we can focus on the following generating function to determine the polynomials P_{2k}. We can write

$$\begin{aligned} G(z;u,v) &= \sum_{k=0}^{\infty} z^{2k} P_{2k}(x;x_1,x_2) = \sum_{k=0}^{\infty} \sum_{j=0}^{k} \frac{z^{2k} v^{2k} p_{k-j,0}}{(2j)!(2k-2j)!} u^{2j} \\ &= \sum_{j=0}^{\infty} \frac{(vuz)^{2j}}{(2j)!} \sum_{k=0}^{\infty} \frac{(vz)^{2k}}{(2k)!} p_{k,0} = \frac{\cosh vuz}{\cosh vz} \end{aligned} \tag{26}$$

$$P_{2k}(x;x_1,x_2) = \frac{1}{(2k)!} \left\{ \frac{d^{2k}}{dz^{2k}} \left(\frac{\cosh vuz}{\cosh vz} \right) \right\}_{z=0} \tag{27}$$

The above generating function depends on real valued v and uv, and complex valued z variables. Numerator and denumerator of this function that consist of known functions are entire functions. There are no singularities. But, if vz takes one of the values $\pm i(n+1/2)\pi$, the denumerator will be set equal to zero. So, it is faced with singularity in that case. For this reason, the Maclaurin series expansion of this generating function converges when the complex norm of vz is less than $\pi/2$, otherwise it diverges. Apart from that case, we have also been worked with divergent generating functions. Convergent integral representations were obtained by using Borel summation of these generating functions. On the other hand, we have also focused on circular sector contour integral to overcome this difficulty even though we do not intend to give the details here.

5 Validity of SNADE on a Sequence Alternating Between Two Values

In this section, we will prove that the SNADE on a sequence whose elements are alternating between two nodal values really represents the target function, f. For this purpose, the infinite sum is splitted into two parts as follows.

$$F_1(x;x_1,x_2) = \sum_{j=0}^{\infty} f^{(2j)}(x_1) \widehat{\mathcal{I}}_{2j}(x;x_1,x_2) 1_f, \qquad \widehat{\mathcal{I}}_0 \equiv 1,$$

 ISBN: 978-84-617-8694-7

$$F_2\left(x;x_1,x_2\right) = \sum_{j=0}^{\infty} f^{(2j+1)}\left(x_2\right)\widehat{\mathcal{I}}_{2j+1}\left(x;x_1,x_2\right)1_f, \tag{28}$$

These expressions can be transformed into other expressions composed of polynomials we have investigated above as follows.

$$\begin{aligned} F_1\left(x;x_1,x_2\right) &= \sum_{j=0}^{\infty} f^{(2j)}\left(x_1\right)P_{2j}\left(x;x_1,x_2\right), \\ F_2\left(x;x_1,x_2\right) &= \sum_{j=0}^{\infty} f^{(2j+1)}\left(x_2\right)P_{2j+1}\left(x;x_1,x_2\right) \end{aligned} \tag{29}$$

Now question "Does the following equality hold for any target function $f(x)$?" is the goal to be answered positively.

$$F_1\left(x;x_1,x_2\right) + F_2\left(x;x_1,x_2\right) = f(x) \tag{30}$$

To get answer, first, u and v are replaced with Υ and $-v$ respectively in (26). Then both sides of the produced equation are integrated over the interval $[\,0,1-u\,]$ with respect to Υ. At the last step, both sides of the resulting equation are multiplied by $-vz$ and the resulting equation can be written in the following simple form

$$P_{2k+1}\left(u,v\right) = -\frac{1}{(2k+1)!}\left\{\frac{d^{2k+1}}{dz^{2k+1}}\left(\frac{\sinh v(1-u)z}{\cosh vz}\right)\right\}_{z=0} \tag{31}$$

Now we focus on the determination of the function $F_1\left(x;x_1,x_2\right)$

$$F_1\left(x;x_1,x_2\right) = \sum_{k=0}^{\infty} f^{(2k)}\left(x_1\right)P_{2k}\left(u,v\right) \tag{32}$$

If the $(2k)$th derivative of the product between $1/\cosh(vz)$ and $\cosh(vuz)$ appearing at the right side of (27) where P_{2k} is given explicitly, is rewritten according to the Leibniz rule and vanished terms are not shown then the following equations can be written.

$$P_{2k}(u,v) = \sum_{j=0}^{k} \frac{(vu)^{2k-2j}}{(2j)!(2k-2j)!}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(vz)}\right)\right\}_{z=0}, \qquad k=0,1,2,... \tag{33}$$

If this result is used in (32) then the following structure is obtained.

$$F_1\left(x;x_1,x_2\right) = \sum_{j=0}^{\infty} \frac{1}{(2j)!}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(vz)}\right)\right\}_{z=0} \sum_{k=0}^{\infty} f^{(2k+2j)}\left(x_1\right)\frac{(vu)^{2k}}{(2k)!} \tag{34}$$

 ISBN: 978-84-617-8694-7

whose rightmost infinite sum can be simplifed in accordance with the following relation which can be established by using even function representation

$$\begin{aligned}\sum_{k=0}^{\infty} f^{(2k+2j)}(x_1)\frac{(vu)^{2k}}{(2k)!} &= \sum_{k=0}^{\infty} f^{(2k+2j)}(x_1)\frac{(x-x_2)^{2k}}{(2k)!} \\ &= \frac{1}{2}f^{(2j)}(x+x_1-x_2)+\frac{1}{2}f^{(2j)}(x_1+x_2-x) \end{aligned} \tag{35}$$

Using (35) in (34) allows us to write the following equality

$$\begin{aligned}F_1(x;x_1,x_2) &= \frac{1}{2}\sum_{j=0}^{\infty}\frac{1}{(2j)!}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(vz)}\right)\right\}_{z=0} \\ &\times\left[f^{(2j)}(x+x_1-x_2)+f^{(2j)}(x_1+x_2-x)\right]\end{aligned} \tag{36}$$

Now it is time to focus on the function $F_2(x;x_1,x_2)$ whose explicit structure is given below.

$$F_2(x;x_1,x_2) = \sum_{k=0}^{\infty} f^{(2k+1)}(x_2)\,P_{2k+1}(u,v) \tag{37}$$

Similar steps we have taken above for the evaluation of F_1 can be traced for this equality and the following result is achieved without explicitly giving the intermediate operations.

$$\begin{aligned}F_2(x;x_1,x_2) &= \frac{1}{2}\sum_{j=0}^{\infty}\frac{1}{(2j)!}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(vz)}\right)\right\}_{z=0} \\ &\times\left[f^{(2j)}(x-v)-f^{(2j)}(x_1+x_2-x)\right]\end{aligned} \tag{38}$$

(36) and (38) allow us to write the following equality

$$\begin{aligned}F_1(x)+F_2(x) &= \sum_{j=0}^{\infty}\frac{1}{(2j)!}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(vz)}\right)\right\}_{z=0} \\ &\times\frac{1}{2}\left[f^{(2j)}(x+x_1-x_2)+f^{(2j)}(x-x_1+x_2)\right]\end{aligned} \tag{39}$$

To proceed, the expression between the brackets can be expanded to series in terms of natural number powers of (x_1-x_2) as follows

$$\begin{aligned}F_1(x;x_1,x_2)+F_2(x;x_1,x_2) &= \sum_{k=0}^{\infty}\frac{f^{(2k)}(x)}{(2k)!}v^{2k}\sum_{j}^{k}\binom{2k}{2j}\left\{\frac{d^{2j}}{dz^{2j}}\left(\frac{1}{\cosh(z)}\right)\right\}_{z=0} \\ &\times\left\{\frac{d^{2k-2j}}{dz^{2k-2j}}(\cosh(z))\right\}_{z=0}\end{aligned} \tag{40}$$

 ISBN: 978-84-617-8694-7

We can write the following equalities for the finite sum in (40)

$$\sum_{j}^{k} \binom{2k}{2j} \left\{ \frac{d^{2j}}{dz^{2j}} \left(\frac{1}{\cosh(z)} \right) \right\}_{z=0} \left\{ \frac{d^{2k-2j}}{dz^{2k-2j}} \left(\cosh(z) \right) \right\}_{z=0} =$$
$$= \left\{ \frac{d^{2k}}{dz^{2k}} \left(\frac{\cosh(z)}{\cosh z} \right) \right\}_{z=0} = \left\{ \frac{d^{2k}}{dz^{2k}} \left(1 \right) \right\}_{z=0} = \delta_{k,0} \tag{41}$$

which takes us to the following conclusion we want to reach in fact.

$$F_1 \left(x; x_1, x_2 \right) + F_2 \left(x; x_1, x_2 \right) = f(x) \tag{42}$$

6 Concluding Remarks

We have constructed Separate Node Ascending Derivatives Expansion (SNADE) on a nodal sequence with elements alternating on two different values in this paper. We enumerate important points below.

1. SNADE is based on the famous integral-of-derivative identity which can be used also in the Taylor series in format with remainder;

2. In contrast to Taylor expansion SNADE can use a denumerable infinite number of values as the nodes;

3. We have focused only on the sequences whose elements alternate between two nodal values here;

4. We could have been able to evaluate all terms of this very specific case;

5. The polynomials we have used in the construction are closely related to so-called "Swiss Knife" polynomials;

6. Despite very special specification we have obtained a lot of key points to focus on the cases of much more complicated sequences. Thus we can proceed to develop SNADE to make it a powerful theory;

7. The form of the specific SNADE we have focused here brings a lot of constraints on the nodal values and the independent variables. However it seems to generalize our findings to more complicated domains.

Abstract

We propose an efficient algorithm for the solution of shifted quasiseparable systems, which exploits the invariance of the quasiseparable structure under diagonal shifting and inversion. This algorithm is applied to compute various functions of matrices, and to solve a class of linear matrix equations. Numerical experiments show the effectiveness of our approach.

Key words: quasiseparable matrices; shifted linear system; QR factorization; matrix function; matrix equation.
MSC 2000: 65F05

1 Introduction

In this work we propose a novel method for computing the solution of shifted quasiseparable systems of the form

$$(A + \sigma_i I_N)\boldsymbol{x}_i = \boldsymbol{y}, \quad i = 1, \ldots, \ell, \tag{1}$$

and of more general parameter dependent linear matrix equations with quasiseparable representations. Our approach also has a noticeable potential for effectively solving some large-scale algebraic problems that reduce to evaluating the action of a quasiseparable matrix function to a vector.

Quasiseparable matrices find their application in several branches of applied mathematics and engineering. For instance, quasiseparable structure often arises in the discretization of continuous operators, due to the local properties of the discretization schemes and/or to the decay properties of the operator or of its finite approximations. As a consequence, in the last decade there has been considerable interest in the development of fast algorithms for working with quasiseparable matrices [3, 4, 9, 10].

2 Main Algorithm

It is well known that several operations with quasiseparable matrices can be performed in linear time with respect to matrix size. In particular, the QR factorization algorithm presented in [2] computes in linear time a QR decomposition of a quasiseparable matrix $A \in \mathbb{C}^{N\times N}$ of the form $A = V \cdot U \cdot R$, where R is upper triangular, whereas U and V are banded unitary matrices and – this is the crucial point – V only depends on the generators of the strictly lower triangular part of A. This implies that any shifted matrix $A + \sigma I_N$, $\sigma \in \mathbb{C}$, can also be factored as $A + \sigma I_N = V \cdot U_\sigma \cdot R_\sigma$ for suitable U_σ and R_σ.

Relying upon this fact, we design and implement an efficient algorithm [1] for solving a sequence of shifted quasiseparable linear systems. Its arithmetic complexity is linear with respect to N and to the number of shifts, and it is halved with respect to straightforward application of structured QR factorization to each shifted linear system. The Matlab code is available at `http://www.unilim.fr/pages_perso/paola.boito/software.html`.

Some applications are presented in the following sections; they include the computation of $f(A)\boldsymbol{v}$ via series expansion or contour integrals, and the solution of linear matrix equations.

3 A Model Problem for Boundary Value ODEs

Consider the non-local boundary value problem:

$$\frac{d\boldsymbol{v}}{dt} = A\boldsymbol{v}, \quad 0 < t < \tau,$$

$$\frac{1}{\tau}\int_0^\tau \boldsymbol{v}(t)\, dt = \boldsymbol{g},$$

where A is a linear operator in $\mathbb{R}^N$ and $\boldsymbol{g} \in \mathbb{R}^N$ is a given vector [11, 12, 5].

If all the numbers $\mu_k = 2\pi ik/\tau,\ k = \pm 1, \pm 2, \pm 3, \ldots$ are regular points of the operator A, the problem has a unique solution, given by

$$\boldsymbol{v}(t) = q_t(A)\boldsymbol{g}, \quad q_t(z) = \frac{\tau z e^{zt}}{e^{z\tau} - 1}.$$

 ISBN: 978-84-617-8694-7

Without loss of generality one can assume $\tau = 2\pi$.

We show that, for a suitable truncation index ℓ, $\boldsymbol{v}(t)$ can be approximated by the finite sum

$$\boldsymbol{v}_\ell(t) = \sum_{j=0}^{3} V_j(t) A^j g - 2 \sum_{k=1}^{\ell} \frac{1}{k^2} (A \cos kt + \frac{1}{k} A^2 \sin kt)(A^2 + k^2 I_N)^{-1} A^3 g,$$

with $0 \leq t \leq 2\pi$ and

$$V_0(t) = 1,\ V_1(t) = t - \pi,\ V_2(t) = \frac{\pi^2}{3} - \pi t + \frac{t^2}{2},\ V_3(t) = \frac{\pi^2}{3} t - \frac{\pi}{2} t^2 + \frac{t^3}{6}.$$

The computation of $\boldsymbol{v}(t_i)$, $0 \leq i \leq M+1$, requires the solution of a possibly large set of shifted systems and our algorithm proves to be effective for this task if A is quasiseparable.

More generally, a similar approach can be applied to the computation of a function of a quasiseparable matrix, multiplied by a vector, whenever the function can be represented as a series of partial fractions. The classes of meromorphic functions admitting such a representation were investigated for instance in [8]. Other partial fraction approximations of certain analytic functions can be found in [7].

4 Sylvester-type Matrix Equations

As a natural extension of the problem (1), the right-hand side $\boldsymbol{y}$ could also depend on the parameter, so that we have a different right-hand side for each linear system. This situation is common in many applications, such as control theory, structural dynamics and time-dependent PDEs [6]. The systems to be solved take the form of a linear matrix equation:

$$AX + XD = Y, \quad A \in \mathbb{R}^{N \times N},\ D = \operatorname{diag}[\sigma_1, \ldots, \sigma_\ell],\ Y = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_\ell].$$

The extension to the case where D is lower triangular can be carried out via backsubstitution, and a further generalization to the case where D is a general matrix is possible using the classical Bartels-Stewart approach based on Schur decomposition. This approach is especially interesting when ℓ is significantly smaller than N. If A is quasiseparable we can apply our structured approach as outlined above, with computational advantages with respect to the widespread method that relies on Kronecker products.

Abstract

A parallel numerical simulation algorithm is presented for fractional-order systems involving Caputo derivatives, based on the Adams-Bashforth-Moulton predictor-corrector scheme. The parallel algorithm is implemented using MPI that runs on an HPC cluster, and the results are compared to others recently reported in the literature. As an applied experiment, we numerically compute the solutions of a fractional-order version of a fractional-order system describing a forced series LCR circuit, depicting cascades of period-doubling bifurcations leading to the onset of chaotic behavior.

Key words: Fractional-order system, parallel numerical algorithm, HPC processing.

1 Introduction

Compared to their integer-order counterparts, over the past decades, fractional-order dynamical systems have proved to provide more accurate and realistic results in the modeling of real world processes arising from diverse applied fields [3, 6, 8, 9, 10].

Although many qualitative properties of fractional-order systems can be studied by analytical tools (such as local stability of equilibrium states), theoretical characterization of chaos in fractional-order dynamical systems is yet to be investigated. In order to assess chaotic behavior of fractional-order dynamical systems, accurate estimation of the solutions over large time intervals is of utmost importance. However, an essential observation is that the employed discretization should use a small step size, with the aim of providing an accurate estimation to the solution of the fractional-order system under investigation.

 ISBN: 978-84-617-8694-7

Several numerical methods are used for fractional-order systems, such as a generalization of the Adams-Bashforth-Moulton predictor-corrector method [5] or a class of p-fractional linear multistep methods [7]. The main drawback of these numerical schemes is that, in order to obtain a reliable estimation of the solution, at every iteration step, all previous iterations have to be taken into account, due to the hereditary nature of the problem. Therefore, this implies extreme computational costs whenever the solution is computed over a large time interval, with a small step size. These difficulties may be overcome using parallel computing algorithms implemented in a conventional way or using available high performance computing systems [1, 2].

In this paper, we will present an efficient parallel algorithm implemented using Message Passing Interface (MPI) and running on a high performance computing system BlueGene/P cluster that has 1024 processors and 4TB of RAM memory. The numerical method considered here for implementing the fractional-order system is the Adams-Bashforth-Moulton predictor-corrector scheme [5]. The main challenge for implementing this method is to parallelize the computation of the solution because, the computation of an iteration step requires to take into account all previous iterations.

2 Preliminaries

Consider an ordinary fractional differential equation of the form:

$$\begin{cases} \mathrm{D}_*^{\alpha} y(t) = f(t, y(t)), & t \in [0, T] \\ y^{(k)}(0) = y_0^k, & k \in \{0, \ldots, \lceil \alpha \rceil - 1\}, \end{cases} \tag{1}$$

where $\alpha > 0$ and $\lceil \cdot \rceil$ denotes the ceiling function that rounds up to the nearest integer. The fractional derivative of Caputo-type is defined as:

$$\mathrm{D}_*^{\alpha} y(t) = \frac{1}{\Gamma(\lceil \alpha \rceil - \alpha)} \int_0^T \frac{y^{(\lceil \alpha \rceil)}(t)}{(t-\tau)^{\alpha - \lceil \alpha \rceil + 1}} \, \mathrm{d}\tau.$$

The numerical method used to solve (1) is a fractional version of the Adams-Bashforth-Moulton predictor corrector scheme [5]. The domain $[0, T]$ is discretized into N intervals with a step size $h = \frac{T}{N}$ and the grid points $t_n = nh$, for $n \in \{0, \ldots, N\}$. We will also denote $y_n = y(t_n)$ and $f_n = f(t_n, y_n)$ with $y_0 = y_0^0$ as the initial condition.

The first step of the scheme is the **predictor**, which will give a first approximation y_{n+1}^P of our solution:

$$y_{n+1}^P = \sum_{k=0}^{\lceil \alpha \rceil - 1} \frac{t_{n+1}^k}{k!} y_0^{(k)} + h^{\alpha} \sum_{k=0}^{n} b_{n-k} f_k, \quad \text{where } b_n = \frac{(n+1)^{\alpha} + n^{\alpha}}{\Gamma(\alpha + 1)}. \tag{2}$$

 ISBN: 978-84-617-8694-7

The final approximation of the solution, called the **corrector**, is given by:

$$y_{n+1} = \sum_{k=0}^{\lceil\alpha\rceil-1} \frac{t_{n+1}^k}{k!} y_0^{(k)} + h^\alpha \left(c_n f_0 + \sum_{k=1}^{n} a_{n-k} f_k + \frac{f(t_{n+1}, y_{n+1}^P)}{\Gamma(\alpha+2)} \right),$$

where the weights a_n and c_n are defined as:

$$a_n = \frac{(n+2)^{\alpha+1} - 2(n+1)^{\alpha+1} + n^{\alpha+1}}{\Gamma(\alpha+2)} \quad \text{and} \quad c_n = \frac{n^{\alpha+1} - (n-\alpha)(n+1)^\alpha}{\Gamma(\alpha+2)}.$$

This numerical scheme can be generalized in a straight-forward way, when one has to deal with a system of fractional-order differential equations.

The main computational difficulty of this scheme arises from the fact that at each step, we require the complete history of the variable, i.e., when computing y_{n+1}, we need to know all previous values y_k that are used to compute f_k, for $k \leq n$. This makes numerical methods addressed at solving fractional differential equations (or systems) notoriously hard to parallelize.

3 Parallel numerical algorithm

The parallel implementation of Adams-Bashforth-Moulton algorithm as a method for solving an fractional-order system was first presented by Diethelm [4]. The solution presented there is not suitable to be running on a HPC cluster because there is an unbalanced workload and waiting (idle) times for the processes that can cause the performance to be very low, due to the HPC parallel implementation rules [12]. Also, the amount of messages passed between processes does not respect the HPC parallel implementation idea [12], and strongly influence the overall performance.

In the previous work [1], we explored how numerical calculations of Adams-Bashforth-Moulton method for fractional-order systems can be accelerated by using parallel computing techniques. We investigated the feasibility of parallel computing algorithms and their efficiency in reducing the computational costs over a large time interval. The results concerning the parallel implementation for the Adams-Bashforth-Moulton method on HPC and CUDA show that some execution times are quite high and thus, they limit the time frame needed for more accurate simulations.

In [1], the HPC implementation was made using a classical approach: a process is the master and all other are slaves to help compute the values for predictor and corrector. The classical execution flow is presented in Figure 1a and shows that the master process is working either by computing or communicating, while the slave processes have idle times. On a HPC architecture these idle times could causes huge delays in communication and drastically increase the overall simulation time.

 ISBN: 978-84-617-8694-7

Algorithm 1: Parallel Algorithm for the Adams-Bashforth-Moulton scheme.

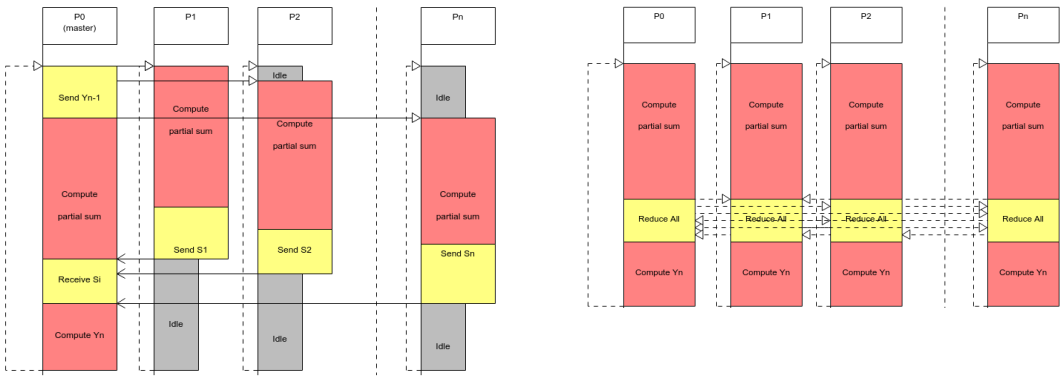
Data: T end of the time interval.
Data: N global number of points.
Data: P number of processes.
Data: p current process.
$N_P \leftarrow N/P$;
$y_0 \leftarrow$ initial condition;
for $n \in [1, N]$ **do**
  $Sp \leftarrow 0$;
  $Sc \leftarrow 0$;
  $n_{min} \leftarrow N_P p$;
  $n_{max} \leftarrow N_P(p+1)$;
  /* compute local sum for predictor and corrector */
  for $k \in [n_{min}, n_{max}]$ **do**
    $Sp \leftarrow Sp + b_{n-k} f_k$;
    $Sc \leftarrow Sc + c_{n-k} f_k$;
  end
  /* compute the global sum and sent to all processes */
  MPI_Allreduce(Sp, Sc);
  /* compute the predictor at time t_n */
  $y_n^P \leftarrow y_0 + a_n * Sp$;
  /* compute the corrector at time t_n */
  $y_n \leftarrow y_0 + c_n * (y_n^P + Sc)$;
end

In order to improve the overall simulation time, the workload needs to be balanced. First, the idle times of the processes need to be removed. Secondly, if possible, we need to decrease the number of messages, thus saving times in the communication part.

The parallel implementation method presented in Algorithm 1 reflects the core of our new implementation. The computation for the partial sum is done by each process and the final sum for the predictor and corrector is reduced to all processes (by MPI_Allreduce(Sp, Sc)). So instead of having the classical architecture where one process is the master and all the other processes are slaves just to compute the partial sum, in this approach all processes P compute the iteration function values (y_n), all acts as master processes.

In our new approach (see Figure 1b) we are able to avoid idle time for the processes, and we obtained a more balanced work load. Another advantage is that the overall communication between processes was reduced by removing the messages between the slaves

 ISBN: 978-84-617-8694-7



(a) The classical approach (b) The new improved approach

Figure 1: Workflow of execution processes

and master processes. There is only one message being exchanged when the global sum is reduced to all processes, and because the workload inside the process is balanced, the synchronized exchange time is very short. A similar method/solution was also presented and tested on PC using CPU core by [13] with very interesting results from the parallel computation point of view.

4 Simulation results

We implemented and tested the presented approach using the HPC cluster of the West University of Timişoara (Romania), namely, a BlueGene/P cluster that consists of a fully loaded single BlueGene/P rack that has more than 1000 CPUs and 4TB of RAM memory and can offer a performance up to 11.7 TFlops.

Table 1: Simulation results in seconds for different numbers of time steps

Case	No of time steps	HPC classic approach	CUDA run time	HPC run time
1	1000000	4621.25	2654.35	549.64
2	1500000	9162.33	4426.59	1158.13
3	2000000	14931.16	6616.77	2009.87
4	2500000	22697.66	9196.54	3066.92
5	3000000	31659.66	12206.16	4381.42

In Table 1 one can see the simulation run time results (in seconds) using different number of time steps (number of global points). We can see from the last column of this

 ISBN: 978-84-617-8694-7

table that the parallel algorithm proposed in this paper is up to 8 times more efficient than the classical approach of running the simulations on HPC, and also at least 3 times faster than CUDA simulations. The graphical representation of the running times (Figure 2) clearly presents the speed up of the new algorithm with all the processes as master processes.

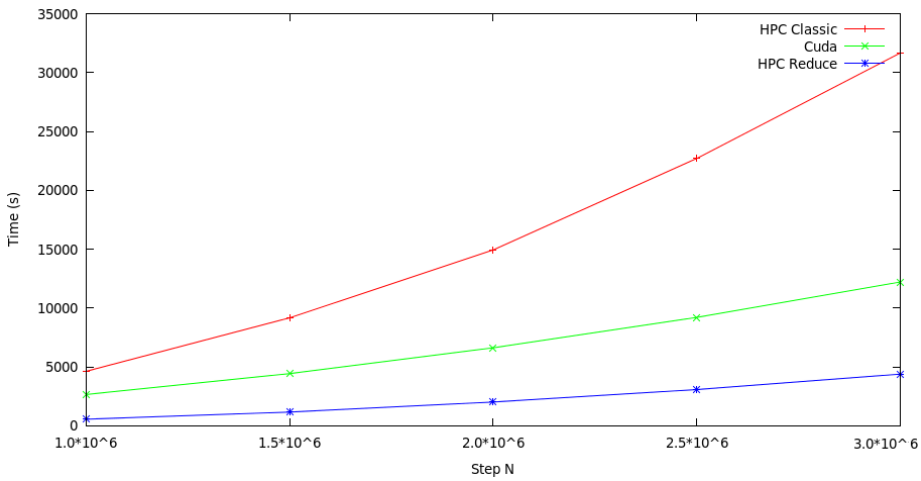


Figure 2: Running time comparison

Because our new implementation is much faster, we were able to implement simulations with even more than 5 million steps. This improvement allows us to compute the numerical solution of a fractional-order system over a large number of steps that provide us a better understanding about the system's behavior from the dynamic point of view. We will present more details about the numerical analysis of the test system in the next section.

In Figure 3 we present the average running time in seconds for the simulation on different number of steps. The time was computed between the simulation starting point until the results have been obtained. Those times include also the communication time between processes, but in our last proposed implementation the communication time is very low due to the fact that there are no idle times, respecting the HPC software development guidelines [12]. We observe from the simulations with the new implementation that the running time increases almost linearly with respect to the number of points even if more than 5 millions points are considered.

 ISBN: 978-84-617-8694-7

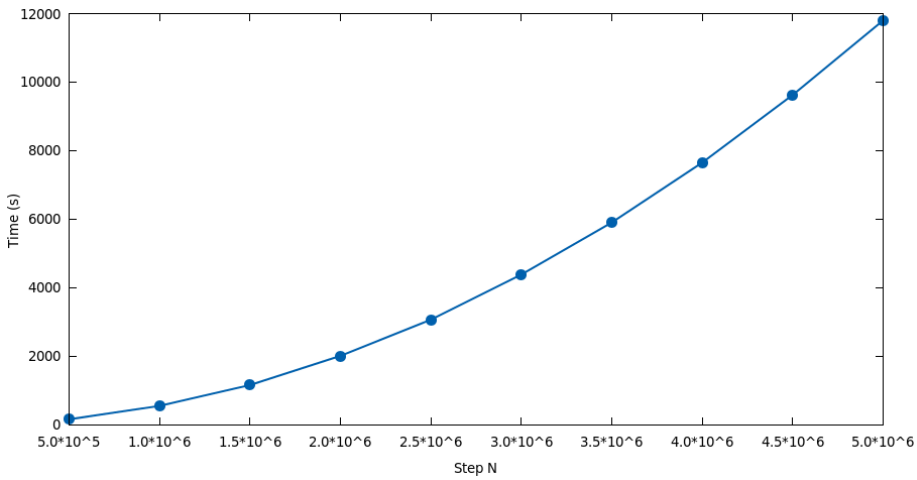

Figure 3: Running time speed HPC

5 Numerical experiment

Our test case is the fractional-order version of the normalized system describing a forced series LCR circuit [11]:

$$\begin{cases} D^{\alpha_1}x(t) = y - g(x) \\ D^{\alpha_2}y(t) = -\sigma y - x + f\sin(\omega t) \end{cases} \tag{3}$$

where $\alpha_1, \alpha_2 \in (0,1)$, $\sigma, f, \omega > 0$ and the function g is piecewise linear and is defined as:

$$g(x) = \begin{cases} bx - a + b, & \text{if } x \leq -1 \\ ax, & \text{if } |x| < 1 \\ bx + a - b, & \text{if } x \geq 1 \end{cases}$$

The parameter values considered for the numerical simulations are: $\sigma = 1.015$, $\omega = 0.55$, $a = -1.02$ and $b = -0.58$.

In the absence of the forcing term (i.e. $f = 0$), system (3) is autonomous and has three equilibrium states: $E_0 = (0,0)$ and $E_\pm = \left(\pm\frac{\sigma(a-b)}{1+\sigma b}, \pm\frac{b-a}{1+\sigma b}\right)$. However, when $f > 0$, the system (3) is non-autonomous and a series of period-doubling bifurcations leading to onset of chaotic behavior has been reported [11] when f is increased from 0 to 0.2, considering the fractional orders $\alpha_1 = \alpha_2 = 0.9$.

Using the HPC implementation of the parallel algorithm described in section 3, we are able to depict the dynamic behavior of system (3) with an improved precision compared to [11], using a small step size and computing the numerical solution over a large time

interval. Figure 4 shows the attractors of (3), for different values of the parameter f. For $f = 0.085$, the existence of two quasi-periodic attractors is observed and the period-doubling cascade actually involves both attractors, eventually leading to the appearance of two chaotic attractors (e.g. for $f = 0.117$). When the value of f is increased, these chaotic attractors collide and a double-scroll attractor takes their place (e.g. for $f = 0.125$). As we further increase f, a sequence of period-doubling bifurcations and reversed period-doubling bifurcations is observed, involving the single attractor of the system.

6 Conclusion and future work

Although the simulation execution times show good results, there is still room for improvement. A similar algorithm was implemented to run on PC using MPI or/and OpenMP which has similar results [13, 14]. Our next direction of research is having the software exploit the Blue Gene/P hardware in order to increase the performance.

This algorithm that implements the Adams-Bashforth-Moulton method is valid for solving any kind of fractional-order system with fractional derivatives of Caputo-type, hence, having the algorithm run with parameters and functions as input and execute the simulation as a black box would be nice to have.

As another direction for future research, the applicability of the Parareal algorithm (which has been initially developed to parallelize in time partial differential equations) to fractional-order differential equations, is also worth exploring.

Abstract

Record linkage is a widely used technique to aggregate data stored in disparate sources that presumably pertain to the same real world entity. This should be done probabilistically if there are no common key attributes in all data sources involved. This approach is very time consuming if we consider the amount of data that must be compared, specifically in big data scenarios. In this manuscript, we propose a methodology for exploiting multicore and multi-GPU architectures to probabilistic link large-scale, national administrative data sources of more than 100 million participants from the Brazilian Public Health System.

Key words: Record Linkage, Performance, Multicore, Multi-GPU

ISBN: 978-84-617-8694-7

1 Introduction

The task of linking multiple, disparate database records representing data from the same real world entity is known as *record linkage* [1, 3], being a technique widely used in biomedical and health research, finance, government and other domains. Specifically in Health research, data stored in disparate information systems need to be combined for diverse purposes including aggregation of medical and hospital services, assessment of public health policies, surveillance and monitoring. This is often a challenging task as data quality, complexity and size dramatically differs among the data sources.

There are two main approaches for record linkage: deterministic and probabilistic. Deterministic linkage uses a combination of one or more unique identifying attributes that are common across the data sources to link records, whereas probabilistic linkage is used when these common attributes are absent. In order to improve their accuracy on matching decisions, probabilistic methods must perform a huge number of comparisons, being characterized as complex and highly time-consuming tasks.

Our research involves the probabilistic linkage of several large governmental databases with socioeconomic and health care data from the Brazilian Public Health System. These databases are linked in order to create accurate "data marts" used for epidemiological studies. Specifically, these studies are part of three ongoing Brazil-UK scientific collaborations: 1) *the 100 million cohort project*, in which the effects of a conditional cash transfer programme on health outcomes (e.g. leprosy, tuberculosis, HIV) from 114 million people are investigated; 2) a *long-term surveillance platform for Zika and microcephaly*, a longitudinal study (2001 to 2015) of children diagnosed with microcephaly and other Zika-related illnesses; and 3) a *platform linking data from Malaria transmission, patient care and monitoring* to provide support for analytical methods targeting the elimination of the disease.

Besides the absence of common key attributes, other important issues related to heterogeneity and privacy arise from the sensitive nature of the data stored in health databases. Methods for data harmonization and anonymization must be applied prior to the record linkage step affecting, in turn, the execution time.

Another technical aspect relates to blocking construction: depending on the hardware capabilities, one must group the records into blocks with some similarity criterion, usually the values of a given set of attributes, to avoid unnecessary comparisons. It can affect accuracy if records that must pertain to similar blocks are not correctly grouped.

Given the complexity involved in implementing probabilistic record linkage methods targeted to huge databases, novel algorithmic approaches to fully exploit the processing power of mutliple resources are required. Hybrid parallel architectures can be considered as a viable approach, even introducing challenges to algorithm design and system software.

Our proposal is to balance the workload across all available CPUs and GPUs present in heterogeneous systems to perform the necessary data operations in a timely and accurate manner. We deal with optimal workload distribution for hybrid systems [5], efficient grid

configurations on GPUs, analysis of data transfers, among other hardware specific issues.

2 Experimental Results

Our execution environment comprises 4 Intel Xeon at 2.93 GHz and 130 GB DDR3 main memory. Each one is a quadcore processor with 24 MB of cache memory. It contains two NVIDIA Tesla K40 GPUs. The installed CUDA toolkit is version 4.0.

In our experiments we used a parallel algorithm for the probabilistic linkage model that uses OpenMP [4] and CUDA. Many parameter values were used at installation time to estimate the best values for system parameters. The available range for CPU cores (c) is 1, 2, ..., 32 (Intel Hyper-Threading [2] is set). We checked for GPUs workloads (w) from 10% to 45%. The input sizes of the problem and the number of records (s) for the experiments were $1,000,000$, $2,000,000$, ..., $20,000,000$. The workload distribution used used is (w) = (GPU, GPU, CPU) = (35%, 35%, 30%).

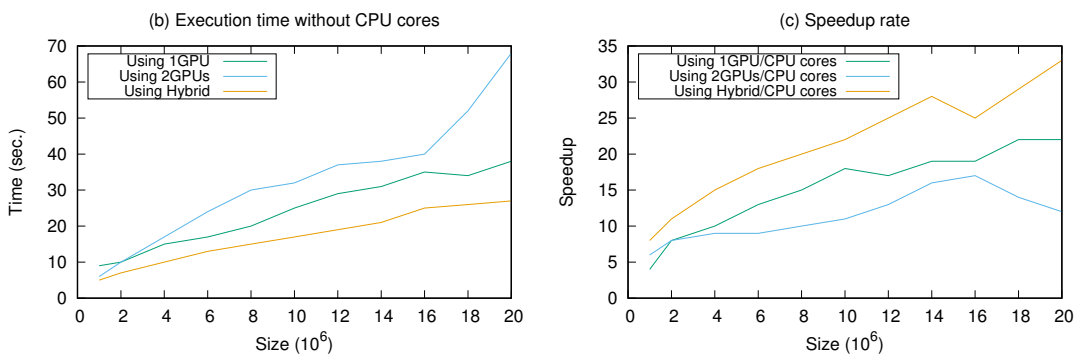

Figure 1: Execution of the parallel probabilistic linkage algorithm. (a) Execution time. (b) Speedup rate.

The execution time with multiple threads is denoted by "CPU cores". It distributes the calculation data mart among the threads and each thread runs exclusively on a CPU core. Versions denoted by "1GPU" and "2GPUs" represent executions in one single and two devices, respectively. The heterogeneous model ("Hybrid") uses all cores available in the heterogeneous system. In this model, the threads are executed by all the elements in the machine with the suitable number of CPU cores and the two GPUs. The results show that the parallel CPU algorithm reduces the execution time significantly.

We show in Fig. 1(a) and Fig. 1(b), the execution time and the speedup, respectively, for the probabilistic linkage algorithms with different sizes ranging from $1,000,000$ to $20,000,000$. The execution was carried out on each subsystem independently (1GPU, 2GPUs and Hybrid) to have a measure for comparison purposes.

 ISBN: 978-84-617-8694-7

Speedup has been obtained with regard to the use of the CPU cores subsystem only. As can be seen in Figure 1(b), the maximum speedup is around 30 with the hybrid subsystem, presenting a difference in performance that can more clearly be observed. Both plots show how the use of GPUs in our system clearly outperforms the computation on the CPU cores. The performance of 1GPU is larger than the performance with 2GPUs (size (s) $<= 20,000,000$). In this case, this is due to the setup time needed for device selection, which is high in our target machine and is not necessary if just one GPU is used. The use of GPU as a standalone tool provides benefits but does not allow to reach the potential performance that could be obtained by adding more GPUs and/or the CPU subsystem.

3 Conclusions and Future Directions

We aim to extend these experiments by exploring multi-GPU with hybrid environments, enjoying the great field of open problems we are dealing with. The parallel algorithm developed enables an efficient computation of the integral that appears in probabilistic record linkage method. Based on this preliminary work and pursuing the challenge of develop more sophisticated solutions, we aim to scale the proposed work to larger databases with more than 100 million records. We claim this proposal is high valuable as it contributes to solve current computational problems related to record linkage of large Brazilian governmental datasets, representing a substantial benefit for public health. Finally, more experiments in systems with larger numbers of cores of different architectures (i.e., multicore + multi-GPU + multi-MIC) and with other linear algebra routines are needed. To achieve this, an adaptation of a technique based on theoretical models should be analyzed.

Modeling CA15-3 longitudinal progression in patients with breast cancer recurrence

Ana Borges[1]

[1] *CIICESI/ESTG, Porto Polytechnic*

[2] *CMAT, DMA-ECUM, University of Minho*

[3] *Senology Unit, Braga's Hospital*

emails: aib@estg.ipp.pt

Abstract

We analyse the progression in time of a tumour marker used on the surveillance of this disease - the Carcinoma Antigen 15-3 (CA15-3) for Braga's Hospital senology unit patients, located in Portugal. Our main purpose is to describe the progression of this tumour marker, for the subset of patients that suffer a recurrence, as a function of possible risk factors. Also, to understand how these risk factors influences that progression. We intend, as well, to detect a possible changing point in the mean progression, that could be used by clinicians as an early detection of the recurrence. The response variable, values of CA15-3, was analysed making use of longitudinal models, testing for different correlation structures. The reference time considered was time from breast cancer recurrence diagnose until blood test data. For diagnostic of the models fitted we have used empirical and theoretical variograms. To evaluate the fixed term of the longitudinal model we have tested for a changing point on the effect of time on the tumour marker progression. Results show that, one year before the detection of breast cancer recurrence there is an abrupt rise on the rate of its progression. The presence of venous vascular invasion of the tumour affects the progression of CA15-3 values, for the subset of patients with breast cancer recurrence.

Key words: Longitudinal models, Breast Cancer, Recurrence, random effects, correlation structure, CA15-3

1 Introduction

As [1] report, breast cancer is the second most common cancer in the world and the most frequent cancer among women. They estimated that 1.67 million new cancer cases were diagnosed in 2012 (25% of all cancers). It is, actually, the most common cancer in women both in more and less developed regions with slightly more cases in less developed (883 000 cases) than in more developed (794 000 cases) regions.

Data were collected directly from the medical records of each patient, listed in the computer system of Braga's Hospital Glintt HS. We therefore have access to baseline and clinical history of each patient (a roll of information such as diagnosis; pre-surgery, post-surgery, group meetings; follow-up and medical exams). The authorization for collect and use of senology data was approved by the Ethical Committee of Braga's Hospital.

We gathered information on all patients diagnosed with breast cancer from 2008 until 2012, in Braga's Hospital, and for all the patients in follow-up at the hospital at the date of 1st January 2008.

Braga's Hospital is situated in the east of the city of Braga, located in northern Portugal. Today it serves a direct area of about 275,000 patients. In 2008, a Senology unit at the Braga's Hospital was created. Currently, it operates an average of 130 new cases of breast cancer per year.

We collected information on 540 patients. The total number of deaths is 74, however the total number of deaths from breast cancer is only 55. Throughout the followup time it was detected a recurrence of breast cancer (local and/or distant) on 81 patients. Of these, 52 died from breast cancer.

From the information gathered in all the medical reports, we were able to collect more than 50 variables that group information at patient level (such as age at diagnosis, residence location, number of births, etc.) and at tumour level (stage, tumour size, estrogen receptor expression, etc.), including measurements of CA15-3 tumour marker values and the date when that measurement was registered.

As [7] explain, Carcinoma Antigen 15-3 (CA15-3) is the most widely used serum marker in breast cancer. It consists in a large transmembrane glycoprotein which is frequently over-expressed and aberrantly glycosylated in cancer. Currently the main uses of CA15-3 are in preclinically detecting recurrent breast cancer and monitoring the treatment of patients with advanced breast cancer, although its clinical value is not validated in a high-level evidence study, as pointed out by the American Society of Clinical Oncology. Nevertheless, as

 ISBN: 978-84-608-6082-2

[8] point out, there are several well-designed studies that show that an increase in CA15-3 after primary and/or adjuvant therapy, can predict recurrence an average of 5 to 6 months before other symptoms or tests.

We only have information on tumour marker CA15-3 values for 534 patients. This translates into a total number of 552 cases analysed, since 18 cases presented bilateral breast cancer. The total number of deaths from breast cancer is 55. There were 5166 measurements of tumour marker CA15-3, with a number of observations per patient varying between 1 and 48 measurements. Being 8 the median number of measurements per person.

Since it is a usual medical procedure to be alert for possible tumor recurrence in the case of detecting a rise in levels of this marker above a certain reference value, our main purpose is to describe the progression of this tumor marker, on patients who were followed and treated in this Unit, that presented a breast cancer recurrence, as a function of possible risk factors. We intend to estimate on average the time to the increase of this tumor marker, as so to characterize the degree of heterogeneity between patients.

In this particular study, the response variable, values of CA15-3 tumour marker, was analysed making use of longitudinal models as defined in [9], where different correlation structures were tested. Also, to evaluate the fixed term of the longitudinal model we have tested for a changing point on the effect of time on the tumour marker progression for the subset of patients that died from breast cancer, and for the subset of patients that presented a breast cancer recurrence.

The analysis presented is an extension of the work published by [10]. Firstly it will be presented the methodology applied, introduced by a summary explanation of the main approaches to analyze longitudinal data, describing the longitudinal models used to infer about the factors that affect the progression of CA15-3 tumour marker values. Subsequently, the main results from the longitudinal analysis of this response will be demonstrated ending with a conclusion section.

The entire analysis was performed using R software, in particular making use of both *nlme* [11] and *JoineR* [12] packages.

2 Methodology

The general longitudinal model described as in [9] is:

$$Y_{ij} = \mu_{ij} + \mathbf{d}_{ij}^{'}\mathbf{U}_i + W_i(t_{ij}) + Z_{ij}. \quad (1)$$

 ISBN: 978-84-608-6082-2

Where $\mathbf{U}_i$ are n i.i.d. realizations of $MVN(0, \nu^2)$, representing the random effects at individual level, and $\mathbf{d}_{ij}^{'}$ is a vector of covariates for the random effects. $W_i(t_{ij})$ is a continuous time Gaussian Process with $E[W_i(t_{ij})] = 0$ and $E[W_i(t_{ij})] = \sigma^2$, representing the variability within subjects, where the correlation between two measurements of an individual is described by: $corr(W_i(t_{ij}), W_i(t_{ik})) = \rho(t_{ij}, t_{ik})$.
Finally, Z_{ij} are N i.i.d. realizations of $N(0, \tau^2)$, representing the measurement error (variability non specified).

Since $W_i(t_{ij})$ is assumed a stationary process we have $\rho(t_{ij}, t_{ik}) = \rho(|t_{ij} - t_{ik}|)$.

We can have different definitions for the function $\rho(|t_{ij} - t_{ik}|)$. That is, if we consider the correlation among $W_i(t_{ij})$, let say between $W_i(t)$ and $W_i(t-u)$, determined by the autocorrelation function $\rho(u)$, we will have for a longitudinal model that accounts for an exponential correlation structure within individuals:

$$\rho(u) = \exp\left(-\frac{1}{\phi}|u|\right), \tag{2}$$

and for a longitudinal model that accounts for a Gaussian correlation structure within individuals:

$$\rho(u) = \exp\left(-\frac{1}{\phi}u^2\right), \tag{3}$$

where ϕ is the range parameter that specifies the rate at which the correlation stables.

To model the fixed term of the longitudinal model, μ_{ij}, we can consider a model with a changing point δ on the effect of time on the response variable. In practice, the changing point is the moment where there is an alteration on the slope of the linear response variable's progression, on average. Considering δ the changing point, we have $E[Y_{ij}] = \mu_{ij}$ with:

$$\mu_{ij} = \begin{cases} X_{ij}\beta + \alpha_1 t_{ij}, & \text{if } t_{ij} < \delta \\ X_{ij}\beta + \alpha_2(t_{ij} - \delta) & \text{if } t_{ij} \geq \delta \end{cases}, \tag{4}$$

where X_{ij} represents the vector of covariates, β the vector of unknown regression coefficients, α_1 and α_2 the coefficients representing the slope before and after the changing point, respectively.

For simplicity, let's consider the complete set of N measurements, y, as a realization of a multivariate Gaussian random vector Y with $Y \sim MVN(X\beta, \eta^2 V)$. Where $\mathbf{X}$ is an $N \times p$ matrix of all values of the p explanatory variables. And $\eta^2 V$ as a block-diagonal matrix with non-zero $n \times n$ blocks $\eta^2 V_0$, each representing the variance matrix for the vector of measurements on a single subjects.

 ISBN: 978-84-608-6082-2

For parameter estimation we adopted the maximum likelihood method, Since we are dealing with unbalance type of data and, also, the missing data detected in our data base does not seem to be related to the progression of the disease, we consider the completely random mechanism of missing data. Which can be ignorable when adopting the likelihood function as the basis for inference [13].

To model the correlation structure for each model we analysed the empirical variogram of OLS residuals from the saturated model for the mean response [9].

The variogram [9] of a stochastic process $Y(t)$ is given by:

$$V(u) = \frac{1}{2}\text{Var}\left\{Y(t) - Y(t-u)\right\},\ u \geq 0. \tag{5}$$

For a stationary process, the autocorrelation function, $\rho(u)$, and the variance of $Y(t)$, σ^2, are related by:

$$\gamma(u) = \sigma^2\{1 - \rho(u)\}. \tag{6}$$

The estimation of the empirical variogram is based on the calculation of the observed half-squared-differences between pair of residuals, $\nu_{ij} = \frac{1}{2}(r_{ij} - r_{ik})^2$, and the corresponding time-differences, $u_{ijk} = t_{ij}t_{ik}$, where $r_{ij} = Y_{ij}\mu_{ij}$, and $j < k = 1, ..., m_i$.

The autocorrelation function at any lag u is estimated from the sample variogram by:

$$\hat{\rho}(u) = 1 - \frac{\hat{\gamma}(u)}{\hat{\sigma}^2}, \tag{7}$$

where $\hat{\gamma}(u)$ is the average of all the ν_{ij} corresponding to that particular value of u, and $\hat{\sigma}^2$ is the estimated process variance.

Diagnostic checking of the longitudinal fitted model can be made by superimposing the fitted mean response profiles on a time-plot of the average observed response within each combination of covariates categories and time, as suggested by [9]. However, this task can be rather difficult if we are dealing with a model that incorporates a great number of covariates. One other form of model fitting diagnose is to superimpose the fitted variogram on a plot of the empirical variogram. Which will allow the validation of the correlation structure by graphical comparison. Another procedure to additionally access which correlation structure best describe data variability, within a longitudinal model, with a predetermined fixed part, is by comparison of the maximized log likelihood values.

Plot of the subject specific residuals versus the fitted responses and a Q-Q plot of the subject-specific residuals can, also, be used for graphical validation of the assumptions of the constant variance and normal distribution of Z_{ij}, respectively.

2.1 Main Results

According to the usual medical procedures, physicians stay alert to a possible recurrence of breast cancer for patients that present values of tumour markers above a certain reference value. We have considered the reference value of 37 U/ml for CA15-3 tumour marker, as this were the values referred in the blood tests analysed.

The normality assumption of both response variables CA15-3 was first tested preforming a Shapiro-Wilk normality test, which returned p-value < 0.0001 and therefore was rejected. It was used a log-transformation of the tumor marker CA15-3 as It is a usual transformation in many biological cancer markers studies.

A longitudinal model was fitted to the subset of patients that presented a breast cancer recurrence. We considered the reference time, in month, from date of recurrence diagnose until blood tests. Note that, doing so, reference time will be on a negative scale. We began with an exploratory analysis and point estimation by modelling a OLS model with all the variables. We then conducted a backward elimination to delete variables not significant, with a limit of 0.08 for the p-value, for inclusion of the variable, until the mean structure was well defined with only significant covariates.

Observing graphical representation of the empirical variogram, patterns suggested the existence of variability between subjects, and a possible variability within subjects. Hence, maintaining the same mean structure we compared two nested models with different covariance structures, such as: (i) random effects, exponential serial correlation and measurement error (REE), and (ii) random effects, Gaussian serial correlation and measurement error (REG).

Figure 1 presents the progression in time, since date of breast cancer recurrence detection, of the CA15-3 values for each patient, with grey lines, against the reference value, and the non-parametric smooth spline line with dash line, indicating the average trend of progression.

The smooth spline of the spaghetti plot suggests that, on average, the marker progression increases at a slow rate until about 20 months before death from breast cancer. In fact, when fitting the saturated general linear model for the subset of patients who died from breast cancer, given by equation 4, we detected a changing point at 1 years before recurrence. Which means that, for the patients which was detected breast cancer recurrence it was detected an abrupt rise of CA15-3 values, above the reference value, 1 years before the detection.

 ISBN: 978-84-608-6082-2

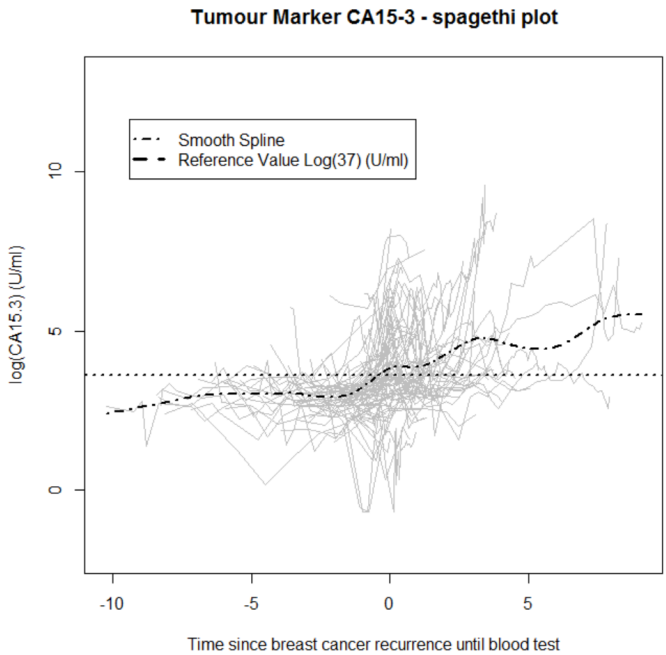

Figure 1: Spaghetti plot for tumor marker CA15-3 values - for the subset of patients with breast cancer recurrence.

Table 1 summarizes and compares the estimated parameters for the two longitudinal models fitted REE and REG - with those of the general linear model (OLS Model). Note that the variable "Time further than 1 year before recurrence" is, in fact, time before the changing point (2 years before death from breast cancer), in the negative scale considered and, equivalently, "Time earlier than 1 year before recurrence" is time after the changing point, in the negative scale considered.

We selected the REE longitudinal model to describe the progression of the tumour marker CA15-3 values in time, since it was the one with higher Log likelihood value.

Results show that time after the changing point, that is before one year prior to the detection of the breast cancer recurrence, has a significant effect (p-value < 0.001) on the mean progression of the tumour marker values, related to an increase of 0.394 per month of the CA15-3 values. However, before changing point the effect of time is not significant (p-value=0.9235) in the mean progression of the tumour marker values.

 ISBN: 978-84-608-6082-2

Table 1: Estimated Parameters Values for General Linear Model and Longitudinal Models For Patients with Breast Cancer Recurrence – CA15-3 Tumour Marker

	REE Model		**REG Model**		**OLS Model**	
	Est	**p-value**	**Est**	**p-value**	**Est**	**p-value**
Intercept	3.110	< 0.001	3.0978098	< 0.001	3.31230	< 0.001
Time further than 1 year before recurrence	0.0055292	0.9235	0.0225484	0.5870	0.07992	0.0168
Time earlier than 1 years before recurrence)	0.3942085	< 0.001	0.3571825	< 0.001	0.31785	< 0.001
Venous Vascular Invasion (Yes)	1.2193974	< 0.001	1.3166430	< 0.001	1.28602	< 0.001
ν^2	0.00000042		0.525		.	
σ^2	0.002		0.091		.	
ϕ	19.958		7.451		.	
τ^2	1.425		0.772		.	
ξ^2	.		.		1.428	
Log Likelihood	-502.163		-523.639		-724.714	

For the subset of patients that presented a breast cancer recurrence, the mean progression of the marker is only composed by one significant covariate on the intercept component of the model - the presence of images of venous vascular invasion (yes versus no). The intercept component of the model, in this particular case, means that a patient with no venous vascular invasion images and a triple negative type of tumour will start the progression of the tumor marker with a value of 3.11, on a logarithmic scale.

As expected, the presence of venous vascular invasion has an increasing effect on the average CA15-3 linear progression in time, as it is related to a worst prognostic case in the previous survival analysis. A case with venous vascular invasion an increment of 1.22 compared to those with no venous vascular invasion.

For this subset, the correlation structure that best represent the variability of the data is the structure that incorporates random effects at individual level with $\hat{\nu}^2 \approx 3 \times 10^{-8}$, an exponential correlation structure to describe the variability within patients with $\hat{\rho}(u) \approx \exp(-\frac{1}{23.247}.|u|)$ and $\hat{\sigma}^2 \approx 0.040$, and a measurement error with variance $\hat{\tau}^2 \approx 1.826$. The superposition of the theoretical variogram of both exponential and exponential correlation structures with the empirical variogram, presented in Figure 2, validates the choice of an exponential correlation structure, since it is the one that best approximates the empirical

 ISBN: 978-84-608-6082-2

variogram curve.

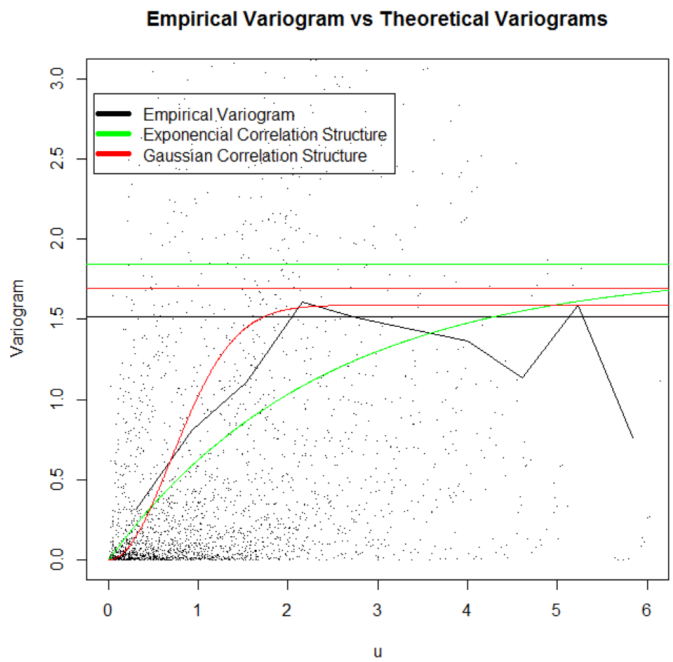

Figure 2: Superposition of empirial variogram and theoretical variograms, for patients with breast cancer recurrence - CA15-3 tumour marker.

2.2 Conclusion

An abrupt rise in values of CA15-3 tumor marker, over a reference value, is an alert sign to a possible recurrence of breast cancer.
When analyzing all patients that were diagnosed with breast cancer, it was detected a changing point on the linear progression of the tumor marker for the subset of patients that died from breast cancer two years before the death. This means that, at that point, there is an abrupt rise on the rate of its progression.
The risk factors for the progression of the marker, for that subset of patients are: bilateral (yes versus no), images of venous vascular invasion (yes versus no) and estrogen receptor expression(positive versus negative). However, for the subset of patients that suffered a breast cancer recurrence it was detected a changing point on the linear progression of the tumour marker one year prior to the detection of the recurrence. And the only covariate with significant effect on the progression was the images of venous vascular invasion. This

 ISBN: 978-84-608-6082-2

is an important result, as it can be used as an alert to a possible state of breast cancer recurrence if the doctor detects an abrupt increase of the tumour marker progression of this nature.
For both models fitted, the fact that the estimated variance of the measurement error is quite lower that the estimated variance of the OLS model means that the fitted REE longitudinal model explains the variability of the data mainly by means of variability between patients and within patients assigning a very low value for measurement error (or *white noise* as usually mentioned in literature).
The fact that, when comparing the REE and the REG models to a longitudinal model with only an intercept random effect, the component the serial correlation was significant stresses the importance incorporating a variability component that translates within subject measurements correlation, in this type of biological data.
The presented longitudinal analysis of this tumor marker, in combination with the previous survival analysis, where the event of interest is breast cancer recurrence, is going to be proceeded, in future work, with a joint modeling of the longitudinal and survival process of the present data.

Abstract

When expressing a distribution in Euclidean space in spherical co-ordinates, derivation with respect to the radial and angular co–ordinates is far from trivial. Exploring the possibilities of defining a radial derivative of the delta distribution $\delta(\underline{x})$ (the angular derivatives of $\delta(\underline{x})$ being zero since the delta distribution is itself radial) led, see [2], to the introduction of a new kind of distributions, the so–called *signumdistributions*, as continuous linear functionals on a space of test functions showing a singularity at the origin. In this paper we search for a definition of the radial and angular derivatives of a general standard distribution and again, as expected, we are inevitably led to consider signumdistributions. Although these signumdistributions provide an adequate framework for the actions on distributions aimed at, it turns out that the derivation with respect to the radial distance of a general (signum)distribution is still not yet unambiguous.

Key words: distribution, radial derivative, angular derivative, signumdistribution
MSC 2000: 46F05, 46F10, 30G35

1 Introduction

Let us consider a scalar–valued distribution $T(\underline{x}) \in \mathcal{D}'(\mathbb{R}^m)$ expressed in terms of spherical co–ordinates: $\underline{x} = r\underline{\omega}$, $r = |\underline{x}|$, $\underline{\omega} = \sum_{j=1}^{m} e_j\,\omega_j \in \mathbb{S}^{m-1}$, $(e_j)_{j=1}^{m}$ being an orthonormal basis of $\mathbb{R}^m$ and $\mathbb{S}^{m-1}$ being the unit sphere in $\mathbb{R}^m$. The aim of this paper is to search for

ISBN: 978-84-617-8694-7

an adequate definition of the radial and angular derivatives $\partial_r T$ and $\partial_{\omega_j} T$, $j = 1, \ldots, m$. This problem was treated in [2] for the special and interesting case of the delta distribution $\delta(\underline{x})$, the following spherical co–ordinates expression of which is often encountered in physics texts:

$$\delta(\underline{x}) = \frac{1}{a_m} \frac{\delta(r)}{r^{m-1}} \tag{1}$$

where $a_m = \frac{2\pi^{\frac{m}{2}}}{\Gamma(\frac{m}{2})}$ is the area of the unit sphere $\mathbb{S}^{m-1}$ in $\mathbb{R}^m$ and $\delta(r)$ is the one–dimensional delta distribution on the real r–axis. Apparently expression (1) can mathematically be explained in the following way. Write the action of the delta distribution as an integral:

$$\begin{aligned} \varphi(0) = \langle\, \delta(\underline{x}), \varphi(\underline{x}) \,\rangle &= \int_{\mathbb{R}^m} \delta(\underline{x})\, \varphi(\underline{x})\, dV(\underline{x}) \\ &= \int_0^\infty r^{m-1} \delta(\underline{x})\, dr \int_{\mathbb{S}^{m-1}} \varphi(r\,\underline{\omega})\, dS_{\underline{\omega}} \\ &= a_m \int_0^\infty r^{m-1}\, \delta(\underline{x})\, \Sigma^0[\varphi](r)\, dr \end{aligned}$$

introducing the so–called *spherical mean* of the test function φ given by

$$\Sigma^0[\varphi](r) = \frac{1}{a_m} \int_{\mathbb{S}^{m-1}} \varphi(r\,\underline{\omega})\, dS_{\underline{\omega}}$$

As it is easily seen that $\Sigma^0[\varphi](0) = \varphi(0)$ it follows that

$$a_m \int_0^\infty r^{m-1}\, \delta(\underline{x})\, \Sigma^0[\varphi](r)\, dr = \int_0^\infty \delta(r)\, \Sigma^0[\varphi](r)\, dr = \langle\, \delta(r), \Sigma^0[\varphi](r) \,\rangle$$

which explains (1). However we prefer to interpret expression (1) mathematically as

$$\varphi(0) = \langle\, \delta(\underline{x}), \varphi(\underline{x}) \,\rangle = \langle\, \delta(r), \Sigma^0[\varphi](r) \,\rangle = \Sigma^0[\varphi](0) \tag{2}$$

Straightforward successive derivation with respect to r of (1) leads to

$$\partial_r^{2\ell}\, \delta(\underline{x}) = \frac{1}{(2\ell)!}(m)(m+1)\cdots(m+2\ell-1)\, \frac{1}{a_m}\, \frac{\delta^{(2\ell)}(r)}{r^{m-1}} \tag{3}$$

$$\partial_r^{2\ell+1}\, \delta(\underline{x}) = \frac{1}{(2\ell+1)!}(m)(m+1)\cdots(m+2\ell)\, \frac{1}{a_m}\, \frac{\delta^{(2\ell+1)}(r)}{r^{m-1}} \tag{4}$$

Expression (3) then is interpreted as

$$\langle\, \partial_r^{2\ell}\, \delta(\underline{x}), \varphi(\underline{x}) \,\rangle = \frac{1}{(2\ell)!}(m)(m+1)\cdots(m+2\ell-1)\, \langle\, \delta^{(2\ell)}(r), \Sigma^0[\varphi](r) \,\rangle$$

which is meaningful and can serve as the definition of the even order derivatives with respect to r of the delta distribution $\delta(\underline{x})$ in $\mathbb{R}^m$. However expression (4) makes no sense at all since

 ISBN: 978-84-617-8694-7

the spherical mean $\Sigma^0[\varphi](r)$ is an even function of r, whose odd order derivatives vanish at the origin:

$$\langle\ -\partial_r^{2\ell+1}\,\delta(r), \Sigma^0[\varphi](r)\ \rangle = \{\partial_r^{2\ell+1}\,\Sigma^0[\varphi](r)\}|_{r=0} = 0$$

How to explain the fact that, proceeding by stepwise derivation with respect to r, the even order derivatives of $\delta(\underline{x})$ apparently make sense, while its odd order derivatives are zero distributions? Let us to that end have a quick look at the functional analytic background of this phenomenon; for a more systematic treatment we refer to [2].

When expressing a scalar–valued test function $\varphi(\underline{x}) \in \mathcal{D}(\mathbb{R}^m)$ in spherical co–ordinates, one obtains a function $\widetilde{\varphi}(r,\underline{\omega}) = \varphi(r\underline{\omega}) \in \mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$, but it is clear that not all functions $\widetilde{\varphi}(r,\underline{\omega}) \in \mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$ stem from a test function in $\mathcal{D}(\mathbb{R}^m)$. However a one–to–one correspondence may be established between the usual space of test functions $\mathcal{D}(\mathbb{R}^m)$ and a specific subspace of $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$, which is the contents of the following lemma.

Lemma 1. *(see [4]) There is a one–to–one correspondence $\varphi(\underline{x}) \leftrightarrow \widetilde{\varphi}(r,\underline{\omega}) = \varphi(r\underline{\omega})$ between the spaces $\mathcal{D}(\mathbb{R}^m)$ and $\mathcal{V} = \{\phi(r,\underline{\omega}) \in \mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1}) : \phi$ is even, i.e. $\phi(-r,-\underline{\omega}) = \phi(r,\underline{\omega})$, and $\{\partial_r^n\,\phi(r,\underline{\omega})\}|_{r=0}$ is a homogeneous polynomial of degree n in $(\omega_1,\ldots,\omega_m), \forall n \in \mathbb{N}\}$.*

Clearly $\mathcal{V}$ is a closed (but not dense) subspace of $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$ and even of $\mathcal{D}_E(\mathbb{R}\times\mathbb{S}^{m-1})$, where the subscript E refers to the even character of the test functions in that space; this space $\mathcal{V}$ is endowed with the induced topology of $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$. The one–to–one correspondence between the spaces of test functions $\mathcal{D}(\mathbb{R}^m)$ and $\mathcal{V}$ translates into a one–to–one correspondence between the standard distributions $T \in \mathcal{D}'(\mathbb{R}^m)$ and the bounded linear functionals in $\mathcal{V}'$; this correspondence is given by

$$\langle\ T(\underline{x}), \varphi(\underline{x})\ \rangle = \langle\ \widetilde{T}(r,\underline{\omega}), \widetilde{\varphi}(r,\underline{\omega})\ \rangle$$

By Hahn–Banach's theorem the bounded linear functional $\widetilde{T}(r,\underline{\omega}) \in \mathcal{V}'$ may be extended to the distribution $\mathbb{T}(r,\underline{\omega}) \in \mathcal{D}'(\mathbb{R}\times\mathbb{S}^{m-1})$; such an extension is called a *spherical representation* of the distribution T (see e.g. [8]). However as the subspace $\mathcal{V}$ is not dense in $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$, the spherical representation of a distribution is *not unique*, but if $\mathbb{T}_1$ and $\mathbb{T}_2$ are two different spherical representations of the same distribution T, their restrictions to $\mathcal{V}$ coincide:

$$\langle\ \mathbb{T}_1(r,\underline{\omega}), \widetilde{\varphi}(r,\underline{\omega})\ \rangle = \langle\ \mathbb{T}_2(r,\underline{\omega}), \widetilde{\varphi}(r,\underline{\omega})\ \rangle = \langle\ \widetilde{T}(r,\underline{\omega}), \varphi(r\underline{\omega})\ \rangle = \langle\ T(\underline{x}), \varphi(\underline{x})\ \rangle$$

For test functions in $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$ the spherical variables r and $\underline{\omega}$ are ordinary variables, and thus smooth functions. It follows that for distributions in $\mathcal{D}'(\mathbb{R}\times\mathbb{S}^{m-1})$ multiplication by r and $\omega_j, j = 1,\ldots,m$, and differentiation with respect to r and $\omega_j, j = 1,\ldots,m$, are standard well–defined operations, whence

$$\langle\ \partial_r\,\mathbb{T}(r,\underline{\omega}), \Xi(r,\underline{\omega})\ \rangle = -\langle\ \mathbb{T}(r,\underline{\omega}), \partial_r\,\Xi(r,\underline{\omega})\ \rangle$$

 ISBN: 978-84-617-8694-7

for all test functions $\Xi(r,\underline{\omega}) \in \mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1})$, and similar expressions for $\partial_{\omega_j}\mathbb{T}$, $r\,\mathbb{T}$ and $\underline{\omega}\,\mathbb{T}$. However if $\mathbb{T}_1$ and $\mathbb{T}_2$ are two different spherical representations of the same distribution $T \in \mathcal{D}'(\mathbb{R}^m)$, then, upon restricting to test functions $\widetilde{\varphi}(r,\underline{\omega}) \in \mathcal{V}$, we are stuck with

$$-\langle\ \mathbb{T}_1(r,\underline{\omega}), \partial_r\,\widetilde{\varphi}(r,\underline{\omega})\ \rangle \neq -\langle\ \mathbb{T}_2(r,\underline{\omega}), \partial_r\,\widetilde{\varphi}(r,\underline{\omega})\ \rangle$$

because $\partial_r\,\widetilde{\varphi}(r,\underline{\omega})$ does no longer belong to $\mathcal{V}$ (and neither do $\partial_{\omega_j}\,\widetilde{\varphi}(r,\underline{\omega})$, $r\,\widetilde{\varphi}(r,\underline{\omega})$ and $\underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega})$) since it is an odd function in the variables $(r,\underline{\omega})$. The conclusion is that the concept of spherical representation of a distribution does *not* allow for an unambiguous definition of the actions proposed. At the same time it becomes clear why even order derivatives with respect to r of the delta distribution and of a standard distribution in general are well-defined instead. Indeed, we have e.g.

$$\langle\ \partial_r^{2\ell}\,\mathbb{T}(r,\underline{\omega}), \Xi(r,\underline{\omega})\ \rangle = \langle\ \mathbb{T}(r,\underline{\omega}), \partial_r^{2\ell}\,\Xi(r,\underline{\omega})\ \rangle$$

where now $\partial_r^{2\ell}\,\Xi(r,\underline{\omega})$ does belong to $\mathcal{D}_E(\mathbb{R}\times\mathbb{S}^{m-1})$ which enables restriction to test functions in $\mathcal{V}$ in an unambiguous way.

2 Signumdistributions

As already remarked in the preceding section, $\underline{\omega}$ is an ordinary (vector) variable in $\mathbb{R}\times\mathbb{S}^{m-1}$, whence it makes sense to consider the following subspace of vector–valued test functions in $\mathbb{R}\times\mathbb{S}^{m-1}$:

$$\mathcal{W} = \underline{\omega}\,\mathcal{V} \subset \mathcal{D}_O(\mathbb{R}\times\mathbb{S}^{m-1};\mathbb{R}^m) \subset \mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1};\mathbb{R}^m)$$

where now the subscript O refers to the odd character of the test functions under consideration, i.e. $\psi(-r,-\underline{\omega}) = -\,\psi(r,\underline{\omega}), \forall\psi \in \mathcal{D}_O(\mathbb{R}\times\mathbb{S}^{m-1};\mathbb{R}^m)$. This space $\mathcal{W}$ is endowed with the induced topology of $\mathcal{D}(\mathbb{R}\times\mathbb{S}^{m-1};\mathbb{R}^m)$. By definition there is a one–to–one correspondence between the spaces $\mathcal{V}$ and $\mathcal{W}$.

From now on we will interpret vectors in $\mathbb{R}^m$ as Clifford 1–vectors in the Clifford algebra $\mathbb{R}_{0,m}$, where the basis vectors $(e_j, j=1,\ldots,m)$ of $\mathbb{R}^m$, satisfy the relations $e_j^2 = -1$, $e_i \wedge e_j = e_i e_j = -e_j e_i = -e_j \wedge e_i$, $e_i \cdot e_j = 0, i \neq j = 1,\ldots,m$. This allows for the use of the efficient *geometric* or *Clifford product* of Clifford vectors:

$$\underline{x}\,\underline{y} = \underline{x}\cdot\underline{y} + \underline{x}\wedge\underline{y}$$

for which, in particular,

$$\underline{x}\,\underline{x} = \underline{x}\cdot\underline{x} = -\,|\underline{x}|^2$$

$\underline{x}$ being the Clifford 1–vector $\underline{x} = \sum_{j=1}^m e_j\,x_j$, whence

$$\underline{\omega}\,\underline{\omega} = \underline{\omega}\cdot\underline{\omega} = -\,|\underline{\omega}|^2 = -1$$

 ISBN: 978-84-617-8694-7

For more on Clifford algebras we refer to e.g. [5].

For each $\mathbb{U}(r,\underline{\omega}) \in \mathcal{D}'(\mathbb{R}\times\mathbb{S}^{m-1};\mathbb{R}^m)$ we define $\widetilde{U}(r,\underline{\omega}) \in \mathcal{W}'$ by the restriction

$$\langle\, \widetilde{U}(r,\underline{\omega}), \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega})\,\rangle = \langle\, \mathbb{U}(r,\underline{\omega}), \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega})\,\rangle, \quad \forall\, \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega}) \in \mathcal{W}$$

In $\mathbb{R}^m$ we consider the space $\Omega(\mathbb{R}^m) = \{\underline{\omega}\,\varphi(\underline{x}) : \varphi(\underline{x}) \in \mathcal{D}(\mathbb{R}^m)\}$. Clearly the functions in $\Omega(\mathbb{R}^m)$ are no longer differentiable in the whole of $\mathbb{R}^m$, since they are not defined at the origin due to the function $\underline{\omega} = \frac{\underline{x}}{|\underline{x}|}$. By definition there is a one–to–one correspondence between the spaces $\mathcal{D}(\mathbb{R}^m)$ and $\Omega(\mathbb{R}^m)$.
For each $\widetilde{U}(r,\underline{\omega}) \in \mathcal{W}'$ we define $U(\underline{x})$ by

$$\langle\, U(\underline{x}), \underline{\omega}\,\varphi(\underline{x})\,\rangle = \langle\, \widetilde{U}(r,\underline{\omega}), \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega}))\,\rangle, \quad \forall\, \underline{\omega}\,\varphi(\underline{x}) \in \Omega(\mathbb{R}^m)$$

Clearly $U(\underline{x})$ is a bounded linear functional on $\Omega(\mathbb{R}^m)$, which, in [2], we called a *signumdistribution*.

Now start with a standard distribution $T(\underline{x}) \in \mathcal{D}'(\mathbb{R}^m)$ and let $\mathbb{T}(r,\underline{\omega}) \in \mathcal{D}'(\mathbb{R}\times\mathbb{S}^{m-1})$ be one of its spherical representations. Put $\mathbb{S}(r,\underline{\omega}) = \underline{\omega}\,\mathbb{T}(r,\underline{\omega})$ which in its turn leads to the signumdistribution $S(\underline{x}) \in \Omega(\mathbb{R}^m)$. Then we consecutively have

$$\begin{aligned}\langle\, S(\underline{x}), \underline{\omega}\,\varphi(\underline{x})\,\rangle = \langle\, \mathbb{S}(r,\underline{\omega}), \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega})\,\rangle &= \langle\, \underline{\omega}\,\mathbb{T}(r,\underline{\omega}), \underline{\omega}\,\widetilde{\varphi}(r,\underline{\omega})\,\rangle \\ &= -\langle\, \mathbb{T}(r,\underline{\omega}), \widetilde{\varphi}(r,\underline{\omega})\,\rangle = -\langle\, T(\underline{x}), \varphi(\underline{x})\,\rangle\end{aligned}$$

since $\underline{\omega}^2 = -1$, and we call $S(\underline{x})$ a signumdistribution associated to the distribution $T(\underline{x})$ and denote it by $T^{\vee}(\underline{x})$. It thus holds that for all test functions $\varphi \in \mathcal{D}(\mathbb{R}^m)$

$$\langle\, T^{\vee}(\underline{x}), \underline{\omega}\,\varphi(\underline{x})\,\rangle = -\langle\, T(\underline{x}), \varphi(\underline{x})\,\rangle$$

It should be emphasized that for a given distribution $T(\underline{x})$ the associated signumdistribution $T^{\vee}(\underline{x})$ is not uniquely defined but instead depends on the spherical representation of $T(\underline{x})$ chosen.
Conversely for a given signumdistribution $U \in \Omega(\mathbb{R}^m)$ we define the associated distribution $U^{\wedge}$ by

$$\langle\, U^{\wedge}(\underline{x}), \varphi(\underline{x})\,\rangle = -\langle\, U(\underline{x}), \underline{\omega}\,\varphi(\underline{x})\,\rangle$$

Clearly it holds that

$$T^{\vee\wedge} = T \qquad \text{and} \qquad U^{\wedge\vee} = U$$

As an example consider the distribution $T(\underline{x}) = \delta(\underline{x})$. Our aim is to define the signumdistribution $\delta^{\vee}(\underline{x})$. A spherical representation of the delta distribution is given by

$$\langle\, \mathbb{T}(r,\omega), \Xi(r,\underline{\omega})\,\rangle = \Sigma^0[\Xi(r,\underline{\omega})]\}|_{r=0}$$

 ISBN: 978-84-617-8694-7

Indeed, when restricting to the space $\mathcal{V}$ and taking into account property (2), we obtain

$$\langle\ \mathbb{T}(r,\omega),\widetilde{\varphi}(r,\underline{\omega})\ \rangle = \Sigma^0[\varphi(r\,\underline{\omega})]\}|_{r=0} = \langle\ \delta(\underline{x}),\varphi(\underline{x})\ \rangle$$

This particular spherical representation of $T(\underline{x})$ induces a signumdistribution associated to $\delta(\underline{x})$, which we define to be $\delta^{\vee}(\underline{x})$. It thus holds that for all test functions $\varphi \in \mathcal{D}(\mathbb{R}^m)$

$$\langle\ \delta^{\vee}(\underline{x}),\underline{\omega}\,\varphi(\underline{x})\ \rangle = -\langle\ \delta(\underline{x}),\varphi(\underline{x})\ \rangle \tag{5}$$

For further examples we refer to [2].

3 The Dirac operator in spherical co–ordinates

The Dirac operator $\underline{\partial} = \sum_{j=1}^{m} e_j\,\partial_{x_j}$, which may be seen as a Stein–Weiss projection of the gradient operator (see e.g. [7]) and which underlies the higher dimensional theory of monogenic functions (see e.g. [3]), linearizes the Laplace operator: $\underline{\partial}^2 = -\Delta$. Its action on a scalar–valued standard distribution $T(\underline{x})$ results into the vector–valued distribution $\underline{\partial}\,T(\underline{x})$ given by

$$\langle\,\underline{\partial}\,T(\underline{x})\,,\varphi(\underline{x})\,\rangle = \sum_{j=1}^{m} e_j\,\langle\,\partial_{x_j}\,T(\underline{x})\,,\varphi(\underline{x})\,\rangle = -\sum_{j=1}^{m} e_j\,\langle\,T(\underline{x})\,,\partial_{x_j}\,\varphi(\underline{x})\,\rangle = -\,\langle\,T(\underline{x})\,,\underline{\partial}\,\varphi(\underline{x})\,\rangle$$

which is a meaningful operation since only derivatives with respect to the cartesian co–ordinates $x_1,\ldots,x_m$ are involved.
Two fundamental formulae in monogenic function theory are

$$\{\underline{x},\underline{\partial}\} = \underline{x}\,\underline{\partial} + \underline{\partial}\,\underline{x} = -\,2\mathbb{E} - m \qquad \text{and} \qquad [\underline{x},\underline{\partial}] = \underline{x}\,\underline{\partial} - \underline{\partial}\,\underline{x} = m - 2\Gamma$$

where $\mathbb{E} = \sum_{j=1}^{m} x_j\,\partial_{x_j}$ is the scalar Euler operator, and $\Gamma = \sum_{j<k} e_j e_k(x_j\partial x_k - x_k\partial_{x_j})$ is the bivector angular momentum operator. It follows that

$$\underline{x}\cdot\underline{\partial} = -\mathbb{E} \qquad \text{and} \qquad \underline{x}\wedge\underline{\partial} = -\Gamma$$

Passing to spherical co–ordinates $\underline{x} = r\underline{\omega}$, $r = |\underline{x}|$, $\underline{\omega} = \sum_{j=1}^{m} e_j\,\omega_j \in \mathbb{S}^{m-1}$, the Dirac operator takes the form

$$\underline{\partial} = \underline{\partial}_{rad} + \underline{\partial}_{ang}$$

with

$$\underline{\partial}_{rad} = \underline{\omega}\,\partial_r \qquad \text{and} \qquad \underline{\partial}_{ang} = \frac{1}{r}\,\partial_{\underline{\omega}}$$

To give an idea what the angular differential operator $\partial_{\underline{\omega}} = \sum_{j=1}^{m} e_j\,\partial_{\omega_j}$ looks like, we mention here its explicit form in dimension $m=2:\partial_{\underline{\omega}} = e_\theta\,\partial_\theta$ and in dimension $m=3:\partial_{\underline{\omega}} =$

 ISBN: 978-84-617-8694-7

$e_\theta\,\partial_\theta + e_\varphi\,\frac{1}{\sin\theta}\,\partial_\varphi$, the meaning of the angular coordinates θ and φ being straightforward.

Taking into account that $\partial_{\underline{\omega}}$ is orthogonal to $\underline{\omega}$, the Euler operator in spherical co–ordinates then reads:

$$\mathbb{E} = -\,\underline{x}\cdot\underline{\partial} = -\,r\underline{\omega}\cdot\underline{\partial}_{rad} = -\,r\underline{\omega}\cdot\underline{\omega}\,\partial_r = r\,\partial_r$$

while the angular momentum operator Γ takes the form

$$\Gamma = -\,\underline{x}\wedge\underline{\partial} = -\,r\underline{\omega}\wedge\underline{\partial}_{ang} = -\,r\underline{\omega}\wedge\frac{1}{r}\,\partial_{\underline{\omega}} = -\,\underline{\omega}\wedge\partial_{\underline{\omega}} = -\underline{\omega}\,\partial_{\underline{\omega}}$$

The question now is how to define, if possible, the action of the $\underline{\partial}_{rad}$ and $\underline{\partial}_{ang}$ operators on a standard distribution. To that end both operators should be expressed in terms of cartesian derivatives, which we achieve by putting

$$\underline{\partial}_{rad} = \underline{\omega}\,\partial_r = -\,\frac{1}{\underline{x}}\,\mathbb{E} \qquad \text{and} \qquad \underline{\partial}_{ang} = \frac{1}{r}\,\partial_{\underline{\omega}} = -\,\frac{1}{\underline{x}}\,\Gamma$$

It becomes clear at once that in this way the actions of $\underline{\partial}_{rad}$ and $\underline{\partial}_{ang}$ on a standard distribution $T(\underline{x})$ are not unambiguously defined. Indeed, due to the division by the analytic function $\underline{x}$, both expressions

$$\underline{\partial}_{rad}\,T(\underline{x}) = \underline{\omega}\,\partial_r\,T(r\underline{\omega}) = -\,\frac{1}{\underline{x}}\,\mathbb{E}\,[T(\underline{x})] \tag{6}$$

and

$$\underline{\partial}_{ang}\,T(\underline{x}) = \frac{1}{r}\,\partial_{\underline{\omega}}\,T(r\underline{\omega}) = -\,\frac{1}{\underline{x}}\,\Gamma\,[T(\underline{x})] \tag{7}$$

represent equivalent classes of distributions each two of which differ by a vector multiple of the delta distribution $\delta(\underline{x})$. But if $S_1 = \underline{\partial}_{rad}\,T(\underline{x})$ and $S_2 = \underline{\partial}_{ang}\,T(\underline{x})$ are distributions arbitrarily chosen in the equivalent classes $\underline{\omega}\,\partial_r\,T(r\underline{\omega}) = -\,\frac{1}{\underline{x}}\,\mathbb{E}\,[T(\underline{x})]$ and $\frac{1}{r}\,\partial_{\underline{\omega}}\,T(r\underline{\omega}) = -\,\frac{1}{\underline{x}}\,\Gamma\,[T(\underline{x})]$ respectively, i.e.

$$\underline{x}\,S_1 = -\,\mathbb{E}\,[T(\underline{x})] \qquad \text{and} \qquad \underline{x}\,S_2 = -\,\Gamma[T(\underline{x})]$$

this choice is not completely arbitrary since S_1 and S_2 always must satisfy the relation

$$S_1 + S_2 = \underline{\partial}_{rad}\,T(\underline{x}) + \underline{\partial}_{ang}\,T(\underline{x}) = \underline{\partial}\,T(\underline{x}) \tag{8}$$

One could say that the differential operators $\underline{\partial}_{rad}$ and $\underline{\partial}_{ang}$ are *entangled* in the sense that the results of their actions on a distribution are always subject to (8).
Let us give an simple example to illustrate this phenomenon. Consider the regular distribution $T(\underline{x}) = \underline{x}$; then $\underline{\partial}\,\underline{x} = -m$, $\mathbb{E}\,\underline{x} = \underline{x}$ and $\Gamma\,\underline{x} = (m-1)\,\underline{x}$, whence

$$\underline{\omega}\,\partial_r\,\underline{x} = -1 + \underline{c}_1\,\delta(\underline{x}) \qquad \text{and} \qquad \frac{1}{r}\,\partial_{\underline{\omega}}\,\underline{x} = 1 - m + \underline{c}_2\,\delta(\underline{x})$$

 ISBN: 978-84-617-8694-7

with the restriction that the vector constants $\underline{c}_1$ and $\underline{c}_2$ always should satisfy $\underline{c}_1 + \underline{c}_2 = 0$.

Apparently there seems to be no possibility to unambiguously define the actions of the $\underline{\partial}_{rad}$ and $\underline{\partial}_{ang}$ operators on a standard distribution by singling out specific distributions in the equivalent classes (6) and (7), except for the following two special cases.
If the distribution $T(\underline{x})$ is *radial*, i.e. only depends on $r = |\underline{x}|$, then we put $\frac{1}{r}\,\partial_{\underline{\omega}}\,T = 0$ and $\underline{\omega}\,\partial_r\,T = \underline{\partial}\,T$, while if the distribution $T(\underline{x})$ is *angular*, i.e. only depends on $\underline{\omega} = \frac{\underline{\omega}}{|\underline{x}|}$, then we put $\underline{\omega}\,\partial_r\,T = 0$ and $\frac{1}{r}\,\partial_{\underline{\omega}}\,T = \underline{\partial}\,T$. The first special case is illustrated by the delta distribution (see also [2]): $\frac{1}{r}\,\partial_{\underline{\omega}}\,\delta(\underline{x}) = 0$ and $\underline{\omega}\,\partial_r\,\delta(\underline{x}) = \underline{\partial}\,\delta(\underline{x})$, the second one by the regular distribution $\underline{\omega}$: $\underline{\omega}\,\partial_r\,\underline{\omega} = 0$ and $\frac{1}{r}\,\partial_{\underline{\omega}}\,\underline{\omega} = \underline{\partial}\,\underline{\omega} = -(m-1)\frac{1}{r}$.
In the next section we will find two other possibilities for an unambiguous definition of the actions of the $\underline{\partial}_{rad}$ and $\underline{\partial}_{ang}$ operators.

4 Radial and angular derivatives of distributions

In Section 1 we explained why it is impossible to define the radial derivative $\partial_r\,T$ and the angular derivative $\partial_{\underline{\omega}}\,T$ of a distribution T within the class of distributions. Neither is it possible to multiply a distribution by the non–analytic functions r and $\underline{\omega}$. For *legitimizing* those *forbidden actions* we have to take the signumdistributions into consideration instead.

Definition 1. *The product of a scalar–valued distribution T by the function $\underline{\omega}$ is the signumdistribution $T^{\vee}$ associated to T, and it holds that*

$$\langle\ \underline{\omega}\,T\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ T^{\vee}\ ,\ \underline{\omega}\,\varphi\ \rangle = -\langle\ T\ ,\varphi\ \rangle$$

Similarly, the product of a scalar–valued signumdistribution U by the function $\underline{\omega}$ is the distribution $-U^{\wedge}$ associated to $-U$, and it holds that

$$\langle\ \underline{\omega}\,U\ ,\ \varphi\ \rangle = \langle\ -U^{\wedge}\ ,\ \varphi\ \rangle = \langle\ U\ ,\underline{\omega}\,\varphi\ \rangle$$

Definition 2. *The product of a scalar–valued distribution T by the function r is the signumdistribution $r\,T$ given by*

$$\langle\ r\,T\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ \underline{x}\,T\ ,\varphi\ \rangle = \langle\ T\ ,\ \underline{x}\,\varphi\ \rangle$$

The product of a scalar–valued signumdistribution U by the function r is the distribution $r\,U$ given by

$$\langle\ r\,U\ ,\ \varphi\ \rangle = \langle\ -\underline{x}\,U\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ -U\ ,\ \underline{\omega}\,(\underline{x}\,\varphi)\ \rangle$$

Definition 3. *The derivative with respect to the radial distance r of a scalar–valued* radial *distribution T is the signumdistribution $\partial_r\,T$ given by*

$$\langle\ \partial_r\,T\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ \underline{\omega}\partial_r\,T\ ,\ \varphi\ \rangle = \langle\ \underline{\partial}\,T\ ,\ \varphi\ \rangle$$

 ISBN: 978-84-617-8694-7

The derivative with respect to the radial distance r of a scalar–valued radial *signumdistribution U is the distribution $\partial_r U$ given by*

$$\langle\ \partial_r U\ ,\ \varphi\ \rangle = \langle\ -\underline{\omega}\partial_r U\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ -\underline{\partial} U\ ,\ \underline{\omega}\,\varphi\ \rangle$$

Definition 4. *The angular $\partial_{\underline{\omega}}$–derivative of a scalar–valued distribution T is the signumdistribution $\partial_{\underline{\omega}} T$ given by*

$$\langle\ \underline{\omega}\,\varphi\ ,\ \partial_{\underline{\omega}} T\ \rangle = \langle\ \varphi\ ,\ \underline{\omega}\,\partial_{\underline{\omega}} T\ \rangle = \langle\ \varphi\ ,\ -\Gamma\, T\ \rangle$$

The angular $\partial_{\underline{\omega}}$–derivative of a scalar–valued signumdistribution U is the distribution $\partial_{\underline{\omega}} U$ given by

$$\langle\ \varphi\ ,\ \partial_{\underline{\omega}} U\ \rangle = \langle\ \underline{\omega}\,\varphi\ ,\ -\underline{\omega}\,\partial_{\underline{\omega}} U\ \rangle = \langle\ \underline{\omega}\,\varphi\ ,\ \Gamma\, U\ \rangle$$

Notice that only for the derivation with respect to r (Definition 3) is was necessary to confine the action to *radial* distributions. If instead general (signum)distributions are involved for this action, the result is an equivalence class of (signum)distributions seen the result obtained in the preceding section on the action of the differential operator $\underline{\omega}\partial_r$ on a distribution:

$$\langle\ \partial_r T\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ \underline{\omega}\partial_r T\ ,\ \varphi\ \rangle = \langle\ S_1\ ,\ \varphi\ \rangle$$

with S_1 any distribution for which $\underline{x} S_1 = -\,\mathbb{E}T$, and a similar result for signumdistributions.

Now it is also possible to unambiguously define the radial derivative of the signumdistribution $T^\vee$ associated to the radial distribution T, $T^\vee$ certainly not being radial, according to the following commutative scheme

$$\begin{array}{ccc} T & \overset{-\underline{\omega}\partial_r = -\underline{\partial}}{\longrightarrow} & (\partial_r T)^\wedge \\ {\scriptstyle -\underline{\omega}}\uparrow\downarrow{\scriptstyle \underline{\omega}} & \nearrow\!\searrow^{-\partial_r}_{\partial_r} & \uparrow\downarrow \\ T^\vee & \underset{-\underline{\omega}\partial_r \neq -\underline{\partial}}{\longrightarrow} & \partial_r T \end{array}$$

Definition 5. *The radial derivative of the signumdistribution $T^\vee$ associated to the distribution T, is given by*

$$\partial_r\, T^\vee = -\,(\partial_r\, T)^\wedge$$

Example 1. Let us illustrate Definition 5 by the following simple example. Take the radial distribution T to be r. Its radial derivative is given by $\partial_r\, r = 1$ since

$$\langle\ \partial_r\, r\ ,\ \underline{\omega}\,\varphi\ \rangle = \langle\ \underline{\omega}\,\partial_r\, r\ ,\ \varphi\ \rangle = \langle\ \underline{\partial}\, r\ ,\ \varphi\ \rangle = \langle\ \underline{\omega}\ ,\ \varphi\ \rangle = \langle\ 1\ ,\ \underline{\omega}\,\varphi\ \rangle$$

 ISBN: 978-84-617-8694-7

It follows that $(\partial_r\, r)^\wedge = 1^\wedge = -\,\underline{\omega}$ and so $\partial_r\, T^\vee = \partial_r\, r^\vee = \partial_r\, r\underline{\omega} = \partial_r\, \underline{x} = -\,(\partial_r\, r)^\wedge = \underline{\omega}$, a result which indeed is quite acceptable!

Now notice that the above scheme implies the definition of the action of the operator $\underline{\omega}\partial_r$ on the signumdistribution $T^\vee$, the distribution T being radial:

$$(\underline{\omega}\,\partial_r)T^\vee = -\,\partial_r\, T = \underline{\omega}(-\,\underline{\omega}\,\partial_r)T = -\,\underline{\omega}\,\underline{\partial}\,T$$

and for all test functions $\underline{\omega}\,\varphi$ it holds that

$$\langle\, -\,\underline{\omega}\,\partial_r\, T^\vee\ ,\ \underline{\omega}\,\varphi\,\rangle = \langle\, (\underline{\omega}\,\partial_r\, T^\vee)^\wedge\ ,\ \varphi\,\rangle = \langle\, \partial_r\, T^\vee\ ,\ \varphi\,\rangle = \langle\, -\,(\partial_r\, T)^\wedge\ ,\ \varphi\,\rangle = \langle\, \partial_r\, T\ ,\ \underline{\omega}\,\varphi\,\rangle$$

In a similar way the definition of the radial derivative of the distribution $U^\wedge$ associated to the radial signumdistribution U, rests on the following commutative scheme

$$\begin{array}{ccc} & \overset{\underline{\omega}\partial_r \neq \underline{\partial}}{} & \\ U^\wedge & \longrightarrow & \partial_r U \\ {\scriptstyle -\underline{\omega}}\uparrow\downarrow{\scriptstyle \underline{\omega}} & \nearrow\searrow\ {\scriptstyle \partial_r,\ -\partial_r} & \uparrow\downarrow \\ U & \longrightarrow & (\partial_r U)^\vee \\ & {\scriptstyle \underline{\omega}\partial_r = \underline{\partial}} & \end{array}$$

Definition 6. *The radial derivative of the distribution $U^\wedge$ associated to the signumdistribution U, is given by*

$$\partial_r\, U^\wedge = -\,(\partial_r\, U)^\vee$$

Example 2. As an illustration of Definition 6 consider the radial signumdistribution $U = r$ for which $\partial_r\, U = \partial_r\, r = 1$, the associated signumdistribution of which is $(\partial_r\, U)^\vee = \underline{\omega}$. The associated distribution of $U = r$ is $U^\wedge = -\,\underline{x}$ and we obtain $\partial_r\, U^\wedge = \partial_r(-\underline{x}) = -\,(\partial_r\, U)^\vee = -\underline{\omega}$.

Notice that the above scheme implies the definition of the action of the operator $\underline{\omega}\partial_r$ on the distribution $U^\wedge$, the signumdistribution U being radial:

$$(\underline{\omega}\,\partial_r)U^\wedge = \partial_r\, U = -\,\underline{\omega}(\underline{\omega}\,\partial_r)U = -\,\underline{\omega}\,\underline{\partial}\,U$$

Finally note that the (signum)distributions appearing in the above examples, are particular cases of two special and useful classes of distributions which were thoroughly studied, see e.g. [1], in the framework of Clifford analysis.

 ISBN: 978-84-617-8694-7

5 Conclusion

In his famous and seminal book [6] Laurent Schwartz writes on page 45: *Using co-ordinate systems other than the cartesian ones should be done with the utmost care* [our translation]. And right he is! Indeed, just consider the delta distribution $\delta(\underline{x})$: it is pointly supported at the origin, it is rotation invariant: $\delta(A\,\underline{x}) = \delta(\underline{x})$, $\forall\, A \in \mathrm{SO}(m)$, it is even: $\delta(-\underline{x}) = \delta(\underline{x})$ and it is homogeneous of order $(-m)$: $\delta(a\underline{x}) = \frac{1}{|a|^m}\,\delta(\underline{x})$. So in a first, naive, approach, one could think of its radial derivative $\partial_r\,\delta(\underline{x})$ as a distribution which remains pointly supported at the origin, rotation invariant, even and homogeneous of degree $(-m-1)$. Temporarily leaving aside the even character, on the basis of the other cited characteristics the distribution $\partial_r\,\delta(\underline{x})$ should take the following form:

$$\partial_r\,\delta(\underline{x}) = c_0\,\partial_{x_1}\delta(\underline{x}) + \cdots + c_m\,\partial_{x_m}\delta(\underline{x})$$

and it becomes immediately clear that this approach to the radial derivation of the delta distribution is impossible since all distributions appearing in the sum at the right–hand side are odd and not rotation invariant, whereas $\partial_r\,\delta(\underline{x})$ is assumed to be even and rotation invariant. It could be that $\partial_r\,\delta(\underline{x})$ is either the zero distribution or is no longer pointly supported at the origin, but both those possibilities are unacceptable. So from the start we are warned by this example that introducing spherical co–ordinates $\underline{x} = r\underline{\omega}$, $r = |\underline{x}|$, $\underline{\omega} \in \mathbb{S}^{m-1}$ makes derivation of distributions in $\mathbb{R}^m$ a far from trivial action, as are, in principle "forbidden", actions such as multiplication by the non–analytic functions r and $\omega_j, j = 1, \ldots, m$. But there is more: functional analytic considerations on the space $\mathcal{D}(\mathbb{R}^m)$ of compactly supported smooth test functions expressed in spherical co–ordinates, forced us to introduce a new space of continuous linear functionals on a auxiliary space of test functions showing a singularity at the origin, for which, in [2], we coined the term *signumdistributions*, bearing in mind that $\underline{\omega} = \frac{\underline{x}}{|\underline{x}|}$ may be interpreted as the higher dimensional counterpart to the *signum* function on the real line. It turns out that the actions by r, $\underline{\omega}$, ∂_r and $\partial_{\underline{\omega}}$ map a distribution to a signumdistribution and vice versa. The basic idea behind the definition of these actions on a distribution $T \in \mathcal{D}'(\mathbb{R}^m)$, is to express the resulting signumdistributions as appropriate and "legal" actions on T. So, for example, we put $\langle rT, \underline{\omega}\varphi\rangle = \langle r\underline{\omega}T, \varphi\rangle = \langle \underline{x}T, \varphi\rangle, \forall\varphi \in \mathcal{D}(\mathbb{R}^m)$. This idea may seem to be rather simple, but it is backed up by the functional analytic considerations mentioned above, which, through the concept of *spherical representation of a distribution*, leave room for a choice, and this choice was made for efficiency's sake, as is amply demonstrated by the easy to handle calculus rules established in [2].

Of the four aforementioned actions only the radial derivative $\partial_r\,T$ escapes, in general, from an unambiguous definition, but leads to an equivalent class of signumdistributions instead. Still we were able to define unambiguously $\partial_r\,T$ in two particular cases: (i) when the given distribution T is radial, i.e. rotation invariant, and (ii) when $T = U^\wedge$ is the associated distribution to a given radial signumdistribution U, these two particular cases being quite

 ISBN: 978-84-617-8694-7

interesting since they correspond to two families of frequently used distributions, such as the fundamental solutions of the Laplace and the Dirac operator, in Clifford analysis.

Abstract

Similarly as hermitian Clifford analysis emerges in Euclidean space $\mathbb{R}^{2n}$ of even dimension as a refinement of euclidean Clifford analysis by the introduction of a complex structure on $\mathbb{R}^{2n}$, quaternionic Clifford analysis arises as a further refinement by the introduction of a so–called hypercomplex structure $\mathbb{Q}$, i.e. three complex structures ($\mathbb{I}$, $\mathbb{J}$, $\mathbb{K}$) which submit to the quaternionic multiplication rules, on Euclidean space $\mathbb{R}^{4p}$, the dimension now being a fourfold. In the hermitian framework, the fundamental symmetry group is $\mathrm{U}(n)$, which is isomorphic to the subgroup of $\mathrm{SO}(2n)$ of matrices which are commuting with the complex structure; in the quaternionic framework, this rôle is taken up by the symplectic group $\mathrm{Sp}(p)$, which is isomorphic with the subgroup of $\mathrm{SO}(4p)$ of matrices which are commuting with all three complex structures. Two, respectively four differential operators are constructed, which are invariant under the action of the corresponding symmetry group. Their simultaneous null solutions are respectively called hermitian and quaternionic monogenic functions. The basics of hermitian monogenicity have been studied in e.g. [2, 3, 9]. Quaternionic monogenicity has been developed in, amongst others, [13, 11, 10, 5, 6]. In this contribution, we compare the ways in which a Cauchy integral representation formula can be established in each of these frameworks.

1 Hermitian and quaternionic monogenicity

Clifford analysis is centered around the notion of a monogenic function, a continuously differentiable function defined in an open region of Euclidean space $\mathbb{R}^m$, taking its values in the Clifford algebra $\mathbb{R}_{0,m}$, or subspaces thereof, and vanishing under the action of the Dirac operator $\underline{\partial} = \sum_{\alpha=1}^{m} e_\alpha \, \partial_{X_\alpha}$, which is the dual of the Clifford variable $\underline{X} = (X_1, \ldots, X_m)$. This notion is the higher dimensional counterpart of a holomorphic function in the complex plane. The Dirac operator factorizes the Laplacian: $\Delta_m = -\underline{\partial}^2$, and is invariant under the action of the Spin(m)–group which doubly covers the SO(m)–group, whence this framework is usually referred to as euclidean (or orthogonal) Clifford analysis.

Taking the dimension to be even: $m = 2n$, renaming the variables as $(X_1, \ldots, X_{2n}) = (x_1, y_1, x_2, y_2, \ldots, x_n, y_n)$ and considering the standard complex structure $\mathbb{I}_{2n}$, i.e. the complex linear real SO$(2n)$–matrix

$$\mathbb{I}_{2n} = \text{diag} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix},$$

for which $\mathbb{I}_{2n}^2 = -E_{2n}$, where E_{2n} denotes the identity matrix, we define the rotated vector variable and the corresponding rotated Dirac operator

$$\begin{aligned} \underline{X}_{\mathbb{I}} &= \mathbb{I}_{2n}[\underline{X}] = \sum_{k=1}^{n} (-y_k e_{2k-1} + x_k e_{2k}) \\ \underline{\partial}_{\mathbb{I}} &= \mathbb{I}_{2n}[\underline{\partial}] = \sum_{k=1}^{n} (-\partial_{y_k} e_{2k-1} + \partial_{x_k} e_{2k}) \end{aligned}$$

A differentiable function F then is called hermitian monogenic in some region Ω of $\mathbb{R}^{2n}$, if and only if in that region F is a solution of the system $\underline{\partial} F = 0 = \underline{\partial}_{\mathbb{I}} F$. However, one can also introduce hermitian monogenics by means of the projection operators $\frac{1}{2}(\mathbf{1} \pm i\, \mathbb{I}_{2n})$, involving a complexification, where we consider the Witt basis vectors $\mathfrak{f}_k = -\frac{1}{2}(\mathbf{1} - i\, \mathbb{I}_{2n})[e_{2k-1}]$ and $\mathfrak{f}_k^\dagger = \frac{1}{2}(\mathbf{1} + i\, \mathbb{I}_{2n})[e_{2k-1}]$, $k = 1, \ldots, n$, as well as the vector variables

$$\underline{z} = -\frac{1}{2}(\mathbf{1} - i\, \mathbb{I}_{2n})[\underline{X}] = \sum_{k=1}^{n} (x_k + i y_k)\mathfrak{f}_k = \sum_{k=1}^{n} z_k \mathfrak{f}_k, \qquad \underline{z}^\dagger = \frac{1}{2}(\mathbf{1} + i\, \mathbb{I}_{2n})[\underline{X}] = \sum_{k=1}^{n} \overline{z}_k \mathfrak{f}_k^\dagger$$

and, correspondingly, the hermitian Dirac operators

$$2\, \partial_{\underline{z}}^\dagger = -\frac{1}{2}(\mathbf{1} - i\, \mathbb{I}_{2n})[\underline{\partial}] = 2 \sum_{k=1}^{n} \partial_{\overline{z}_k} \mathfrak{f}_k, \qquad 2\, \partial_{\underline{z}} = \frac{1}{2}(\mathbf{1} + i\, \mathbb{I}_{2n})[\underline{\partial}] = 2 \sum_{k=1}^{n} \partial_{z_k} \mathfrak{f}_k^\dagger$$

It follows that the hermitian monogenic system is equivalent to $\partial_{\underline{z}} F = 0 = \partial_{\underline{z}}^\dagger F$, which can be shown to be invariant under the action of the group U(n).

 ISBN: 978-84-617-8694-7

A refinement of hermitian Clifford analysis is obtained by considering the hypercomplex structure $\mathbb{Q} = (\mathbb{I}_{4p}, \mathbb{J}_{4p}, \mathbb{K}_{4p})$ on $\mathbb{R}^{4p} \simeq \mathbb{C}^{2p} \simeq \mathbb{H}^p$, where the dimension $m = 2n = 4p$ now is assumed to be a 4-fold. This hypercomplex structure arises by introducing, next to the complex structure $\mathbb{I}_{4p}$, a second one, $\mathbb{J}_{4p}$, given by

$$\mathbb{J}_{4p} = \text{diag} \begin{pmatrix} & & 1 & \\ & & & -1 \\ -1 & & & \\ & 1 & & \end{pmatrix}$$

Clearly $\mathbb{J}_{4p} \in \text{SO}(4p)$, with $\mathbb{J}_{4p}^2 = -E_{4p}$, and it anti–commutes with $\mathbb{I}_{4p}$. A third $\text{SO}(4p)$–matrix $\mathbb{K}_{4p} = \mathbb{I}_{4p}\mathbb{J}_{4p} = -\mathbb{J}_{4p}\mathbb{I}_{4p}$ then arises, for which $\mathbb{K}_{4p}^2 = -E_{4p}$ and which anti–commutes with both $\mathbb{I}_{4p}$ and $\mathbb{J}_{4p}$. We introduce the concept of quaternionic monogenicity by means of the additional rotated Dirac operators $\underline{\partial}_{\mathbb{J}} = \mathbb{J}_{4p}[\underline{\partial}]$ and $\underline{\partial}_{\mathbb{K}} = \mathbb{K}_{4p}[\underline{\partial}]$. A differentiable function $F : \mathbb{R}^{4p} \longrightarrow \mathbb{S}$ is called quaternionic monogenic in some region Ω of $\mathbb{R}^{4p}$, if and only if in that region F is a solution of the system $\underline{\partial}F = \underline{\partial}_{\mathbb{I}}F = \underline{\partial}_{\mathbb{J}}F = \underline{\partial}_{\mathbb{K}}F = 0$. Also here an alternative characterization is possible in terms of the hermitian Dirac operators, which in the actual dimension read:

$$\partial_{\underline{z}} = \sum_{j=1}^{p} (\partial_{z_{2j-1}} \mathfrak{f}_{2j-1}^{\dagger} + \partial_{z_{2j}} \mathfrak{f}_{2j}^{\dagger}), \qquad \partial_{\underline{z}}^{\dagger} = \sum_{j=1}^{p} (\partial_{\overline{z}_{2j-1}} \mathfrak{f}_{2j-1} + \partial_{\overline{z}_{2j}} \mathfrak{f}_{2j})$$

and their images under the action of $\mathbb{J}_{4p}$:

$$\partial_{\underline{z}}^{J} = \mathbb{J}_{4p}[\partial_{\underline{z}}] = \sum_{j=1}^{p} (\partial_{z_{2j}} \mathfrak{f}_{2j-1} - \partial_{z_{2j-1}} \mathfrak{f}_{2j}), \qquad \partial_{\underline{z}}^{\dagger J} = \mathbb{J}_{4p}[\partial_{\underline{z}}^{\dagger}] = \sum_{j=1}^{p} (\partial_{\overline{z}_{2j}} \mathfrak{f}_{2j-1}^{\dagger} - \partial_{\overline{z}_{2j-1}} \mathfrak{f}_{2j}^{\dagger})$$

The quaternionic system above then is equivalent to $\partial_{\underline{z}}F = \partial_{\underline{z}}^{\dagger}F = \partial_{\underline{z}}^{J}F = \partial_{\underline{z}}^{\dagger J}F = 0$, which can be shown to be invariant under the action of the symplectic group action of $\text{Sp}(p)$.

2 The Clifford Cauchy formula

The Cauchy integral formula is an important result for holomorphic functions in the complex plane; for a bounded domain D in $\mathbb{C}$ with (piecewise) smooth boundary ∂D it reads

$$f(z) = \frac{1}{2\pi i} \int_{\partial D} \frac{f(\xi)}{\xi - z}\, d\xi, \quad z \in \overset{\circ}{D}$$

It was generalized to monogenic functions in the euclidean Clifford framework in the following way:

$$f(\underline{X}) = \int_{\partial D} E(\underline{\Xi} - \underline{X})\, d\sigma_{\underline{\Xi}}\, f(\underline{\Xi}) \ , \quad \underline{X} \in \overset{\circ}{D}$$

 ISBN: 978-84-617-8694-7

where

$$E(\underline{X}) = \frac{1}{a_m}\,\frac{\overline{\underline{X}}}{|\underline{X}|^m}$$

is the fundamental solution of the Dirac operator, the so-called Cauchy kernel, with a_m denoting the area of the unit sphere S^{m-1} in $\mathbb{R}^m$, $\bar{\cdot}$ being the Clifford conjugation and $d\sigma_{\underline{\Xi}}$ being a Clifford algebra valued differential form of order $m-1$.

For hermitian monogenic functions arriving at a suitable Cauchy formula necessitated a formulation in terms of circulant matrices, see e.g. [4]. The fundamental solutions of the Dirac operators $\underline{\partial}$ and $\underline{\partial}_{\mathbb{I}}$, i.e. the euclidean Cauchy kernels, are respectively given by

$$E(\underline{X}) = \frac{1}{a_{2n}}\,\frac{\overline{\underline{X}}}{|\underline{X}|^{2n}}, \quad E_{\mathbb{I}}(\underline{X}) = \frac{1}{a_{2n}}\,\frac{\overline{\underline{X}}_{\mathbb{I}}}{|\underline{X}_{\mathbb{I}}|^{2n}}$$

where now a_{2n} denotes the area of the unit sphere S^{2n-1} in $\mathbb{R}^{2n}$; they give rise to their hermitian counterparts $\mathcal{E} = -\left(E + i\,E_{\mathbb{I}}\right)$ and $\mathcal{E}^{\dagger} = \left(E - i\,E_{\mathbb{I}}\right)$, or explicitly:

$$E(\underline{Z}) = \frac{2}{a_{2n}}\,\frac{\underline{Z}}{|\underline{Z}|^{2n}}, \quad E^{\dagger}(\underline{Z}) = \frac{2}{a_{2n}}\,\frac{\underline{Z}^{\dagger}}{|\underline{Z}|^{2n}}$$

Introducing the particular circulant (2×2) matrices

$$\boldsymbol{\mathcal{D}}_{(\underline{Z},\underline{Z}^{\dagger})} = \begin{pmatrix} \partial_{\underline{Z}} & \partial_{\underline{Z}^{\dagger}} \\ \partial_{\underline{Z}^{\dagger}} & \partial_{\underline{Z}} \end{pmatrix}, \quad \mathbf{E} = \begin{pmatrix} E & E^{\dagger} \\ E^{\dagger} & E \end{pmatrix}, \quad \text{and} \quad \boldsymbol{\delta} = \begin{pmatrix} \delta & 0 \\ 0 & \delta \end{pmatrix}$$

it was obtained that $\boldsymbol{\mathcal{D}}_{(\underline{Z},\underline{Z}^{\dagger})}\mathbf{E}(\underline{\mathbf{Z}}) = \boldsymbol{\delta}(\underline{\mathbf{Z}})$, whence the concept of a fundamental solution had to be reinterpreted in a matrix context. Consequently, this also turned out to be the case for hermitian monogenicity: a circulant matrix

$$\boldsymbol{G}_2^1 = \begin{pmatrix} g_1 & g_2 \\ g_2 & g_1 \end{pmatrix}$$

with continuously differentiable entries g_1 and g_2 defined in Ω and taking values in $\mathbb{C}_{2n}$ was then called $\boldsymbol{G}_2^1$ hermitian monogenic if and only if it satisfies the system

$$\boldsymbol{\mathcal{D}}_{(\underline{Z},\underline{Z}^{\dagger})}\boldsymbol{G}_2^1 = \boldsymbol{O}$$

where $\boldsymbol{O}$ denotes the matrix with zero entries. A formal Cauchy integral formula for hermitian monogenic circulant matrix functions then reads

$$\int_{\partial D} \mathbf{E}(\underline{Z} - \underline{V})\, \boldsymbol{d\Sigma}_{(\underline{Z},\underline{Z}^{\dagger})}\, \boldsymbol{G}_2^1(\underline{X}) = c_n \boldsymbol{G}_2^1(\underline{Y}), \quad \underline{Y} \in \overset{\circ}{D}$$

where $\boldsymbol{d\Sigma}_{(\underline{Z},\underline{Z}^{\dagger})}$ is a suitable differential form in circulant matrix format, giving rise to a normalization constant c_n at the right hand side, $\underline{Z}$ is the hermitian variable corresponding to $\underline{X}$ and $\underline{V}$ is the one corresponding to $\underline{Y}$. Taking for $\boldsymbol{G}_2^1$ a diagonal matrix, the above formula reduces to a genuine Cauchy formula for hermitian monogenic functions.

 ISBN: 978-84-617-8694-7

Remark 1. *It is well known in complex analysis that an alternative way of generalizing the Cauchy formula to higher dimension is by means of the Martinelli–Bochner kernel, see e.g. [12], which is not holomorphic but still harmonic, in this way establishing a connection between harmonic and holomorphic functions. The above hermitian Cauchy formula reduces to the Martinelli-Bochner formula when the considered functions take their values in a particular homogeneous subspace of complex spinor space, and thus establishes a connection between hermitian Clifford analysis and complex analysis in several variables.*

In the quaternionic context a formally identical formula was obtained in [1], involving the fundamental solutions of the Dirac operators $\underline{\partial}$, $\underline{\partial}_{\mathbb{I}}$, $\underline{\partial}_{\mathbb{J}}$ and $\underline{\partial}_{\mathbb{K}}$ and their quaternionic counterparts , as well as the quaternionic Dirac operators $\partial_{\underline{z}}$, $\partial_{\underline{z}}^{\dagger}$, $\partial_{\underline{z}}^{J}$ and $\partial_{\underline{z}}^{\dagger J}$ themselves, placed in their respective corresponding circulant 4×4 matrices.

3 Future work and ideas

As mentioned in the remark, interesting results were obtained in the hermitian framework by restricting the values of the considered functions to the different homogenous parts of spinor space, which are suggested by the $\mathrm{U}(n)$ symmetry. Thence for quaternionic monogenics the effect of a restriction to the $\mathrm{Sp}(p)$ invariant parts, the so-called symplectic cells arising in the quaternionic setting, will be investigated.

To this end we will need to include in our analysis two additional operators: a scalar Euler operator

$$\mathcal{E} = \sum_{k=1}^{p} z_{2k-1}\, \partial_{\overline{z}_{2k}} - z_{2k}\, \partial_{\overline{z}_{2k-1}}$$

and a multiplication operator $P = \mathfrak{f}_2\mathfrak{f}_1 + \mathfrak{f}_4\mathfrak{f}_3 + \ldots + \mathfrak{f}_{2p}\mathfrak{f}_{2p-1}$, leading to the definition of so-called $\mathfrak{osp}(4|2)$–monogenics, a explained in [7, 8].

Abstract

For two-dimensional autonomous linear incommensurate fractional-order dynamical systems with Caputo derivatives of different orders, necessary and sufficient conditions are obtained for the asymptotic stability and instability of the null solution. These conditions are expressed in terms of the elements of the system's matrix, as well as of the fractional orders of the Caputo derivatives, leading to a generalization of the well known Routh-Hurwitz conditions. These theoretical results are then used to investigate the stability properties of a two-dimensional fractional-order FitzHugh-Nagumo neuronal model. The occurrence of Hopf bifurcations is also discussed. Numerical simulations are provided with the aim of exemplifying the theoretical results, revealing rich spiking behavior, in comparison with the classical integer-order FitzHugh-Nagumo model.

Key words: Caputo derivative; FitzHugh-Nagumo; mathematical model; fractional order derivative; stability; instability; bifurcation; numerical simulation.

1 Introduction

In many real world applications [5, 8, 10, 11, 15], fractional-order dynamical systems have proven to provide more accurate and realistic results than their classical integer-order counterparts, due to the fact that fractional-order derivatives are able to reflect memory and hereditary properties. However, it is important to emphasize that important qualitative differences may appear when generalizing properties of integer-order dynamical systems to the fractional-order case, and such generalizations have to be done with great care.

 ISBN: 978-84-617-8694-7

Stability analysis is one of the most important research topics of the qualitative theory of fractional-order systems. Two recent surveys [13, 19] provide comprehensive overviews of stability properties of fractional-order systems. In the particular case of linear autonomous commensurate fractional order systems, the most important starting point is Matignon's stability theorem [16], which has been generalized in [20]. Linearization theorems (or analogues of the classical Hartman-Grobman theorem) for fractional-order systems have been recently proved in [12, 21]. Up to this date, incommensurate order systems have not received as much attention as their commensurate order counterparts. Linear incommensurate fractional order systems with rational orders have been analyzed in [17]. Oscillations in two-dimensional incommensurate fractional order systems have been investigated in [6, 18].

The first aim of this paper is to explore necessary and sufficient conditions for the asymptotic stability of two-dimensional linear autonomous incommensurate fractional-order systems with Caputo derivatives of different orders. These results are later applied to investigate stability properties of a fractional-order FitzHugh-Nagumo neuronal model. It is worth emphasizing that fractional-order formulation of neuronal dynamics is strongly justified by experimental results concerning biological neurons [1, 14].

2 Stability results for linear systems with two Caputo derivatives of different orders

Consider the following two-dimensional linear autonomous incommensurate fractional-order system:

$$\begin{cases} {}^cD^{q_1}x(t) = a_{11}x(t) + a_{12}y(t) \\ {}^cD^{q_2}x(t) = a_{21}x(t) + a_{22}y(t) \end{cases} \tag{1}$$

where $A = (a_{ij})$ is a real 2-dimensional matrix and $q_1, q_2 \in (0, 1)$ are the fractional orders of the Caputo derivatives.

Applying the Laplace transform to system (1) we obtain the following system:

$$\begin{bmatrix} s^{q_1}X(s) - s^{q_1-1}x(0) \\ s^{q_2}Y(s) - s^{q_2-1}y(0) \end{bmatrix} = A \cdot \begin{bmatrix} X(s) \\ Y(s) \end{bmatrix},$$

where $X(s) = \mathscr{L}(x)(s)$ and $Y(s) = \mathscr{L}(y)(s)$ represent the Laplace transforms of the functions x and y, and s^{q_1}, s^{q_2} represent the principal values (first branches) of the corresponding complex power functions [7]. Therefore:

$$(\mathrm{diag}(s^{q_1}, s^{q_2}) - A) \cdot \begin{bmatrix} X(s) \\ Y(s) \end{bmatrix} = \begin{bmatrix} s^{q_1-1}x(0) \\ s^{q_2-1}y(0) \end{bmatrix}.$$

Next, we denote

$$\Delta_A(s) = \det\left(\mathrm{diag}(s^{q_1}, s^{q_2}) - A\right) = s^{q_1+q_2} - a_{11}s^{q_2} - a_{22}s^{q_1} + \det(A)$$

 ISBN: 978-84-617-8694-7

and we can easily observe that

$$X(s)=\frac{s^{q_1}(s^{q_2}-a_{22})x(0)+a_{12}s^{q_2}y(0)}{s\Delta_A(s)} \quad \text{and} \quad Y(s)=\frac{s^{q_2}(s^{q_1}-a_{11})y(0)+a_{21}s^{q_1}x(0)}{s\Delta_A(s)} \tag{2}$$

The following result provides necessary and sufficient conditions for the global asymptotic stability of system (1). The proof is based on the Final Value Theorem and asymptotic expansion properties of the Laplace transform [3, 4, 7].

Theorem 2.1.

1. *Denoting $q=\min\{q_1,q_2\}$, system (1) is $\mathcal{O}(t^{-q})$-globally asymptotically stable if and only if all the roots of $\Delta_A(s)$ are in the open left half-plane ($\Re(s)<0$).*
2. *If $\Delta_A(s)$ has a root in the open right half-place ($\Re(s)>0$), system (1) is unstable.*

With the aim of exploring the distribution of the roots of the characteristic function $\Delta_A(s)$ given above, the following result is given, which is a generalization of Proposition 2 from [4].

Proposition 2.2. *Consider the complex-valued function*

$$\Delta(s)=s^{q_1+q_2}+as^{q_2}+bs^{q_1}+c,$$

where $0<q_1\leq q_2<1$, s^{q_1} and s^{q_2} represent the principal values (first branches) of the corresponding complex power functions and $a,b,c\in\mathbb{R}$, $b>0$.

1. *If $c<0$, then $\Delta(s)$ has at least one positive real root.*
2. *$\Delta(0)=0$ if and only if $c=0$.*
3. *Assume that $c>0$.*
   (a) *If $a\geq 0$ then all roots of $\Delta(s)$ have the property that $\Re(s)<0$.*
   (b) *$\Delta(s)$ has a pair of pure imaginary roots if and only if*

$$a=a^{\star}(b,c,q_1,q_2)=-\frac{b^{\frac{q_1}{q_2}}}{\sin\frac{q_2\pi}{2}}\omega^{q_1-q_2}\left[\sin\frac{q_1\pi}{2}+\omega^{q_2}\sin\frac{(q_1+q_2)\pi}{2}\right]. \tag{3}$$

where $\omega=h_{q_1,q_2}^{-1}\left(\dfrac{\sin\frac{q_2\pi}{2}\cdot c}{b^{1+\frac{q_1}{q_2}}}\right)$ and h_{q_1,q_2} is the function defined by

$$h_{q_1,q_2}:\left(\left[\frac{\sin\frac{(q_2-q_1)\pi}{2}}{\sin\frac{q_1\pi}{2}}\right]^{\frac{1}{q_2}},\infty\right)\to(0,\infty)$$

$$h_{q_1,q_2}(\omega)=\omega^{q_1}\Big(\omega^{q_2}\sin\frac{q_1\pi}{2}-\sin\frac{(q_2-q_1)\pi}{2}\Big).$$

 ISBN: 978-84-617-8694-7

(c) If $s(a,b,c,q_1,q_2)$ is one of the roots of $\Delta(s)$ such that

$$\Re(s(a^\star,b,c,q_1,q_2))=0,$$

where $a^\star=a^\star(b,c,q_1,q_2)$ defined at (b), the following transversality condition is satisfied:

$$\frac{\partial\Re(s)}{\partial a}\Big|_{a=a^*}<0.$$

(d) All roots of $\Delta(s)$ are in the left half-plane if and only if $a>a^\star(b,c,q_1,q_2)$.

(e) $\Delta(s)$ has a pair of roots in the right half-plane if and only if $a<a^\star(b,c,q_1,q_2)$.

(f) For any $q_1,q_2\in(0,1)$, the following inequality holds:

$$a^\star(b,c,q_1,q_2)\leq -b^{\frac{q_1}{q_2}}.$$

Furthermore, sufficient stability conditions which do not depend on the fractional orders q_1 and q_2 will be obtained using the following:

Proposition 2.3. *Let $b>0$, $c>0$ and the complex-valued function $\Delta(s)$ defined in Proposition 2.2.*

1. *If $a>-\min\{b,1\}$ then all roots of $\Delta(s)$ are in the open left-half plane, regardless of q_1 and q_2.*
2. *Let $a\leq-\min\{b,1\}$. If $a+b+c+1\leq 0$ or $0<a+b+c+1<(\sqrt{c}-1)^2$ and $c>1$ then the equation $\Delta(s)$ has at least one positive real root, regardless of q_1 and q_2.*

Based on Theorem 2.1 and Propositions 2.2 and 2.3, the following conditions for the stability of system (1) are obtained, with respect to its coefficients and the fractional orders q_1,q_2:

Corrolary 2.4. *We consider the linear system (1) with $q_1,q_2\in(0,1)$ the fractional orders of the Caputo derivatives. If we denote $a=-a_{11}$, $b=-a_{22}$, $c=\det(A)$ and we assume that $b>0$, it results that:*

1. *If $c<0$, system (1) is unstable, regardless of the fractional orders q_1 and q_2.*
2. *We suppose that that $c>0$.*
   (a) System (1) is $\mathcal{O}(t^{-q})$-asymptotically stable if and only if $a>a^\star(b,c,q_1,q_2)$, where $a^\star(b,c,q_1,q_2)$ is defined by (3) and $q=\min\{q_1,q_2\}$.
   (b) If $a>-\min\{b,1\}$, system (1) is asymptotically stable, regardless of the fractional orders q_1 and q_2.
   (c) System (1) is unstable if $a<a^\star(b,c,q_1,q_2)$.
   (d) If $a\leq-\min\{b,1\}$ and $a+b+c+1\leq 0$ or $0<a+b+c+1<(\sqrt{c}-1)^2$ and $c>1$ then system (1) is unstable, regardless of the fractional orders q_1 and q_2.

3 Investigation of a fractional-order FitzHugh-Nagumo model

The FitzHugh-Nagumo neuronal model [9] is a simplification of the well-known Hodgkin-Huxley model, which describes a biological neuron's spiking behavior. In this paper, we consider an extension on the classical FitzHugh-Nagumo model, by replacing the integer-order derivatives by fractional-order Caputo derivatives:

$$\begin{cases} {}^cD^{q_1}v(t) = v - \dfrac{v^3}{3} - w + I \\ {}^cD^{q_2}w(t) = r(v + c - dw) \end{cases} \tag{4}$$

where v represents the membrane potential, w is a recovery variable, I is an external excitation current and $0 < q_1 \leq q_2 \leq 1$. A similar model has been investigated by means of numerical simulations in [2].

The second equation of system (4) can be rewritten as follows:

$${}^cD^{q_2}w(t) = rd\Big(\frac{1}{d}v + \frac{c}{d} - w\Big) = \phi(\alpha v + \beta - w)$$

where $\phi = rd \in (0,1)$, $\alpha = \dfrac{1}{d} > 1$ and $\beta = \dfrac{c}{d}$. Therefore, system (4) is equivalent to the following two-dimensional conductance-based model:

$$\begin{cases} {}^cD^{q_1}v(t) = I - I(v,w) \\ {}^cD^{q_2}w(t) = \phi(w_\infty(v) - w) \end{cases} \tag{5}$$

where $I(v,w) = w - v + \dfrac{v^3}{3}$ and $w_\infty(v) = \alpha v + \beta$ is a linear function.

The equilibrium states of the fractional-ordel neuronal model (5) are the solutions of the algebraic system

$$\begin{cases} I = I_\infty(v) \\ w = w_\infty(v) \end{cases}$$

where

$$I_\infty(v) = I(v, w_\infty(v)) = w_\infty(v) - v + \frac{v^3}{3} = (\alpha - 1)v + \frac{v^3}{3} + \beta.$$

We observe that $I_\infty \in C^1$, $\lim\limits_{v\to-\infty} I_\infty(v) = -\infty$ and $\lim\limits_{v\to\infty} I_\infty(v) = \infty$.

Moreover, $I'_\infty(v) = v^2 + \alpha - 1 > 0$, so the function I_∞ is increasing and, as it is also continuous, it results that I_∞ is bijective. Therefore, there exists an unique solution for the equation $I_\infty(v) = I$, which we denote by $v^* = v^*(I, \alpha, \beta)$.

For the investigation of the stability of the equilibrium states, we consider the Jacobian matrix associated to system (5) at an equilibrium state $(v^*, w^*) = (v^*, w_\infty(v^*))$:

$$J = \begin{bmatrix} 1 - (v^*)^2 & -1 \\ \phi \cdot \alpha & -\phi \end{bmatrix}$$

 ISBN: 978-84-617-8694-7

The characteristic equation at the equilibrium state (v^*, w^*) is

$$s^{q_1+q_2} + a(v^*)s^{q_2} + b(v^*)s^{q_1} + c(v^*) = 0 \tag{6}$$

where

$$\begin{aligned} a(v^*) &= -1 + (v^*)^2 \\ b(v^*) &= \phi > 0 \\ c(v^*) &= \det(J) = \phi \cdot I'_\infty(v^*). \end{aligned}$$

Based on Corrolary 2.4 2.b, we obtain:

Proposition 3.1. *Any equilibrium state (v^*, w^*) with $|v^*| > \sqrt{1-\phi}$ is asymptotically stable, regardless of the fractional orders q_1 and q_2.*

The stability of any equilibrium state (v^*, w^*) with $|v^*| \leq \sqrt{1-\phi}$ depends on the fractional orders q_1 and q_2 (see Figs. 1 and 2).

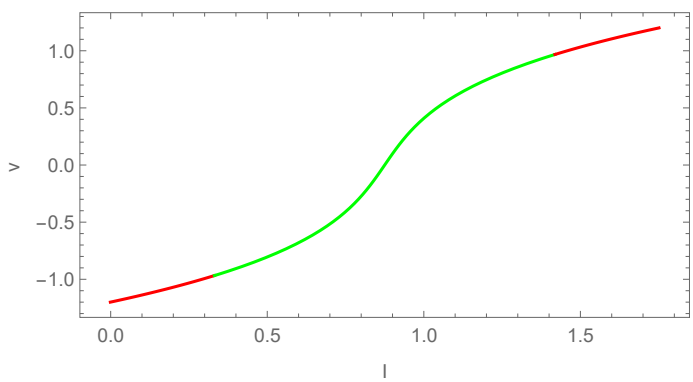

Figure 1: Membrane potential (v^*) of the equilibrium state (v^*, w^*) of system (4) (with parameter values: $r = 0.08$, $c = 0.7$, $d = 0.8$) with respect to the external excitation current I and their stability: red represents asymptotic stability, regardless of the fractional orders q_1 and q_2; green represents equilibrium states whose stability depends on the fractional orders q_1 and q_2.

Let us know consider an arbitrarily fixed equilibrium state (v^*, w^*) of system (4), such that $|v^*| \leq \sqrt{1-\phi}$. According to Proposition 2.2, at the critical values of the fractional orders $(q_1^\star, q_2^\star)$ defined implicitly by the equality

$$a(v^\star) = a^\star(b(v^\star), c(v^\star), q_1, q_2),$$

a Hopf bifurcation is expected to occur (see Fig. 2).

 ISBN: 978-84-617-8694-7

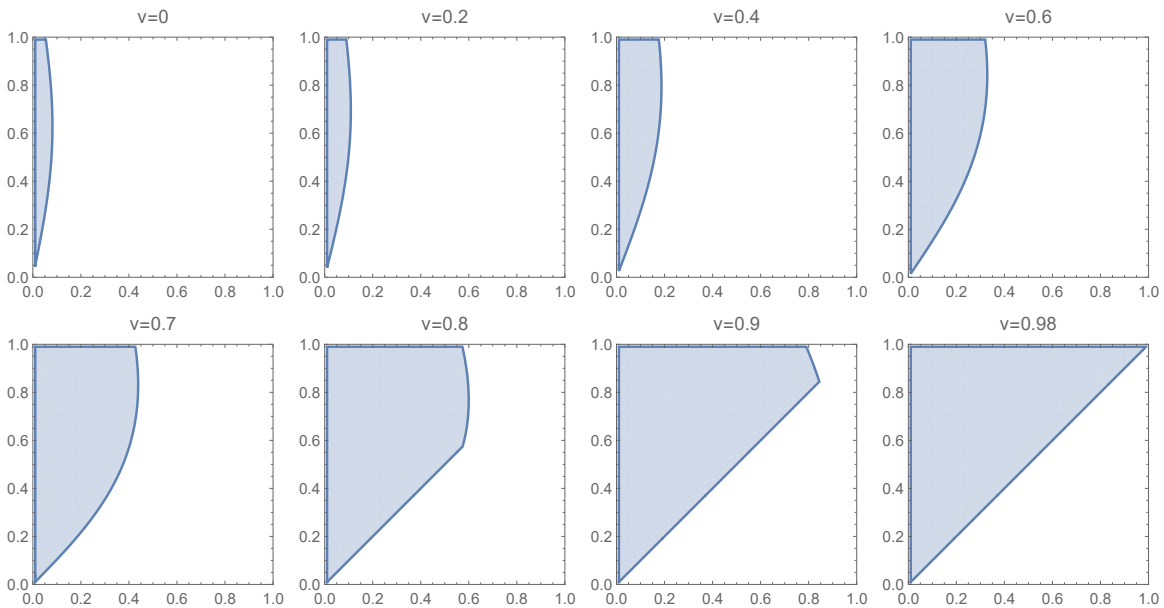

Figure 2: Stability regions (shaded) in the (q_1, q_2)-plane for equilibrium states (v^*, w^*) of system (4) (with parameter values: $r = 0.08$, $c = 0.7$, $d = 0.8$), with different values of the membrane potential v^* satisfying the inequality $|v^*| \leq \sqrt{1-\phi} \approx 0.98$. In each case, the part of the blue curve strictly above the first bisector represents the Hopf bifurcation curve in the (q_1, q_2)-plane.

Indeed, considering the following values for the system parameters: $r = 0.08$, $c = 0.7$, $d = 0.8$ and $I = 1.24567$, the equilibrium state is $(v^*, w^*) = (0.8, 1.875)$. In Fig. 3, the evolution of the state variables is shown, considering an initial condition in a small neighborhood of the equilibrium point. For a fixed value $q_2 = 0.8$, the critical value of the fractional order q_1 for which a Hopf bifurcation occurs is $q_1^* = 0.599$. Indeed, for $q_1 = 0.58$, asymptotically stable behavior is observed. For $q_1 = 0.63$, numerical simulations show quasi-periodic behavior, corresponding to the existence of a stable limit cycle. As q_1 is increased, the frequency of the oscillations increases. Numerical simulations suggest that fractional-order versions of the FitzHugh-Nagumo system provide a more realistic modelling of individual spikes than the corresponding integer-order counterpart (as seen in the last image from Fig. 3).

 ISBN: 978-84-617-8694-7

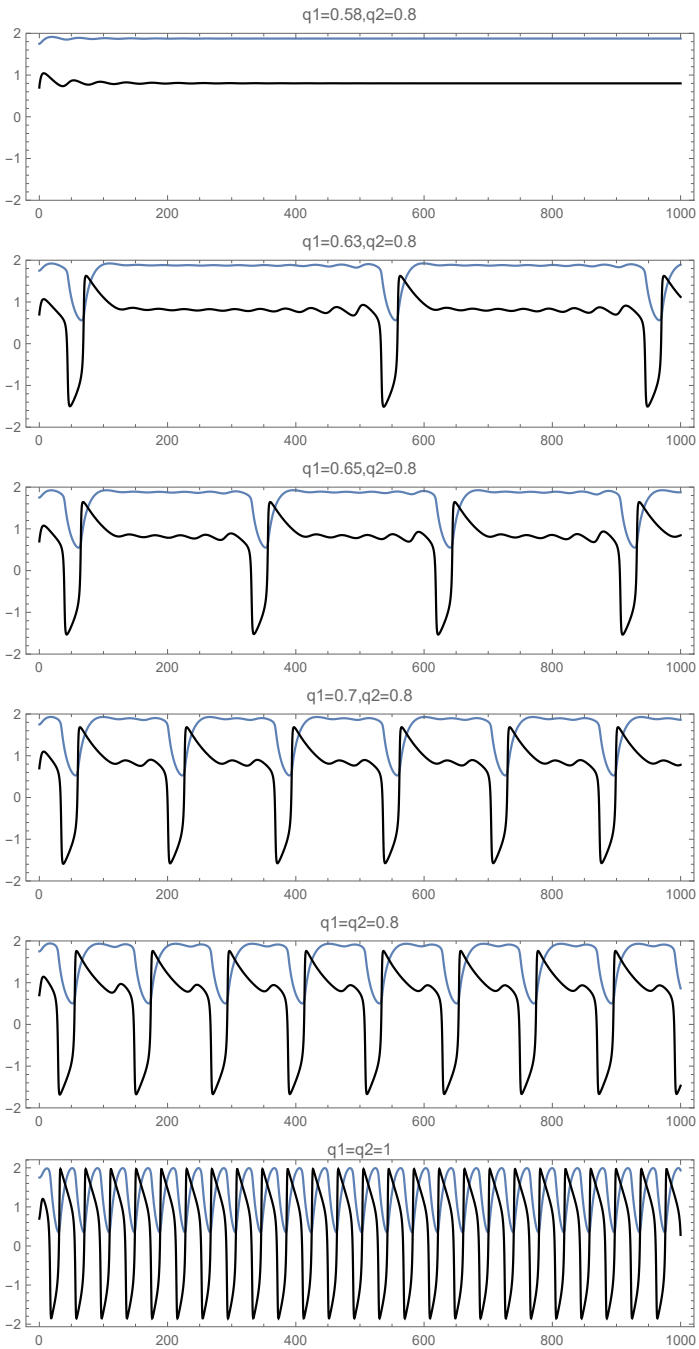

Figure 3: Evolution of the state variables of system (4) (with parameter values: $r = 0.08$, $c = 0.7$, $d = 0.8$ and $I = 1.24567$) for different values of the fractional orders.

 ISBN: 978-84-617-8694-7

4 Conclusions

Necessary and sufficient conditions have been obtained for the asymptotic stability of a two-dimensional incommensurate order linear autonomous system with Caputo derivatives of different fractional orders. These results can be regarded as a generalization of the classical Routh-Hurwitz stability conditions. As an application, the stability properties of a fractional-order FitzHugh-Nagumo system have been explored. Numerical simulations are provided to exemplify the theoretical findings, additionally revealing the occurrence of Hopf bifurcations when critical values of the fractional orders are encountered.

Abstract

Description of attracting sets in specific dynamical systems arising in the gene regulatory theory is provided.

Key words: gene regulatory networks, dynamical systems, attracting sets
MSC 2000: 34B15, 34B23, 34C60, 34D45

1 Introduction

There are different kinds of models of bioregulatory networks. Among them one of widespread mathematical tools are nonlinear ordinary differential equations. Differential relations can be used to describe the regulatory interactions between genes. The time-dependent variables $x(t)$ represent the concentration of gene products mRNAs or protein. These variables are positive valued.

It was noticed by biologists that cells of living organisms are adaptable to unknown and unpredictable changes in environment even if these changes are very rapid. This mechanism was described, for instance, by [2]. It was proposed to use the attractor selection as principal mechanism of adaptation to unknown changes of biological systems [3].

The main idea of attractor selection is that the system is driven by two components, namely, deterministic and stochastic. Attractors are a part of the equilibrium points in the solution space. Conditions of such system are controlled by very simple feedback. When conditions of a system are suitable (close to one of the attractors), it is driven almost only by deterministic behavior, stochastic influence is very limited. When conditions of the systems are poor, deterministic behavior influence is close to zero and in this case system is driven by stochastic behavior. In this case the system randomly fluctuates searching for a

 ISBN: 978-84-617-8694-7

new attractor. When this attractor is found, deterministic behavior again dominates over stochastic [3].

If we use attractor selection mechanism for network resource management, at first we should define regulatory matrix W, which shows relationships between node pairs, that is, how each node pair affects each other including itself. As it was described in [2], three types of influence exist - activation, inhibition and no relation, corresponding to W_{ij} values of 1,-1 and 0.

2 System

Systems used for modeling gene regulatory networks are generally in the form

$$x_i' = f(\Sigma W_{ij}x_j - \Theta)v_g - x_i v_g + \eta,$$

where $f(z)$ is a continuous bounded monotonically increasing function (sigmoidal regulatory function) and matrix W_{ij} consists of entries describing the relation between nodes of the networks. There are various functions f possessing the desired properties. For instance, the function $f(z) = \frac{1}{1+e^{-\mu z}}$ meets the requirements. The argument z is $z = \Sigma W_{ij}x_j - \Theta$ and it represents the input on a gene with threshold Θ for increasing x_i. The parameter μ changes the slope of a function f and it indicates the gain parameter of the sigmoidal function. The term $-x_i v_g$ represents the rate of decrease in the expression level on gene i. The last term η stands for fluctuations and represents stochastic behaviour. The deterministic and stochastic behaviors are controlled by growth rate v_g, which represents the conditions of the metabolic reaction network. We consider this model under the simplifying conditions $\eta = 0$ and $v_g = 1$.

In extended form the system looks

$$\begin{cases} x_1' = f(W_{11}x_1 + \ldots + W_{1n}x_n - \Theta) - x_1, \\ x_2' = f(W_{21}x_1 + \ldots + W_{2n}x_n - \Theta) - x_2, \\ \ldots \quad \ldots \quad \ldots, \\ x_n' = f(W_{n1}x_1 + \ldots + W_{nn}x_n - \Theta) - x_n, \end{cases} \tag{1}$$

where W_{ij} are entries of the regulatory matrix W. We consider the specific case

$$W = \begin{vmatrix} 0 & 1 & \ldots & 1 \\ 1 & 0 & \ldots & 1 \\ \ldots & \ldots & \ldots & \ldots \\ 1 & 1 & \ldots & 0 \end{vmatrix}, \tag{2}$$

and, consequently,

$$\begin{cases} x_1' = f(x_2 + x_3 + \ldots + x_n - \Theta) - x_1, \\ x_2' = f(x_1 + x_3 + \ldots + x_n - \Theta) - x_2, \\ \ldots \quad \ldots \quad \ldots, \\ x_n' = f(x_1 + x_2 + \ldots + x_{n-1} - \Theta) - x_n. \end{cases} \tag{3}$$

ISBN: 978-84-617-8694-7

We study the system (3) following the standard scheme.

First, the critical points are to be found. The critical points are solutions of the system

$$\begin{cases} x_1 = f(x_2 + x_3 + \ldots + x_n - \Theta), \\ x_2 = f(x_1 + x_3 + \ldots + x_n - \Theta), \\ \ldots \quad \ldots \quad \ldots, \\ x_n = f(x_1 + x_2 + \ldots + x_{n-1} - \Theta). \end{cases} \tag{4}$$

Due to properties of a function f all critical points are located in a bounded n-dimensional cube. Moreover, all critical points are in the form $(x, \ldots, x)$, that is, $x_1 = \ldots = x_n$. This is easy to see, considering pairs x_1 and x_2, x_2 and x_3 and so on. Indeed, let a critical point be $x_1, \ldots, x_n$. If $x_2 > x_1$, then due to monotonicity of f one has that

$$x_1 = f(x_2 + x_3 + \ldots + x_n - \Theta) > f(x_1 + x_3 + \ldots + x_n - \Theta) = x_2.$$

Similarly, if $x_2 < x_1$, then $x_1 < x_2$. The contradictions prove that $x_1 = x_2$.

This is true also for regulatory matrices W with equal positive entries everywhere except the main diagonal. This is important in light of the remark from [4, p. 1823] that "An important step will be to move away from the binary idealization in order to analyze experimental data which is measured on a continuous scale."

Therefore the following is true for the case under consideration.

Proposition 2.1 *Any critical point is of the form $(x, \ldots, x)$ (n times), where x satisfies*

$$x = f((n-1)x - \Theta). \tag{5}$$

3 Linearization

Linearization of system (3) at a critical point $(x, \ldots, x)$ yields

$$\begin{cases} u_1' = -u_1 + a(u_2 + u_3 + \ldots + u_n), \\ u_2' = -u_2 + a(u_1 + u_3 + \ldots + u_n), \\ \ldots \quad \ldots \quad \ldots, \\ u_n' = -u_n + a(u_1 + u_3 + \ldots + u_{n-1}), \end{cases} \tag{6}$$

where $a = \frac{df(s)}{ds}|_{s=((n-1)x)}$. The characteristic equation for the linearization is

$$\det(A - \lambda I) = \begin{vmatrix} -1-\lambda & a & \ldots & a \\ a & -1-\lambda & \ldots & a \\ \ldots & \ldots & \ldots & \ldots \\ a & a & \ldots & -1-\lambda \end{vmatrix} = 0. \tag{7}$$

ISBN: 978-84-617-8694-7

It can be solved analytically and the roots are

$$\lambda_1 = \lambda_2 = \ldots = \lambda_{n-1} = -1 - a, \quad \lambda_n = -1 + (n-1)a. \tag{8}$$

Since $f(s)$ is monotonically increasing, a is positive. Therefore all characteristic values but one are negative (and equal). The sign of the last λ_n depends on the dimensionality n and on the value of a for a particular critical point.

We arrived therefore at the following result.

Theorem 3.1 *An attracting set for the system (3) is a complex of critical points of the form $(x, \ldots, x)$, where x solves (5). Any critical point is either fully attractive (all λ-s are negative) or semi-attractive (the last λ is positive). The case of $\lambda_n = 0$ is possible also and the respective critical point is attractive.*

Visualizations and examples for several choices of f are planned for full version of the article.

On the similarity solutions and conservation laws of the Cooper-Shepard-Sodano equation

M.S. Bruzón[1], A.P. Márquez[1] and R. de la Rosa [1]

[1] *Department of Mathematics, University of Cádiz*

emails: m.bruzon@uca.es, almudena.marquez@uca.es, rafael.delarosa@uca.es

Abstract

In this paper, we study the Cooper-Shepard-Sodano equation from the point of view of Lie symmetries. We perform an analysis of the symmetry reductions taking into account the similarity variables and the similarity solutions which allow us to transform our equation into ordinary differential equations. Furthermore, some conservation laws are derived by applying the multipliers method.

Key words: Conservation laws, Lie symmetries, Partial differential equations, Similarity solutions.

1 Introduction

In [7] the authors considered the Cooper-Shepard-Sodano equation (CSS) given by

$$u_t - c_0 u_x + \eta u_{xxxx} + \frac{1}{l-1}(u^{l-1})_x - \gamma p(u^{p-1}u_x^2)_x + \frac{2\gamma}{p+2}(u^{p+1})_{xxx} = 0, \tag{1}$$

where $u(x,t)$ is time evolved in the moving frame of reference with velocity c_0, l, $p \neq -2$, and γ are arbitrary constants whereas ηu_{xxxx} represents the presence of an artificial dissipation (hyperviscosity). The discussion on the necessity of adding the hyperviscosity term was given in [4]. The authors argued that this term is needed to damp out explicitly the numerical high-frequency dispersive errors introduced by the lack of smoothness at the edge of the discrete representation of the compacton.

In this paper, we consider a generalization of equation (1)

$$u_t - c_0 u_x + \eta u_{xxxx} + (f(u))_x - \gamma(p+1)(g(u)u_x^2)_x + \frac{2\gamma}{p+2}(g(u)u^2)_{xxx} = 0, \tag{2}$$

 ISBN: 978-84-617-8694-7

where $f(u)$ and $g(u)$ are arbitrary functions. We apply Lie theory to equation (2). Firstly, we perform an analysis of the Lie symmetries. From the infinitesimal generators obtained we determine the similarity variables and the similarity solutions which allow us to reduce our equation into ordinary differential equations. Furthermore, the direct method of the multipliers method is used to determine conservation laws.

2 Basic definitions

Let $x = (x^1, \ldots, x^n)$ be n independent variables, and $u = (u^1, \ldots, u^m)$ be m dependent variables with the partial derivatives $u_{(1)} = \{u_i^\alpha\}$, $u_{(2)} = \{u_{ij}^\alpha\}, \ldots$ of the first, second, etc. orders, where $u_i^\alpha = \partial u^\alpha / \partial x^i$, $u_{ij}^\alpha = \partial^2 u^\alpha / \partial x^i \partial x^j$. Let

$$E_\alpha \left(x, u, u_{(1)}, \ldots, u_{(k)}\right) = 0, \quad \alpha = 1, \ldots, m. \tag{3}$$

Denoting

$$D_i = \frac{\partial}{\partial x^i} + u_i^\alpha \frac{\partial}{\partial u^\alpha} + u_{ij}^\alpha \frac{\partial}{\partial u_j^\alpha} + \cdots \tag{4}$$

the total differentiation with respect to x^i, we have:

$$u_i^\alpha = D_i(u^\alpha), \qquad u_{ij}^\alpha = D_i(u_j^\alpha) = D_i D_j(u^\alpha), \quad \cdots$$

The variables u^α are also known as *differential variables*.

A function $f(x, u, u_{(1)}, \ldots)$ of a finite number of variables x, u, $u_{(1)}$, $u_{(2)}, \ldots$ is called a *differential function* if it is locally analytic. The set of all differential functions of all finite orders is denoted by $\mathcal{A}$.

Let ξ^i, $\eta^\alpha \in \mathcal{A}$ be differential functions depending on any finite number of variables x, u, $u_{(1)}$, $u_{(2)}, \ldots$. A first-order linear differential operator

$$X = \xi^i \frac{\partial}{\partial x^i} + \eta^\alpha \frac{\partial}{\partial u^\alpha} + \zeta_i^\alpha \frac{\partial}{\partial u_i^\alpha} + \zeta_{i_1 i_2}^\alpha \frac{\partial}{\partial u_{i_1 i_2}^\alpha} + \cdots, \tag{5}$$

where

$$\begin{aligned} \zeta_i^\alpha &= D_i(\eta^\alpha - \xi^j u_j^\alpha) + \xi^j u_{ij}^\alpha, \\ \zeta_{i_1 i_2}^\alpha &= D_{i_1} D_{i_2}(\eta^\alpha - \xi^j u_j^\alpha) + \xi^j u_{i_1 i_2}^\alpha, \ \ldots \end{aligned} \tag{6}$$

is called a *Lie-Bäcklund operator* [5, 6].

The vector $T = (T^1, T^2, \ldots, T^n)$ where $T^j \in \mathcal{A}$ and $j = 1, \ldots, n$ is a conserved vector if T^i satisfy

$$D_i T^i = 0. \tag{7}$$

Equation (7) is called conservation law.

 ISBN: 978-84-617-8694-7

From the multiplier method [1, 2, 3], every conservation law arises from multipliers $Q^\alpha(x,u,u_{(1)},\ldots)$ such that

$$Q^\alpha E_\alpha = D_i T^i, \tag{8}$$

all the multipliers can be determined solving the determining equation obtained from the variational derivative of

$$\frac{\delta}{\delta u^\beta}(Q^\alpha E_\alpha) = 0, \tag{9}$$

for arbitrary functions of $u(x^1, x^2, \ldots, x^n)$.

In this paper we prove that for $f(u) = u^l$ and $g(u) = u^p$, $l \neq 0$ and p arbitrary constants, equation (2) admits the multiplier

$$Q_1 = 1.$$

Moreover, if $f(u) = u$ and $g(u) = \frac{1}{u}$ besides Q_1 we obtain the following multipliers

$$Q_2 = c_0 t - t + x, \quad Q_3 = \frac{1}{2}\left(c_0 t - t + x\right)^2.$$

3 Lie point symmetries

A vector field

$$X = \xi(x,t,u)\frac{\partial}{\partial x} + \tau(x,t,u)\frac{\partial}{\partial t} + \phi(x,t,u)\frac{\partial}{\partial u}, \tag{10}$$

where $\xi(x,t,u)$, $\tau(x,t,u)$ and $\phi(x,t,u)$ are the infinitesimals, is a generator of a point symmetry of (2) if

$$X^{[4]}[u_t - c_0 u_x + \eta u_{xxxx} + (f(u))_x - \alpha(p+1)(g(u)u_x^2)_x + \frac{2\alpha}{p+1}(g(u)u^2)_{xxx}] = 0, \tag{11}$$

on (2). Here the operator $X^{[4]}$ is the fourth prolongation of the operator X. Requiring the vanishment of the coefficients of the derivatives of u, we obtain an overdetermined system of linear partial differential equations. Solving this system we deduce that when $f(u)$ and $g(u)$ are arbitrary functions and c_0, l, p, γ are arbitrary constants the infinitesimal generators are

$$X_1 = \partial_x, \qquad X_2 = \partial_t.$$

• If $f = a + bu + cu^{3a+4}$ and $g = bu^a$, where a, b, c are constants, the infinitesimal generators are X_1, X_2 and

$$X_3^1 = (3(b+c_0)t + x)\partial x + 4t\partial t - \left(\frac{u}{a+1}\right)\partial u.$$

 ISBN: 978-84-617-8694-7

• If $f = a + bu + cu\ln(u)$, and $g(u) = \frac{a}{u}$, where a, b, c are constants, the infinitesimal generators are X_1, X_2 and

$$X_3^2 = t\partial x + \left(\frac{u}{c}\right)\partial u.$$

From these generators we obtain the similarity solutions.

Abstract

Systems, containing a finite set of N cells (vertices) and particles with *deterministic* or *random* movement between the vertices, are the objects of study. This set of vertices is divided into *cycles* (*contours*), which are closed non self-intersecting sequence of *cells.* Contours have fixed direction of particles movement and may have common cells.

Key words: dynamical system, Contour network, Resolution rule of conflict, Self-organization, Collapse, Variation of function

1 Cellular automaton and BML model of traffic

(1.1) The Biham – Middleton - Levine model was published in 1992, [1]. It is a model of cellular automaton on Manhattan network on torus with two fixed types of particles. Particles move in one of two directions – up or right –, and with deterministic or random rules of priority in alternating times or in each step. A main result of this paper is to obtain the effect of self-organization of the system, when the conflicts disappear over some time, for any admissible initial position of particles. It was also obtained the fact that, at certain load of network, the system will stop, i.e. comes to the state of collapse. Thus it can be aware of the authors, *laid down the foundation of the spectral theory for considered systems.*

(1.2) In the next works there are considered analogical models in spaces with different dimensions, [2], [3]. But the results were using computer simulation methods. Exact results in these works are very small.

(1.3) In the original work of 1992 there was announced the exact result about the movement on an elementary contour that later became the object of study in [4].

 ISBN: 978-84-617-8694-7

2 Description of the systems

(2.1) $(k,1)-$ **networks** We introduce the concept of *system with k-structure (k-networks).* Considered networks consist of contours - closed sequences of cells. Standard characteristic of cell (vertices) V of network is *a degree* $deg(V)$, i.e. the number of contours, to which the considered vertex belongs. We consider networks such that the degree of each vertex is equal to 1 or k.

(2.2)Dynamical parameters of network

(2.2.1) Flow capacity of arc. Between each two neighbour contour cells more than one particle can not simultaneously move in both directions.

(2.2.2) The volume of the cell. In each cell there is simultaneously no more than one particle.

(2.3) Rules of particles movement

(2.3.1) Isolated movement. Initially each contour has a set of particles, S which can move only on this contour.

(2.3.2) Individual movement (I). We assume that the particle in the next moment can not go to the next cell, which is occupied at the moment.

(2.3.3)One-way movement (IOW). Each particle of this set S in one cycle makes an attempt to move forward by one cell, if it is impossible, it remains in it's cell.

(2.3.4)Shake-way motion (ISW). Each particle of this set S alternately in one cycle makes an attempt to move forward by one cell, if not possible, then back by one cell and, otherwise it remains in it's cell.

(2.3.5) Total connected one-way motion (TOW). Each cluster of particles of set S in one cycle alternately makes an attempt to move forward by one cell, if it is impossible, it remains in it's cell. If two sets of particles unite in a certain moment of time, subsequently will be considered as a single cluster.

(2.3.6) Control (Collective one-way (CIOW) and Collective shake-way (CISW)). Allocated area of flow selects behavior based on some criterion. For example, a particle moves or stays in accordance with the maximum of so-called *potential velocity.*

(2.4) The interaction of particles of different circuits (Competition and resolution rules). If particles of different contours are trying to move in the same common cell, there is *a conflict (competition)* of the particles, which is resolved in accordance with a given rule, this rule can be *deterministic* or *stochastic.*

(2.4.1) Deterministic local rule. Deterministic rule is, for example, *the priority rule* to resolve the conflict, in which competition always is won by *the particle with a higher priority* or *a particle in a cell with a higher priority.*

(2.4.2) Stochastic local rule. Stochastic rule is, for example, *a fair rule*, in which the particles involved in the competition are winning with equal probability.

(2.4.3) Collective control. The priority rule is determined by the objective function of a collective of particles on the network.

 ISBN: 978-84-617-8694-7

3 Flows on the contours, trajectory on $N-$ simplex and Rolle theorem

(3.1) Flows on the contours and trajectory on the simplex. Cells are located in the vertices of the canonical simplex

$$\left(0,0,\ldots,0,\underbrace{1,}_{i+1}0,\ldots,0\right), \quad i=0,\ldots,N-1 \tag{1}$$

in N-dimensional space, i.e. the location of the particles in the discrete moments of time. Each cell has no more than one particle. The unit of time a particle either remains in place or moves, which is determined by additional conditions.

There are M particles in the vertices of the canonical simplex. Their locations are given by N-vector, such that M coordinates of the vector are equal to 1, and the other is equal to zero. Thus, the flow of particles can be considered as a movement on the vertices of $M-$ simplex in $N-$ dimensional space. Each contour is associated with a cyclic vector of ones and zeros on the simplex $X(N,M)=\{x\}$, $X=(x_1,x_2,\cdots,x_N)$, where $x_i=0\vee 1$, $i=1,\cdots,N$ $\sum_{i=0}^{N}x_i=M$. Cyclicality means that the first and last coordinates are neighbors.

Cluster *is called any maximum connected sequence of ones.*

Variation *$var(X)$ of cyclic vector is called the double number of clusters.* **Each rule of movement gives a mapping** $A:X\to X$.

We assume, that *mapping A does not reduce the variation,* if

$$Var(A(x))\geq Var(x) \tag{2}$$

$\forall x\in X$. *Mapping A does not increase the variation,* if

$$Var(Ax)\leq Var(x) \tag{3}$$

$\forall x\in X$.

(3.2) Rolle theorem for IOW flows on contour.

Theorem 1.*For IOW flows on a contour, mapping A does not reduce variation, and, if there are two clusters with a distance of more than 1, then variation increases. The flow velocity reaches a stable state over a finite time, and coincides with the relative number of clusters, separated by single empty cells.*

(3.3) Rolle theorem for ISW flows on contour.

Theorem 2. *For ISW flows on a contour, mapping A does not reduce the variation, and if there are two clusters with a distance of more than 1, the variation increases. The flow velocity reaches a stable state over a finite time, and coincides with the relative number of clusters, separated by single empty cells. Other things being equal, the time of reaching steady state for ISW flows does not exceed the value of similar value for IOW flows.*

 ISBN: 978-84-617-8694-7

Remark 1. Nagel-Shrekenberg-Blank state function. In [1],[4] the formula was obtained for the dependence of the velocity of OW-movement of particles on a closed contour

$$v = \begin{cases} 1, \ 0 < r \leq \frac{1}{2}, \\ \frac{1}{r} - 1, \ \frac{1}{2} < r \leq 1. \end{cases}$$

In particular, it is proved, that if density r is less than $\frac{1}{2}$, then velocity of particles is equal to 1, i.e. particles move at each step.

Remark 2. The state function of stochastic IOW-flow on infinite contour. On infinite lattice the movements of particles into cell, which is next empty to the right, occur with probability p. If $N \to \infty$, $M \to \infty$ at constant density $r = M/N$, then we have in the limit of velocity, [6]

$$v = \frac{1 - \sqrt{1 - 4pr(1-r)}}{2r}.$$

4 Flows on contour networks and Rolle theorem

(4.1.) Flows on the two contours with one node (eight).

For this example it is clear, that Rolle theorem must be modified, because it becomes wrong in the above formulation. It is not our purpose here to formulate its analog in the most general terms, but we would like to show that the result tested for centuries can be "rejuvenated".

Let OW-priority rule takes place on one of the contours. Then, after a finite number of steps on the priority contour the flow becomes stationary, and corresponding mapping does not reduce the variation. As for the similar value for minor contour, it behaves much more difficult. Since the movement is locked through a common cell for both contours, as soon as the distance between consecutive clusters on the priority contour near the common cell is not greater than 1.

We introduce COW-movement on the minor contour. Then, during a time interval of length at least three steps, when particles on priority contour will not occupy a common cell, we can pass a particle on minor contour through the common cell.

If there exists a time interval of length at least five steps, when particles on priority contour will not occupy a common cell, then we can pass two particles on minor contour through the common cell.

Thus, control on priority contour is become urgent.

(4.2) Rolle theorem for CIOW flows on Eight-figure contour.

Let m be the number of particles on the priority loop length N, k be the number of particles on the minor contour with the same capacity. If we now introduce the collective control on the priority contour, then we will represent all distances between the particles as a linear combination of odd numbers.

 ISBN: 978-84-617-8694-7

For simplicity, let suppose that $m < N/2$. Define $n = N - m$. We express the number n as a sum of m natural numbers as following

$$n = n_1 + n_2 + \cdots + n_m. \tag{4}$$

Suppose that

$$K = \left[\frac{n_1 - 1}{2}\right] + \left[\frac{n_2 - 1}{2}\right] + \cdots + \left[\frac{n_m - 1}{2}\right]. \tag{5}$$

Denote by K^* the maximum possible value of the numbers K (3) among all possible representations of n in the form (4).

Theorem 3. *If $k < K^*$, then there exists a collective control, resulting in a finite number of steps to non conflict CIOW-flow with maximum velocity and maximum variation of the corresponding operator A.*

(4.3) Rolle theorem for SIOW - flows on linear contour graph.

The linear contour graph is a sequence of contours C_i, $i = 1, \cdots, M$ with the same length, such that neighbor contours C_i, C_{i+1} have a common node. Each IOW-flow on the contour C_i, such that has no conflicts with the contour C_{i-1}, defines demands to the IOW-flow on C_{i+1} with the same conditions. Thus, it is possible to obtain constructive conditions for existence of non conflict flow with a maximum variation on the linear sequence of contours.

5 Logistics of flows on networks

(5.1) Reduction of networks with physical measuring devices.

We suppose a graph is given with weights of edges corresponding to physical distances in the real network. Then we want to construct that the number of movement of particles corresponds to traveled distance, and particle velocity corresponds the number of movements per unit time. Therefore we add to each edge the number of vertices proportional to the edge weight, so that each edge of new graph corresponds the same physical distance. This new graph is an abstract graph with vertices corresponding of simplex with equal distances.

(5.2) Abstract model of traffic and scheduling.

In this section, we go from the description of existing flows to the problems of optimization of networks and flows.

(5.3) Logistic plan of particles

Each i-th particle, $1 \leq i \leq M$, has a location plan (movement) onto the vertices of the simplex. The plan is encoded as a sequence of "numbers" from 0 to $N - 1$ as the follow

$$\{b_1 b_2 b_3 \ldots\ldots b_T b_{T+1} \ldots\}.$$

 ISBN: 978-84-617-8694-7

It is a one-to-one mapping to a positional system with base N.

(5.4) Rules of logistic plan realization. If we assume in the original problem formulation that the canonical simplex is flow supporter, then solution of implementation plan problem for an individual particle can be considered obvious. If, however, flow supporter is an arbitrary graph G, then the use of the abstract scheme for graph G contains a one-to-one correspondence between the vertices, connectivity matrix (adjacency, incidence), and finally the weight (distance, price of movements) between adjacent vertices. Then a question of physical non-proportionality of particles moving to the neighbor vertex per the unit of standard time can be appear. In this case we add the necessary number of vertices to the original graph for correspondence between number of time steps and price (distance).

6 Computer exercises for IOW and SOW flows

We consider the contour of which is composed of N cells which is located M particles, where $1 \leq M \leq N$. Using computer simulation we have evaluated variation of mapping. A for IOW and SOW flow on contour by charging the value of density $r = \frac{M}{N}$ brow 0 to 1 with step $\Delta r = \frac{1}{N}$.

(6.1) IOW flows

With computer modeling was developed for IOW-flow on counter cells $N = 200$ during. Time interval $T = 1000$. It is shown in Fig.1,2 the dynamics of IOW-flow variation for $r = \frac{1}{2}$ and variation interval at changing of density r from 0 to 1.

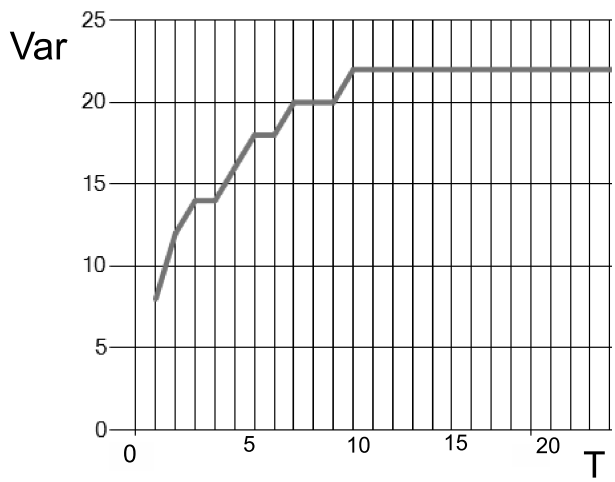

Figure 1: Dynamics of IOW-flow variation, $N = 2000$, $r = \frac{1}{2}$

(6.2) IOW flows

 ISBN: 978-84-617-8694-7

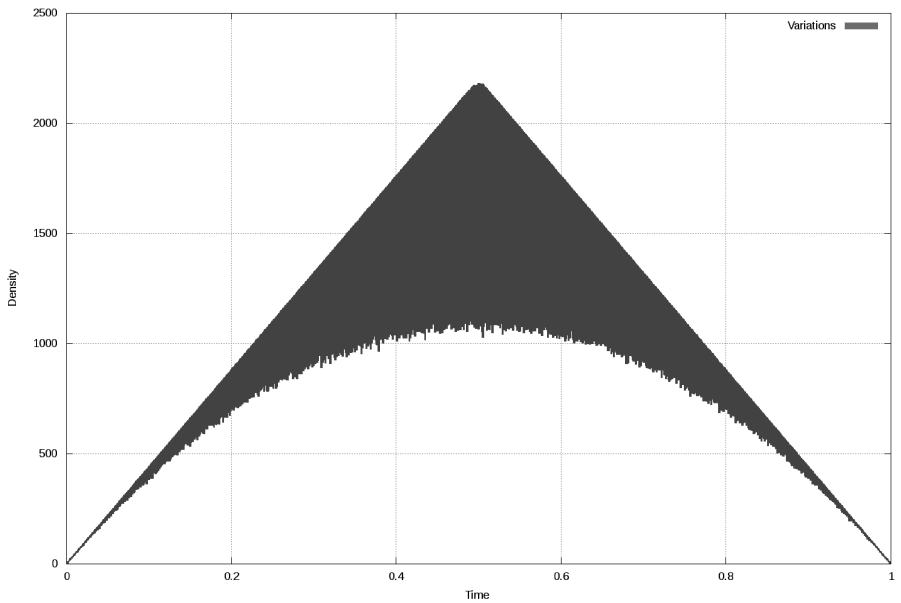

Figure 2: Dependence of IOW-flow variation interval on density r ($N = 2000$)

In Fig.3 it is shown the numerical results of variation interval for ISW-flows on contour.

(6.3) IOW flows at Eight-figure graph

Eight-figure graph consists of two contours with dimensions N_1 and N_2 (numbers of cells) correspondingly, which are connected by one common cell (node). The node connects two cells of each ring and prevents the passage of two particles at the same time. Resolution rule for competition is *stochastic local rule*. In Fig.4 it is shown the dynamics of total variation of the two contours, and variation on each contour with fixed parameters $N_1 = N_2 = 2200$, density $r = 0.5$, modeling time $T = 1000$.

In Fig.5 it is shown the total variation of two contours on dependence the density.

7 Comments. Three-pendulum, Cantor classes and Kolmogorov ideology

Let us assume that a system contains three cells V_0, V_1, V_2 and three particles P_0, P_1, P_2. At any given time there is a single particle in a cell. Particles moving realizes in accordance with their logistic plans given by the number belonging to the interval $(0, 1)$ and represented in the ternary calculus system. Plan of particle P_0 contains only numbers 0 and 1; plan of particle P_1 contains only numbers 1 and 2; plan of particle P_2 contains only numbers 0 and

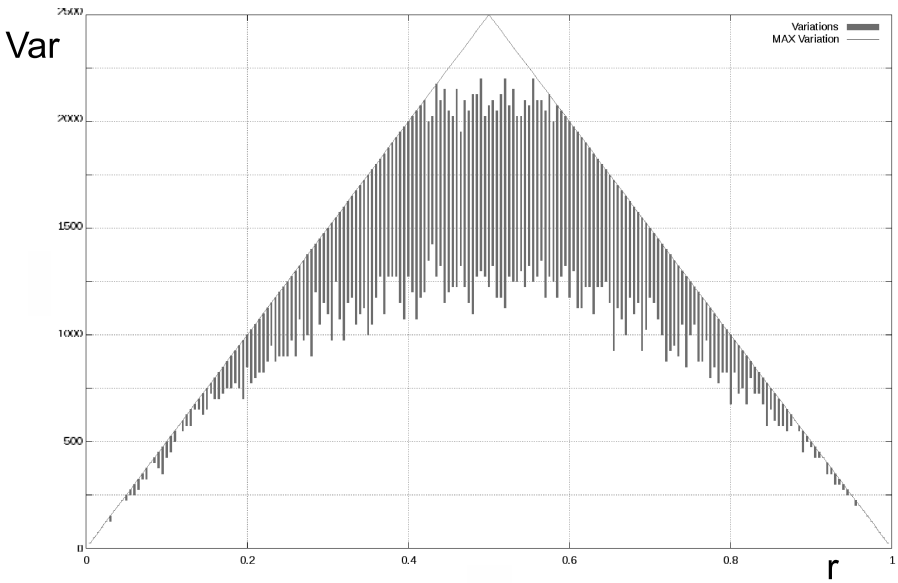

Figure 3: Dependence of SOW-flow variation interval on density r ($N = 2000$)

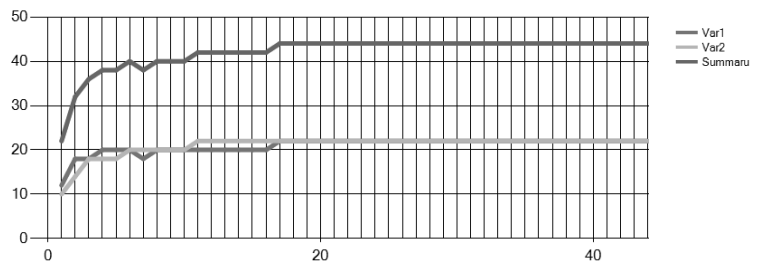

Figure 4: Eight-figure graph: dynamics of variations on each contour $N_1 = N_2 = 2200$ cells, $r = 0.5$, $T = 1000$

2. Thus, the set of admissible plans of each particle is *Cantor set.*

There are only two possible states of the system. In the first state, the particle P_i is located in cell V_i, $i = 0, 1, 2$. In the second state, the particle P_i is located in cell V_{i+1} (addition modulo 3). The system state change occurs, if each particle is scheduled to go to another cell. Kolmogorov ideology is in the follow. We calculate the considered characteristics for classes of plans, which we are interested in extreme values (extremum, "unfashionable" word). In this case, we are interested in the extreme values of coherence or conflict of plans on Cantor subsets of the interval. However, this problem is still open. Assume that each digit of plan takes any of two possible values with a probability $\frac{1}{2}$. Then,

 ISBN: 978-84-617-8694-7

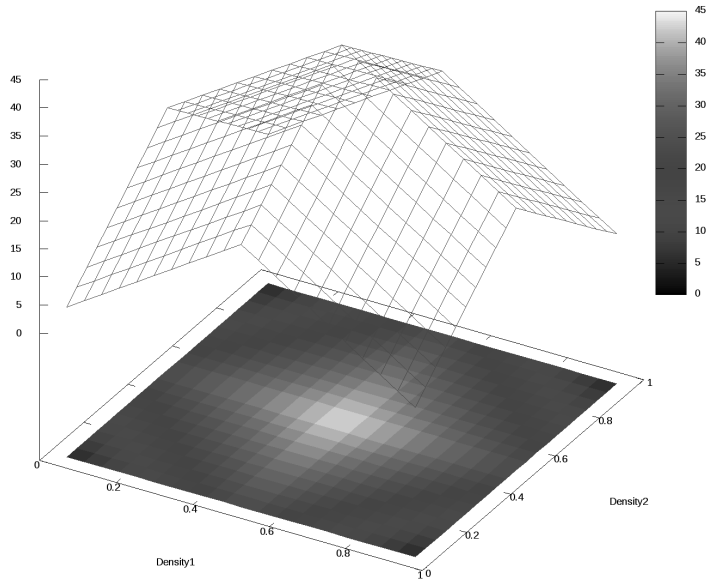

Figure 5: Variation in dependence on densities of both contours of Eight-figure graph

the probability of the event that all three particles have to move to another cell by the plan is equal to $\frac{1}{8}$. Thus, under these conditions the particle velocity is equal to $\frac{1}{8}$.

Abstract

This paper addresses the distributed fusion estimation problem for discrete-time linear stochastic systems with multi-sensor measurements including random parameter matrices. It is assumed that the random parameter matrices in the observation equations are one-step autocorrelated and cross-correlated between the different sensors and the additive noises are also correlated. Under these assumptions, a recursive algorithm is proposed to obtain local least squares linear filters based on the measurements of each sensor, and the distributed fusion filter is designed as the matrix-weighted linear combination of these estimators which minimizes the mean squared estimation error. This research is illustrated by a numerical simulation example where a multi-sensor system with randomly delayed measurements is considered and the performance of the proposed estimators is analyzed by comparing the estimation error variances of the distributed and centralized fusion filters.

Key words: distributed fusion filter, correlated random parameter matrices, randomly delayed measurements

MSC 2000: 60G35, 62M20, 93E11

1 Introduction

In recent years, the use of sensor networks has received significant attention in many practical domains, since they usually provide more information than traditional single-sensor communication systems. For this reason, the fusion estimation problem in sensor network stochastic systems has been widely studied in many fields of science, technology and military, such as navigation and detection.

 ISBN: 978-84-617-8694-7

Although there are several information fusion techniques, the most common fusion estimation approaches are the centralized and distributed ones. The former is based on the measurements from all the sensors, which are sent to a fusion centre, and so, it provides the optimal estimator when all the sensors work accurately. However, a sensor error can spoil the performance of the centralized filter and may give rise to heavy computational burden and poor reliability. In the distributed fusion estimation approach, each single sensor sends a local estimator to the fusion centre, where the state is estimated by a combination of all the received local filters using a certain optimality criterion. Thus, the distributed approach has lower estimation accuracy, which is compensated with considerable advantages, such as greater robustness and reliability. Therefore, the distributed fusion method is usually more attractive and has become an interesting research topic (see e.g. [1]-[4] and references therein).

In general, there are many situations with network-induced phenomena, such as multiplicative noise uncertainties, random delays, packet dropouts and missing measurements, in which the state estimation problem can be addressed by transforming the original system into one with random parameter matrices. For example, in [1] and [5] systems with packet dropouts and/or random delays are transformed into systems with random parameter matrices. Also, systems with multiplicative noises in the state and observation equations as those investigated in [3] are special cases of this kind of systems. The optimal filtering problem is addressed for a class of discrete-time stochastic systems with multiplicative noises and random sensor delays in [6] and, later, also with missing measurements in [7], by transforming the original system into one with random parameter matrices.

Accordingly, the study of the estimation problem in systems with random parameter matrices has become an active research field. In [8] a distributed Kalman filtering fusion is proposed for systems with independent random state transition and measurement matrices and white noises. For a class of discrete-time multisensor stochastic systems also with independent random parameter matrices but autocorrelated and cross-correlated noises, the centralized fusion estimation problem has been addressed under the phenomena of fading measurements in [9]. Moreover, by considering this same correlation assumption of the noise processes and one-step correlated and cross-correlated random measurement matrices, the centralized fusion linear filter is obtained in [10], where the results are applied to systems with missing measurements and randomly delayed observations. The distributed fusion estimation problem has also been studied for sensor network systems with independent random parameter matrices and correlated noises in [11]. Centralized and distributed fusion estimation problems are both studied in [12] for networked systems with random parameter matrices, from measurements subject to random delays and packet dropouts during the transmission, using only covariance information.

Motivated by the above discussion, this paper deals with the distributed fusion estimation problem for discrete-time linear stochastic systems with multi-sensor measurements

 ISBN: 978-84-617-8694-7

including correlated and cross-correlated random parameter matrices and noises. On the one hand, it complements [10], where the centralized fusion estimation problem is analyzed for an analogous class of discrete-time stochastic systems with the same correlation assumptions. In this way, the results obtained are applied to multi-sensor systems with correlated randomly delayed measurements as a particular case. On the other, it is different from [11], where the distributed fusion filtering estimators are obtained for networked systems with independent random state transition and measurement matrices, whereas correlation of the random parameter matrices in the observation equation is considered in the current paper.

The rest of the paper is organized as follows. Section 2 describes the system model with correlated and cross-correlated random parameter matrices and noises, specifying the assumptions under which the distributed fusion estimation problem is addressed. In Section 3, the local least squares linear filtering algorithm is given, and the proposed distributed fusion filter is designed by a matrix-weighted linear combination of the local filters using the mean squared error optimality criterion. An illustrative simulation example is given in Section 4 to show the applicability of the proposed filtering algorithm. Finally, some conclusions are drawn in Section 5.

2 System model

Let us consider the following discrete-time linear stochastic system with measurements coming from m different sensors:

$$\begin{aligned} &x_{k+1} = F_k x_k + w_k, \quad k \geq 0, \\ &y_k^{(i)} = H_k^{(i)} x_k + B_k^{(i)} v_k^{(i)}, \quad k \geq 1, \quad i = 1, \ldots, m, \end{aligned} \tag{1}$$

where $x_k \in \mathbb{R}^{n_x}$ is the state vector to be estimated and $y_k^{(i)} \in \mathbb{R}^{n_y}$, $i = 1, \ldots, m$, is the output measurement of the $i-$th sensor at the sampling time k. $w_k \in \mathbb{R}^{n_x}$ and $v_k^{(i)} \in \mathbb{R}^{n_v}$ are the process and measurement noise vectors, respectively. F_k is the state transition matrix and $H_k^{(i)}$ and $B_k^{(i)}$ are the measurement matrices, all of them with random parameters and suitable dimensions.

The following assumptions about the initial state, the random parameter matrices and the noises involved in system (1) are required.

Assumption 1. The initial state x_0 is a zero-mean random vector with $Cov[x_0] = \Sigma_0$. Also, it is assumed to be independent of the random parameter matrices and noise processes.

Assumption 2. $\{F_k;\, k \geq 0\}$, $\{H_k^{(i)};\, k \geq 1\}$ and $\{B_k^{(i)};\, k \geq 1\}$ have known means, which will be denoted $\overline{F}_k \equiv E[F_k]$, $\overline{H}_k^{(i)} \equiv E[H_k^{(i)}]$ and $\overline{B}_k^{(i)} \equiv E[B_k^{(i)}]$, $i = 1, \ldots, m$. Also, for

 ISBN: 978-84-617-8694-7

$i, j = 1, \ldots, m$, the following expectations are assumed to be known

$$\begin{aligned}
&E[f_{pq}(k) f_{p'q'}(s)] = E[f_{pq}(k) f_{p'q'}(k)]\delta_{k,s},\\
&E[h_{pq}^{(i)}(k) h_{p'q'}^{(j)}(s)] = E[h_{pq}^{(i)}(k) h_{p'q'}^{(j)}(k)]\delta_{k,s} + E[h_{pq}^{(i)}(k) h_{p'q'}^{(j)}(k-1)]\delta_{k-1,s}, \quad s \leq k,\\
&E[b_{pq}^{(i)}(k) b_{p'q'}^{(j)}(s)] = E[b_{pq}^{(i)}(k) b_{p'q'}^{(j)}(k)]\delta_{k,s} + E[b_{pq}^{(i)}(k) b_{p'q'}^{(j)}(k-1)]\delta_{k-1,s}, \quad s \leq k,\\
&E[h_{pq}^{(i)}(k) b_{p'q'}^{(j)}(s)] = E[h_{pq}^{(i)}(k) b_{p'q'}^{(j)}(k)]\delta_{k,s} + E[h_{pq}^{(i)}(k) b_{p'q'}^{(j)}(k-1)]\delta_{k-1,s}\\
&\qquad\qquad + E[h_{pq}^{(i)}(k) b_{p'q'}^{(j)}(k+1)]\delta_{k+1,s},
\end{aligned}$$

where $f_{pq}(k)$, $h_{pq}^{(i)}(k)$ and $b_{pq}^{(i)}(k)$ denote the (p,q)-th entries of F_k, $H_k^{(i)}$ and $B_k^{(i)}$, respectively.

Assumption 3. $\{w_k;\, k \geq 0\}$ and $\{v_k^{(i)};\, k \geq 1\}$, $i = 1, \ldots, m$, are zero-mean sequences and the following covariances and cross-covariances are known

$$\begin{aligned}
&E[w_k w_s^T] = Q_k \delta_{k,s} + Q_{k,k-1}\delta_{k-1,s}, \quad s \leq k,\\
&E[v_k^{(i)} v_s^{(j)T}] = R_k^{(ij)}\delta_{k,s} + R_{k,k-1}^{(ij)}\delta_{k-1,s}, \quad s \leq k, \quad i, j = 1, \ldots, m,\\
&E[w_k v_s^{(i)T}] = S_k^{(i)}\delta_{k,s} + S_{k,k+1}^{(i)}\delta_{k+1,s} + S_{k,k+2}^{(i)}\delta_{k+2,s}, \quad i = 1, \ldots, m.
\end{aligned}$$

Assumption 4. Independence assumptions:

- $\{F_k;\, k \geq 0\}$ is independent of $\Big(\{H_k^{(i)};\, k \geq 1\},\, \{B_k^{(i)};\, k \geq 1\},\, \{w_k;\, k \geq 0\},\, \{v_k^{(i)};\, k \geq 1\},\, i = 1, \ldots, m\Big)$
- $\Big(\{H_k^{(i)};\, k \geq 1\},\, \{B_k^{(i)};\, k \geq 1\},\, i = 1, \ldots, m\Big)$ is independent of $\Big(\{F_k;\, k \geq 0\},\, \{w_k;\, k \geq 0\},\, \{v_k^{(i)};\, k \geq 1\},\, i = 1, \ldots, m\Big)$

The following property will be used to calculate some expectations involving the random parameter matrices F_k, $H_k^{(i)}$ and $B_k^{(i)}$, $i = 1, \ldots, m$:

Let $A = \Big(a_{rs}\Big)_{\substack{r=1,\ldots,n_1\\ s=1,\ldots,n_2}}$, $B = \Big(b_{rs}\Big)_{\substack{r=1,\ldots,m_1\\ s=1,\ldots,m_2}}$ *and* $C = \Big(c_{rs}\Big)_{\substack{r=1,\ldots,n_2\\ s=1,\ldots,m_2}}$ *be random parameter matrices, such that* C *is independent of* (A, B)*; then, the* (p,q)*-th entries of the matrix* $E[ACB^T]$ *are given by*

$$\Big(E[ACB^T]\Big)_{pq} = \sum_{r=1}^{n_2}\sum_{s=1}^{m_2} E[a_{pr}b_{qs}]E[c_{rs}], \quad p = 1, \ldots, n_1, \quad q = 1, \ldots, m_1.$$

Our aim is to address the least squares (LS) linear filtering problem in this class of systems with correlated and cross-correlated random parameter matrices and noises using the distributed fusion approach.

 ISBN: 978-84-617-8694-7

3 Distributed fusion filtering estimators

In this section, the distributed fusion filter of the state x_k based on the available measurements $y_1^{(i)}, \ldots, y_k^{(i)}$, $i = 1, \ldots, m$, is designed. First, at each sensor, a local LS linear filtering recursive algorithm is obtained using its own measurement data. Then, these estimators are sent to the fusion centre where the distributed fusion filter is computed.

3.1 Local LS linear filters

In order to simplify the expressions of the local linear filtering estimators and the subsequent calculations, let us first present the following properties [10]:

1. The matrices $\mathcal{D}_{k+1} \equiv E[x_{k+1}x_{k+1}^T]$ and $\mathcal{D}_{k+1,k} \equiv E[x_{k+1}x_k^T]$ are recursively calculated by

$$\begin{array}{l} \mathcal{D}_{k+1} = E[F_k\mathcal{D}_kF_k^T] + \overline{F}_kQ_{k-1,k} + Q_{k,k-1}\overline{F}_k^T + Q_k, \quad k \geq 1; \\ \mathcal{D}_1 = E[F_0\mathcal{D}_0F_0^T] + Q_0; \quad \mathcal{D}_0 = \Sigma_0, \\ \mathcal{D}_{k+1,k} = \overline{F}_k\mathcal{D}_k + Q_{k,k-1}, \quad k \geq 1; \quad \mathcal{D}_{1,0} = \overline{F}_0\mathcal{D}_0. \end{array} \tag{2}$$

2. The noise processes $\{w_k;\, k \geq 0\}$ and $\{v_k^{(i)};\, k \geq 1\}$, $i = 1, \ldots, m$, satisfy the following correlation properties

$$\begin{array}{l} \mathcal{W}_k^{(i)} \equiv E[w_k y_k^{(i)T}] = Q_{k,k-1}\overline{H}_k^{(i)T} + S_k^{(i)}\overline{B}_k^{(i)T}, \quad k \geq 1, \\ \mathcal{E}_k^{(i)} \equiv E[x_k v_k^{(i)T}] = \overline{F}_{k-1}S_{k-2,k}^{(i)} + S_{k-1,k}^{(i)}, \quad k \geq 2; \quad \mathcal{E}_1^{(i)} = S_{0,1}^{(i)}, \\ \mathcal{E}_{k,k-1}^{(i)} \equiv E[x_k v_{k-1}^{(i)T}] = \overline{F}_{k-1}\mathcal{E}_{k-1}^{(i)} + S_{k-1}^{(i)}, \quad k \geq 2, \\ \mathcal{V}_{k,k-1}^{(ij)} \equiv E[B_k^{(i)}v_k^{(i)}y_{k-1}^{(j)T}] = E[B_k^{(i)}S_{k-2,k}^{(i)T}H_{k-1}^{(j)T}] + E[B_k^{(i)}R_{k,k-1}^{(ij)}B_{k-1}^{(j)T}], \quad k \geq 2. \end{array} \tag{3}$$

For each sensor $i = 1, \ldots, m$, a recursive algorithm for the local LS linear filter, $\widehat{x}_{k/k}^{(i)}$, together with its filtering error covariance matrix, $\Sigma_{k/k}^{(i)}$, is given in the following theorem.

Theorem 1 *For system* (1)*, under assumptions 1-4, the local LS linear filter for the* i*-th sensor,* $\widehat{x}_{k/k}^{(i)}$*,* $i = 1, \ldots, m$*, is given by*

$$\widehat{x}_{k/k}^{(i)} = \widehat{x}_{k/k-1}^{(i)} + \mathcal{X}_k^{(i)}\Pi_k^{(i)-1}\mu_k^{(i)}, \quad k \geq 1; \quad \widehat{x}_{0/0}^{(i)} = 0,$$

where the one-step predictor, $\widehat{x}_{k/k-1}^{(i)}$*, is calculated by*

$$\widehat{x}_{k/k-1}^{(i)} = \overline{F}_{k-1}\widehat{x}_{k-1/k-1}^{(i)} + \mathcal{W}_{k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mu_{k-1}^{(i)}, \quad k \geq 2; \quad \widehat{x}_{1/0}^{(i)} = 0.$$

 ISBN: 978-84-617-8694-7

The innovation, $\mu_k^{(i)}$*, is obtained by*

$$\mu_k^{(i)} = y_k^{(i)} - \overline{H}_k^{(i)}\widehat{x}_{k/k-1}^{(i)} - \mathcal{Y}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mu_{k-1}^{(i)}, \quad k \geq 2; \quad \mu_1^{(i)} = y_1^{(i)},$$

where, denoting $\widetilde{H}_k^{(i)} \equiv H_k^{(i)} - \overline{H}_k^{(i)}$*, the matrix* $\mathcal{Y}_{k,k-1}^{(i)} \equiv E[y_k^{(i)}\mu_{k-1}^{(i)T}]$ *satisfies*

$$\mathcal{Y}_{k,k-1}^{(i)} = E[\widetilde{H}_k^{(i)}\mathcal{D}_{k,k-1}H_{k-1}^{(i)T}] + E[\widetilde{H}_k^{(i)}\mathcal{E}_{k,k-1}^{(i)}B_{k-1}^{(i)T}] + \mathcal{V}_{k,k-1}^{(i)}, \quad k \geq 2.$$

The matrix $\mathcal{X}_k^{(i)} \equiv E[x_k\mu_k^{(i)T}]$ *is obtained by*

$$\begin{aligned}
\mathcal{X}_k^{(i)} &= \Sigma_{k/k-1}^{(i)}\overline{H}_k^{(i)T} + \mathcal{E}_k^{(i)}\overline{B}_k^{(i)T} - \mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{Y}_{k,k-1}^{(i)T}, \quad k \geq 2;\\
\mathcal{X}_1^{(i)} &= \Sigma_{1/0}^{(i)}\overline{H}_1^{(i)T} + \mathcal{E}_1^{(i)}\overline{B}_1^{(i)T},
\end{aligned}$$

where $\mathcal{X}_{k,k-1}^{(i)} \equiv E[x_k\mu_{k-1}^{(i)T}]$ *is given by* $\mathcal{X}_{k,k-1}^{(i)} = \overline{F}_{k-1}\mathcal{X}_{k-1}^{(i)} + \mathcal{W}_{k-1}^{(i)}$, $k \geq 2$.
The innovation covariance matrix, $\Pi_k^{(i)}$*, satisfies*

$$\begin{aligned}
\Pi_k^{(i)} &= E[\widetilde{H}_k^{(i)}\mathcal{D}_k H_k^{(i)T}] + E[\widetilde{H}_k^{(i)}\mathcal{E}_k^{(i)}B_k^{(i)T}] + E[B_k^{(i)}\mathcal{E}_k^{(i)T}\widetilde{H}_k^{(i)T}] + E[B_k^{(i)}R_k^{(i)}B_k^{(i)T}]\\
&\quad + \overline{H}_k^{(i)}\mathcal{X}_k^{(i)} + \mathcal{X}_k^{(i)T}\overline{H}_k^{(i)T} - \overline{H}_k^{(i)}\Sigma_{k/k-1}^{(i)}\overline{H}_k^{(i)T} - \mathcal{Y}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{Y}_{k,k-1}^{(i)T}, \quad k \geq 2;\\
\Pi_1^{(i)} &= E[\widetilde{H}_1^{(i)}\mathcal{D}_1 H_1^{(i)T}] + E[H_1^{(i)}\mathcal{E}_1^{(i)}B_1^{(i)T}] + E[B_1^{(i)}\mathcal{E}_1^{(i)T}H_1^{(i)T}]\\
&\quad + E[B_1^{(i)}R_1^{(i)}B_1^{(i)T}] + \overline{H}_1^{(i)}\Sigma_{1/0}^{(i)}\overline{H}_1^{(i)T}.
\end{aligned}$$

The filtering error covariance matrix, $\Sigma_{k/k}^{(i)}$*, is computed by*

$$\Sigma_{k/k}^{(i)} = \Sigma_{k/k-1}^{(i)} - \mathcal{X}_k^{(i)}\Pi_k^{(i)-1}\mathcal{X}_k^{(i)T}, \quad k \geq 1; \quad \Sigma_{0/0}^{(i)} = \Sigma_0,$$

where the prediction error covariance matrix, $\Sigma_{k/k-1}^{(i)}$*, is given by*

$$\begin{aligned}
\Sigma_{k/k-1}^{(i)} &= \mathcal{D}_k + \overline{F}_{k-1}(\Sigma_{k-1/k-1}^{(i)} - \mathcal{D}_{k-1})\overline{F}_{k-1}^T + \mathcal{W}_{k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{W}_{k-1}^{(i)T}\\
&\quad - \mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{W}_{k-1}^{(i)T} - \mathcal{W}_{k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{X}_{k,k-1}^{(i)T}, \quad k \geq 2;\\
\Sigma_{1/0}^{(i)} &= \mathcal{D}_1.
\end{aligned}$$

Finally, $\mathcal{D}_k$*,* $\mathcal{D}_{k,k-1}$ *and* $\mathcal{W}_k^{(i)}$*,* $\mathcal{E}_k^{(i)}$*,* $\mathcal{E}_{k,k-1}^{(i)}$*,* $\mathcal{V}_{k,k-1}^{(i)}$ *are given in* (2) *and* (3)*, respectively.*

3.2 Distributed fusion filter weighted by matrices

As we have already indicated, our aim is to design a distributed fusion filter, $\widehat{x}_{k/k}^{(D)}$, as a matrix-weighted sum of the local filters, $\widehat{x}_{k/k}^{(i)}$, $i=1,\ldots,m$, such that the optimal weighting matrices are computed to minimize the mean squared estimation error. The following two lemmas provide some expectations required to obtain the proposed fusion estimator. Hereafter, the assumptions and notations used are the same as those in Theorem 1.

Lemma 1 *For $i,j=1,\ldots,m$ and $i\neq j$, the expectation $L_k^{(ij)}\equiv E[\widehat{x}_{k/k-1}^{(i)}\mu_k^{(j)T}]$ satisfies*

$$\begin{aligned}L_k^{(ij)}&=\left(\overline{F}_{k-1}K_{k-1/k-2}^{(i)}\overline{F}_{k-1}^T-K_{k/k-1}^{(ij)}\right)\overline{H}_k^{(j)T}\\&\quad+\mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\left(\Delta_{k,k-1}^{(ji)T}+\mathcal{V}_{k,k-1}^{(ji)T}\right)-L_{k,k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\mathcal{Y}_{k,k-1}^{(j)T},\quad k\geq 2;\ L_1^{(ij)}=0,\end{aligned}$$

where the expectation $\Delta_{k,k-1}^{(ij)}\equiv E[H_k^{(i)}x_k\mu_{k-1}^{(j)T}]$ is obtained by

$$\begin{aligned}\Delta_{k,k-1}^{(ij)}&=E[H_k^{(i)}\mathcal{D}_{k,k-1}H_{k-1}^{(j)T}]+E[H_k^{(i)}\mathcal{E}_{k,k-1}^{(j)}B_{k-1}^{(j)T}]\\&\quad-\overline{H}_k^{(i)}\overline{F}_{k-1}\left(K_{k-1/k-2}^{(j)}\overline{H}_{k-1}^{(j)T}+\mathcal{X}_{k-1,k-2}^{(j)}\Pi_{k-2}^{(j)-1}\mathcal{Y}_{k-1,k-2}^{(j)T}\right),\quad k\geq 3;\\\Delta_{2,1}^{(ij)}&=E[H_2^{(i)}\mathcal{D}_{2,1}H_1^{(j)T}]+E[H_2^{(i)}\mathcal{E}_{2,1}^{(j)}B_1^{(j)T}]-\overline{H}_2^{(i)}\overline{F}_1K_{1/0}^{(j)}\overline{H}_1^{(j)T},\end{aligned}$$

and $L_{k,k-1}^{(ij)}\equiv E[\widehat{x}_{k/k-1}^{(i)}\mu_{k-1}^{(j)T}]$ is computed by $L_{k,k-1}^{(ij)}=\overline{F}_{k-1}L_{k-1}^{(ij)}+\mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\Pi_{k-1}^{(ij)}$, $k\geq 2$. The cross-covariance matrices, $K_{k/k-1}^{(ij)}\equiv E[\widehat{x}_{k/k-1}^{(i)}\widehat{x}_{k/k-1}^{(j)T}]$ are computed by

$$\begin{aligned}K_{k/k-1}^{(ij)}&=\overline{F}_{k-1}K_{k-1/k-2}^{(ij)}\overline{F}_{k-1}^T+\overline{F}_{k-1}L_{k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\mathcal{X}_{k,k-1}^{(j)T}\\&\quad+\mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}L_{k-1}^{(ji)T}\overline{F}_{k-1}^T+\mathcal{X}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\Pi_{k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\mathcal{X}_{k,k-1}^{(j)T},\quad k\geq 2,\ i\neq j;\\K_{k/k-1}^{(i)}&=\mathcal{D}_k-\Sigma_{k/k-1}^{(i)},\quad k\geq 2;\quad K_{1/0}^{(ij)}=0.\end{aligned}$$

Lemma 2 *For $i,j=1,\ldots,m$ and $i\neq j$, the cross-covariance matrices of the innovations, $\Pi_k^{(ij)}\equiv E[\mu_k^{(i)}\mu_k^{(j)T}]$, are given by*

$$\begin{aligned}\Pi_k^{(ij)}&=\Delta_k^{(ij)}+E[B_k^{(i)}\mathcal{E}_k^{(i)T}H_k^{(j)T}]+E[B_k^{(i)}R_k^{(ij)}B_k^{(j)T}]\\&\quad-\mathcal{V}_{k,k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\left(\overline{H}_k^{(j)}\mathcal{X}_{k,k-1}^{(j)}+\mathcal{Y}_{k,k-1}^{(j)}\right)^T-\overline{H}_k^{(i)}L_k^{(ij)}-\mathcal{Y}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\Pi_{k-1,k}^{(ij)},\quad k\geq 2;\\\Pi_1^{(ij)}&=\Delta_1^{(ij)}+E[B_1^{(i)}\mathcal{E}_1^{(i)T}H_1^{(j)T}]+E[B_1^{(i)}R_1^{(ij)}B_1^{(j)T}],\end{aligned}$$

where the expectations $\Delta_k^{(ij)}\equiv E[H_k^{(i)}x_k\mu_k^{(j)T}]$ are obtained by

$$\begin{aligned}\Delta_k^{(ij)}&=E[H_k^{(i)}\mathcal{D}_kH_k^{(j)T}]+E[H_k^{(i)}\mathcal{E}_k^{(j)}B_k^{(j)T}]-\overline{H}_k^{(i)}\overline{F}_{k-1}K_{k-1/k-2}^{(j)}\overline{F}_{k-1}^T\overline{H}_k^{(j)T}\\&\quad-\Delta_{k,k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\left(\overline{H}_k^{(j)}\mathcal{X}_{k,k-1}^{(j)}+\mathcal{Y}_{k,k-1}^{(j)}\right)^T,\quad k\geq 2;\\\Delta_1^{(ij)}&=E[H_1^{(i)}\mathcal{D}_1H_1^{(j)T}]+E[H_1^{(i)}\mathcal{E}_1^{(j)}B_1^{(j)T}],\end{aligned}$$

 ISBN: 978-84-617-8694-7

and $\Pi_{k-1,k}^{(ij)} \equiv E[\mu_{k-1}^{(i)}\mu_k^{(j)T}]$ *are given by*

$$\Pi_{k-1,k}^{(ij)} = \Delta_{k,k-1}^{(ji)T} + \mathcal{V}_{k,k-1}^{(ji)T} - L_{k,k-1}^{(ji)T}\overline{H}_k^{(j)T} - \Pi_{k-1}^{(ij)}\Pi_{k-1}^{(j)-1}\mathcal{Y}_{k,k-1}^{(j)T}, \quad k \geq 2.$$

The distributed fusion filter, $\widehat{x}_{k/k}^{(D)}$, and its error covariance matrix, $\Sigma_{k/k}^{(D)}$, are given in the following theorem.

Theorem 2 *Let* $\widehat{X}_{k/k} = (\widehat{x}_{k/k}^{(1)T}, \ldots, \widehat{x}_{k/k}^{(m)T})^T$ *be the vector consisting of the local filters obtained in Theorem 1. Then, the distributed fusion filter for the system* (1) *is given by*

$$\widehat{x}_{k/k}^{(D)} = \Xi_{k/k}K_{k/k}^{-1}\widehat{X}_{k/k}, \quad k \geq 1,$$

where $K_{k/k} = \left(K_{k/k}^{(ij)}\right)_{i,j=1,\ldots,m}$ *and* $\Xi_{k/k} = (K_{k/k}^{(1)}, \ldots, K_{k/k}^{(m)})$, *with the cross-covariance matrices,* $K_{k/k}^{(ij)}$, $i,j = 1,\ldots,m$, *between any two local filters calculated as*

$$\begin{aligned} K_{k/k}^{(ij)} &= K_{k/k-1}^{(ij)} + L_k^{(ij)}\Pi_k^{(j)-1}\mathcal{X}_k^{(j)T} + \mathcal{X}_k^{(i)}\Pi_k^{(i)-1}L_k^{(ji)T} \\ &\quad + \mathcal{X}_k^{(i)}\Pi_k^{(i)-1}\Pi_k^{(ij)}\Pi_k^{(j)-1}\mathcal{X}_k^{(j)T}, \quad k \geq 1,\, i \neq j; \quad K_{k/k}^{(i)} = \mathcal{D}_k - \Sigma_{k/k}^{(i)}, \quad k \geq 1. \end{aligned}$$

The error covariance matrices of the distributed fusion filtering estimators are computed by

$$\Sigma_{k/k}^{(D)} = \mathcal{D}_k - \Xi_{k/k}K_{k/k}^{-1}\Xi_{k/k}^T, \quad k \geq 1.$$

Finally, the matrices $L_k^{(ij)}$, $K_{k/k-1}^{(ij)}$ *and* $\Pi_k^{(ij)}$ *are given in Lemmas 1 and 2, respectively.*

4 Numerical simulation example

In this section we show that the results obtained in the current paper for the system model with random measurement matrices (1) can be applied to multi-sensor systems with correlated randomly delayed measurements as a particular case.

Consider a discrete-time linear stochastic system with state-dependent multiplicative noise and scalar randomly delayed measurements coming from two sensors:

$$\begin{aligned} &x_k = (0.95 + 0.2\epsilon_{k-1})x_{k-1} + w_{k-1}, \quad k \geq 1, \\ &z_k^{(i)} = C^{(i)}x_k + v_k^{(i)}, \quad k \geq 1, \quad i = 1,2, \\ &y_k^{(i)} = (1-\gamma_k^{(i)})z_k^{(i)} + \gamma_k^{(i)}z_{k-1}^{(i)}, \quad k \geq 2, \quad y_1^{(i)} = z_1^{(i)}, \quad i = 1,2 \end{aligned} \tag{4}$$

where $\{\epsilon_k;\ k \geq 0\}$ is a zero-mean Gaussian white process with unit variance. Let us assume that $C^{(1)} = 0.7$ and $C^{(2)} = 0.6$. The additive noises are defined as $w_k = 0.6(\eta_k + \eta_{k+1})$ and

 ISBN: 978-84-617-8694-7

$v_k^{(i)} = c^{(i)}\eta_k,\ i = 1, 2$, where $c^{(1)} = 1$, $c^{(2)} = 0.8$ and $\{\eta_k;\, k \geq 0\}$ is a zero-mean Gaussian white process with variance 0.5.

For $i = 1, 2$, the random variables $\gamma_k^{(i)}$, which model the random delays, are defined by two independent sequences of independent Bernoulli random variables, $\{\alpha_k^{(i)};\, k \geq 1\}$, $i = 1, 2$, with probabilities $P[\alpha_k^{(i)} = 1] = \overline{\alpha}^{(i)}$; specifically, for $i = 1, 2$, $\gamma_k^{(i)} = \alpha_{k+1}^{(i)}(1 - \alpha_k^{(i)})$.

Taking into account the previous definition, at each sensor the variables $\gamma_k^{(i)}$ and $\gamma_s^{(i)}$ are independent for $|k - s| \neq 0, 1$ but correlated at consecutive sampling times. The mean of these variables is $\overline{\gamma}^{(i)} = \overline{\alpha}^{(i)}(1 - \overline{\alpha}^{(i)})$, $i = 1, 2$ and the correlation function is given by $E[\gamma_k^{(i)}\gamma_s^{(i)}] = \begin{cases} \overline{\gamma}^{(i)}, & |k-s| = 0 \\ 0, & |k-s| = 1 \end{cases}$.

In order to apply the theoretical results established in Section 3, system (4) can be equivalently rewritten as the following one, with random parameter matrices:

$$\begin{aligned} &X_{k+1} = \mathcal{F}_k X_k + W_k, \quad k \geq 0, \\ &y_k^{(i)} = H_k^{(i)} X_k + B_k^{(i)} V_k^{(i)}, \quad k \geq 1, \quad i = 1, 2, \end{aligned} \tag{5}$$

where

$$X_k = \begin{pmatrix} x_k \\ x_{k-1} \end{pmatrix}, \quad k \geq 1, \quad X_0 = \begin{pmatrix} x_0 \\ 0 \end{pmatrix}, \quad \mathcal{F}_k = \begin{pmatrix} 0.95 + 0.2\epsilon_k & 0 \\ 1 & 0 \end{pmatrix}, \quad W_k = \begin{pmatrix} w_k \\ 0 \end{pmatrix},\ k \geq 0$$

$$H_k^{(i)} = \begin{cases} \left(C^{(i)}, 0\right), & k = 1 \\ \left((1 - \gamma_k^{(i)})C^{(i)}, \gamma_k^{(i)} C^{(i)}\right), & k \geq 2 \end{cases}, \quad B_k^{(i)} = \begin{cases} \left(1, 0\right), & k = 1 \\ \left(1 - \gamma_k^{(i)}, \gamma_k^{(i)}\right), & k \geq 2 \end{cases},$$

$$V_k^{(i)} = \begin{cases} \left(v_1^{(i)}, 0\right)^T, & k = 1 \\ \left(v_k^{(i)}, v_{k-1}^{(i)}\right)^T, & k \geq 2 \end{cases}.$$

The new noise processes and the random parameter matrices of system (5) satisfy the assumptions 1-4 to apply the algorithm proposed in this paper. Specifically, we have:

- $\{H_k^{(i)};\, k \geq 1\}$ and $\{B_k^{(i)};\, k \geq 1\}$ are correlated and cross-correlated at consecutive sampling times.
- The additive noises $\{W_k;\, k \geq 0\}$ and $\{V_k^{(i)};\, k \geq 1\}$ are correlated, with

$$\begin{aligned} &Q_k = \begin{pmatrix} 0.36 & 0 \\ 0 & 0 \end{pmatrix},\ k \geq 0, \quad Q_{k,k-1} = \begin{pmatrix} 0.18 & 0 \\ 0 & 0 \end{pmatrix},\ k \geq 1, \\ &R_1^{(ij)} = \begin{pmatrix} 0.5c^{(i)}c^{(j)} & 0 \\ 0 & 0 \end{pmatrix}, \quad R_k^{(ij)} = \begin{pmatrix} 0.5c^{(i)}c^{(j)} & 0 \\ 0 & 0.5c^{(i)}c^{(j)} \end{pmatrix}, \\ &R_{k,k-1}^{(ij)} = \begin{pmatrix} 0 & 0 \\ 0.5c^{(i)}c^{(j)} & 0 \end{pmatrix},\ k \geq 2, \end{aligned}$$

 ISBN: 978-84-617-8694-7

$$S_k^{(i)} = \begin{pmatrix} 0.3c^{(i)} & 0 \\ 0 & 0 \end{pmatrix}, \; k \geq 1,$$

$$S_{0,1}^{(i)} = S_1^{(i)}, \quad S_{k-1,k}^{(i)} = \begin{pmatrix} 0.3c^{(i)} & 0.3c^{(i)} \\ 0 & 0 \end{pmatrix}, \quad S_{k-2,k}^{(i)} = \begin{pmatrix} 0 & 0.3c^{(i)} \\ 0 & 0 \end{pmatrix}, \; k \geq 2.$$

To illustrate the feasibility of the proposed estimators, the corresponding algorithms were implemented in MATLAB, and one hundred iterations of the centralized linear filtering algorithm ([10]) and the proposed distributed filtering algorithm were run. The error variances of both distributed and centralized fusion filters were calculated for several values of $\overline{\alpha}^{(i)}$ which provide different values of the delay probabilities $\overline{\gamma}^{(i)}$, $i = 1, 2$. Only the cases $\overline{\alpha}^{(i)} \leq 0.5$ are displayed due to the symmetry of $\overline{\gamma}^{(i)} = \overline{\alpha}^{(i)}(1 - \overline{\alpha}^{(i)})$.

Figure 1 shows local, centralized, and distributed filtering error variances considering $\overline{\alpha}^{(1)} = 0.5$ and $\overline{\alpha}^{(2)} = 0.1$. This figure confirms that the distributed fusion filter outperforms each local filter and that the centralized method is more accurate than the distributed one.

Next, in order to show the dependence of the error variances upon the values $\overline{\alpha}^{(1)}$ and $\overline{\alpha}^{(2)}$, Figure 2 displays the filtering error variances, at a fixed iteration (namely, $k = 100$), when both $\overline{\alpha}^{(1)}$ and $\overline{\alpha}^{(2)}$ are varied from 0.1 to 0.5, which provide different values of the delay probabilities $\overline{\gamma}^{(1)}$ and $\overline{\gamma}^{(2)}$ ($\overline{\gamma}^{(i)} = 0.09, 0.16, 0.21, 0.24, 0.25$). In both graphs we can see that worse estimations are obtained as the delay probabilities increase. Also, this figure confirms the similar accuracy of both methods, centralized and distributed.

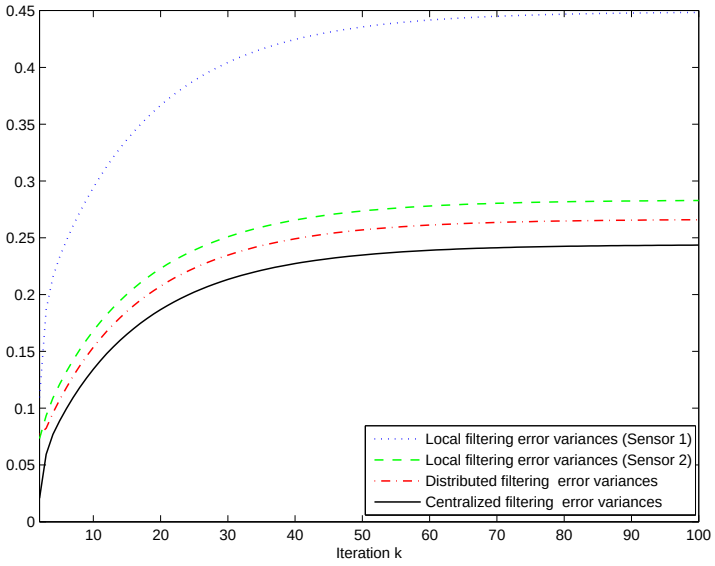

Figure 1: Filtering error variances for $\overline{\alpha}^{(1)} = 0.5$ and $\overline{\alpha}^{(2)} = 0.1$.

 ISBN: 978-84-617-8694-7

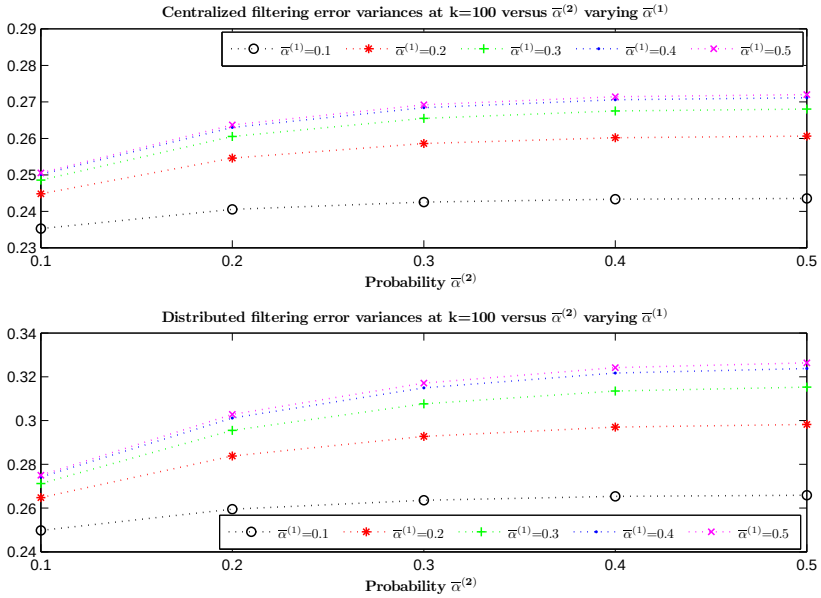

Figure 2: Filtering error variances at $k = 100$ versus $\overline{\alpha}^{(2)}$ with $\overline{\alpha}^{(1)}$ varying from 0.1 to 0.5.

5 Conclusion

The distributed fusion filtering problem has been addressed for multi-sensor stochastic systems with correlated random parameter matrices and additive noises. Firstly, recursive algorithms for the local LS linear filters of the system state based on the measurements coming from each sensor have been obtained. Next, a distributed fusion filter has been designed as a matrix-weighted linear combination of such local estimators by minimizing the mean squared estimation error. The applicability of the proposed estimators has been illustrated by a numerical simulation example, where an error variance comparison has been carried out to show the performance of the centralized and distributed fusion estimators.

Abstract

The centralized fusion estimation problem is addressed for a class of discrete-time multisensor networked systems subject to random transmission one-step delays and non-consecutive packet dropouts with different rates. For each sensor, a different sequence of Bernoulli variables is used to model these random transmission failures, and the measured outputs are perturbed by both random parameter matrices and white noises. Using an innovation approach and without requiring full knowledge of the signal evolution model, but only the first and second order moments of the processes involved, a computationally simple and easily implementable recursive algorithm is obtained for the centralized prediction and filtering problems. The proposed estimators depend on the delay probabilities at each sampling time, but do not need to know if a particular measurement is delayed or well-timed. A numerical example is given which support our analysis and shows how the random delays influence the estimation accuracy.

Key words: centralized fusion estimation, random delays and packet dropouts

1 Introduction

Over the past few decades, the scientific community has been concerned with networked systems, where the observations provided by all the network sensors are transmitted to a fusion center for being processed, and considerable attention has been paid to the fusion estimation of signals over multisensor systems with networked-induced random phenomena, such as missing and fading measurements, sensor gain degradation or multiplicative noise uncertainties, among others (see e.g. [1]-[5]).

 ISBN: 978-84-617-8694-7

Also, due to the limited bandwidths of the communication channels, random delays and/or packet losses are inevitable during the data transmission through the network and, hence, the measurements received by the processing center may be imperfect. Standard observation models are not appropriate under these transmission uncertainties, and classical estimation algorithms cannot be applied directly. For this reason, random delays and packet dropouts are two important issues which have received significant attention in the research of the estimation problem in networked systems (see e.g. [6]-[10]). Due to the random nature of transmission delays and packet dropouts, they can be described by Bernoulli random variables; however, different observation models are employed depending on whether each packet at sensor side is transmitted several times, in order to avoid losses as far as possible (see, e.g. [6]), or just once in order to avoid the network congestion (see e.g. [8]).

In relation to the mentioned networked-induced random phenomena, it is worth noting that random parameter measurement matrices can be used to describe, for example, missing or fading sensor measurements, and the networked systems involving stochastic multiplicative noises can be rewritten by using random parameter measurement matrices. Also, based on an augmentation approach, systems with random delays and packet dropouts, or systems with two-step random delays, can be transformed into systems with random parameter matrices. Consequently, this kind of systems with random parameter matrices provide an appropriate unified framework to model some of the aforementioned networked-induced random phenomena; this fact has encouraged an increasing research interest in the fusion estimation problems in this class of systems (see e.g. [11]- [16], and references therein).

Driven by the above considerations, this paper is concerned with the centralized fusion problem over multisensor networked systems using measurements perturbed by random parameter matrices and additive white noises, which are transmitted to the fusion center and one-step random delays and non-consecutive losses, with different rates, may occur during the transmission process. In order to avoid the network congestion, at each sampling time, the measured output of each sensor is sent just once and only one packet or no packet is available at the fusion center. The main contributions of this paper can be highlighted as follows: (1) the observation model considers random parameter matrices in the measured outputs and, simultaneously, random one-step delays and non-consecutive packet dropouts with different rates in the transmission; (2) an optimal least-squares linear recursive prediction and filtering algorithm is obtained without requiring full knowledge of the state-space model generating the signal process; and (3) the innovation technique is used, simplifying substantially the derivation of the algorithm, due to the fact that the innovation process is a white noise.

The rest of the paper is organized as follows. Section 2 presents the observation model with random parameter matrices and random one-step delays and non-consecutive packet dropouts to be considered. In Section 3, a recursive algorithm for the centralized least-squares linear prediction and filtering estimators is derived. In Section 4, the performance

 ISBN: 978-84-617-8694-7

of the proposed algorithm is illustrated by a numerical simulation example. Section 5 summarizes the main conclusions of the current study and points out some future research lines.

Notation: The notation used throughout the paper is standard. $\mathbb{R}^n$ denotes the n-dimensional Euclidean space. A^T and A^{-1} denote the transpose and inverse of a matrix A, respectively. The shorthand $Diag(a_1, \ldots, a_m)$ denotes a diagonal matrix whose diagonal entries are $a_1, \ldots, a_m$. $\mathbf{1} = (1, \ldots, 1)^T$ denotes the all-ones vector and I the identity matrix. If the dimensions of matrices are not explicitly stated, they are assumed to be compatible for algebraic operations. The notation $\otimes$ and $\circ$ represent the Kronecker and Hadamard products, respectively. Finally, $\delta_{k,s}$ represents the Kronecker delta function.

2 Problem formulation

Our aim is to find a recursive algorithm for the optimal least-squares (LS) linear prediction and filtering problem of a multidimensional discrete-time random signal using measurements perturbed by random parameter matrices and additive white noises, which are transmitted by multiple sensors, assuming that one-step random delays and non-consecutive losses may occur during the transmission process, with different rates at the different sensors. Next, we present the observation model and the assumptions under which the estimation problem will be addressed.

Observation model. Consider a networked system with m sensor nodes, which provide measured outputs, $z_k^{(i)} \in \mathbb{R}^{n_z}$, of the signal vector, $x_k \in \mathbb{R}^{n_x}$, according to the following model:

$$z_k^{(i)} = H_k^{(i)} x_k + v_k^{(i)}, \quad k \geq 1; \quad i = 1, \ldots, m, \tag{1}$$

where:

(H1) $\{x_k;\ k \geq 1\}$, the signal process, has zero mean and its autocovariance function is given by: $E[x_k x_s^T] = A_k B_s^T,\ s \leq k$, where $A_k, B_k,\ k \geq 1$, are known matrices.

(H2) $\{H_k^{(i)};\ k \geq 1\}$, $i = 1, \ldots, m$, are independent sequences of independent random parameter matrices, whose entries have known means and second-order moments; we will denote $\overline{H}_k^{(i)} \equiv E[H_k^{(i)}],\ k \geq 1$.

(H3) $\{v_k^{(i)};\ k \geq 1\},\ i = 1, \ldots, m$, are white noise sequences with zero mean and known second-order moments, satisfying $E[v_k^{(i)} v_s^{(j)T}] = R_k^{(ij)} \delta_{k,s}, \quad i, j = 1, \ldots, m$.

It is assumed that, at any sampling time, the outputs are transmitted from the m different sensors to a data processing center, where the signal estimation is performed and,

 ISBN: 978-84-617-8694-7

as a consequence of possible failures during the transmission process, one-step delays and non-consecutive packet dropouts may occur randomly in the transmission. In order to avoid the network congestion, for each $i = 1, \ldots, m$, the measured output $z_k^{(i)}$ of the i-th sensor is sent just once and only one packet or no packet is available at the processing center. Namely, for $i = 1, \ldots, m$, the measurements received are modelled as follows:

$$y_k^{(i)} = (1 - \gamma_k^{(i)}) z_k^{(i)} + \gamma_k^{(i)} \gamma_{k-1}^{(i)} z_{k-1}^{(i)}, \quad k \geq 2, \qquad y_1^{(i)} = (1 - \gamma_1^{(i)}) z_1^{(i)}, \tag{2}$$

where:

(H4) $\{\gamma_k^{(i)};\ k \geq 1\},\ i = 1, \ldots, m$, are independent sequences of independent Bernoulli random variables with known means, $\overline{\gamma}_k^{(i)} \equiv E[\gamma_k^{(i)}],\ k \geq 1$.

Also, it is assumed that,

(H5) For $i = 1, \ldots, m$, the processes $\{x_k;\ k \geq 1\}$, $\{H_k^{(i)};\ k \geq 1\}$, $\{v_k^{(i)};\ k \geq 1\}$, $\{\gamma_k^{(i)};\ k \geq 1\}$ are mutually independent.

Stacked observation model. To address the estimation problem through the centralized fusion method, the observations of the different sensors $\{y_1^{(i)}, \ldots, y_k^{(i)},\ i = 1, \ldots, m\}$, are gathered and jointly processed at each sampling time; for this purpose, the observation equations (1) and (2) are combined yielding the following observation model:

$$\begin{array}{l} z_k = H_k x_k + v_k, \quad k \geq 1. \\ y_k = (I - \Gamma_k) z_k + \Gamma_k \Gamma_{k-1} z_{k-1}, \quad k \geq 2; \qquad y_1 = (I - \Gamma_1) z_1, \end{array} \tag{3}$$

where $z_k = (z_k^{(1)T}, \ldots, z_k^{(m)T})^T$, $H_k = (H_k^{(1)T}, \ldots, H_k^{(m)T})^T$, $v_k = (v_k^{(1)T}, \ldots, v_k^{(m)T})^T$ and $\Gamma_k = Diag(\gamma_k^{(1)}, \ldots, \gamma_k^{(m)}) \otimes I$.

Hence, the problem is to obtain the LS linear estimator of the signal, x_k, based on the randomly delayed observations $\{y_1, \ldots, y_L\}$, $L \leq k$, given in (3). Next, we present the statistical properties of the processes involved in the observation model (3), from which the LS linear prediction and filtering algorithm of the signal x_k will be derived; these properties are easily inferred from the model hypotheses *(H1)-(H5)* previously established.

(P1) $\{H_k;\ k \geq 1\}$ is a sequence of independent random parameter matrices with known means, $\overline{H}_k \equiv E[H_k] = \left(\overline{H}_k^{(1)T}, \ldots, \overline{H}_k^{(m)T}\right)^T$, and

$$E[H_k x_k x_s^T H_s^T] = E[H_k A_k B_s^T H_s^T] = \left(E[H_k^{(i)} A_k B_s^T H_s^{(j)T}]\right)_{i,j=1\ldots,m}, \quad s \leq k,$$

 ISBN: 978-84-617-8694-7

where $E[H_k^{(i)}A_kB_s^TH_s^{(j)T}] = \overline{H}_k^{(i)}A_kB_s^T\overline{H}_s^{(j)T}$, for $j \neq i$ or $s \neq k$, and the entries of $E[H_k^{(i)}A_kB_k^TH_k^{(i)T}]$ are computed as follows:

$$\left(E[H_k^{(i)}A_kB_k^TH_k^{(i)T}]\right)_{pq} = \sum_{a=1}^{n_x}\sum_{b=1}^{n_x} E[h_{pa}^{(i)}(k)h_{qb}^{(i)}(k)](A_kB_k^T)_{ab}, \quad p,q = 1,\ldots,n_z,$$

where $h_{pq}^{(i)}(k)$ denotes the $(p,q)-$entry of the matrix $H_k^{(i)}$.

(P2) The noise $\{v_k;\ k \geq 1\}$ is a zero-mean sequence with known second-order moments defined by the matrices $R_k \equiv (R_k^{(ij)})_{i,j=1,\ldots,m}$.

(P3) The random matrices $\{\Gamma_k;\ k \geq 1\}$ are independent or, equivalently, the process $\{\gamma_k;\ k \geq 1\}$, where $\gamma_k = (\gamma_k^{(1)},\ldots,\gamma_k^{(m)})^T \otimes \mathbf{1}$, is a white sequence; their first and second-order moments are known, and the following notation will be used

- $\overline{\Gamma}_k \equiv E[\Gamma_k] = Diag\left(\overline{\gamma}_k^{(1)},\ldots,\overline{\gamma}_k^{(m)}\right) \otimes I.$
- $K_k^{\gamma} \equiv E\left[\gamma_k\gamma_k^T\right], \quad K_k^{\mathbf{1}-\gamma} \equiv E\left[(\mathbf{1}-\gamma_k)(\mathbf{1}-\gamma_k)^T\right], \quad K_k^{\gamma,\mathbf{1}-\gamma} \equiv E\left[\gamma_k(\mathbf{1}-\gamma_k)^T\right].$

(P4) The processes $\{x_k;\ k \geq 1\}$, $\{H_k;\ k \geq 1\}$, $\{v_k;\ k \geq 1\}$ and $\{\Gamma_k;\ k \geq 1\}$ are mutually independent.

Remark 1: From the previous properties, it is clear that $\{z_k;\ k \geq 1\}$ and $\{y_k;\ k \geq 1\}$ are zero-mean processes whose correlation functions, $\Sigma_{k,s}^z \equiv E[z_kz_s^T]$ and $\Sigma_{k,s}^y \equiv E[y_ky_s^T]$, for $s = k, k-1$, are obtained by the following expressions:

$$\begin{array}{l}
\Sigma_{k,s}^z = E[H_kA_kB_s^TH_s^T] + R_k\delta_{k,s}, \quad s \leq k. \\
\Sigma_k^y = K_k^{\mathbf{1}-\gamma} \circ \Sigma_k^z + K_k^{\mathbf{1}-\gamma,\gamma} \circ \Sigma_{k,k-1}^z\overline{\Gamma}_{k-1} + K_k^{\gamma,\mathbf{1}-\gamma} \circ \overline{\Gamma}_{k-1}\Sigma_{k-1,k}^z + K_k^{\gamma} \circ K_{k-1}^{\gamma} \circ \Sigma_{k-1}^z, \ k \geq 2; \\
\Sigma_1^y = K_1^{\mathbf{1}-\gamma} \circ \Sigma_1^z. \\
\Sigma_{k,k-1}^y = (I-\overline{\Gamma}_k)\Sigma_{k,k-1}^z(I-\overline{\Gamma}_{k-1}) + (I-\overline{\Gamma}_k)\Sigma_{k,k-2}^z\overline{\Gamma}_{k-2}\overline{\Gamma}_{k-1} + \overline{\Gamma}_kK_{k-1}^{\gamma,\mathbf{1}-\gamma} \circ \Sigma_{k-1}^z \\
\qquad\qquad + \overline{\Gamma}_kK_{k-1}^{\gamma} \circ \Sigma_{k-1,k-2}^z\overline{\Gamma}_{k-2}, \ k \geq 3; \\
\Sigma_{2,1}^y = (I-\overline{\Gamma}_2)\Sigma_{2,1}^z(I-\overline{\Gamma}_1) + \overline{\Gamma}_2K_1^{\gamma,\mathbf{1}-\gamma} \circ \Sigma_1^z.
\end{array} \tag{4}$$

3 Centralized fusion estimators

In this section, a recursive algorithm for the LS linear centralized fusion prediction and filtering estimators of the signal is obtained by an innovation approach. According to such approach, the observation process $\{y_k;\ k \geq 1\}$ is transformed into an equivalent one (innovation process) of orthogonal vectors $\{\mu_k;\ k \geq 1\}$, defined by $\mu_k = y_k - \widehat{y}_{k/k-1}$, where

$\widehat{y}_{k/k-1}$ is the orthogonal projection of y_k onto the linear space generated by $\{\mu_1,\ldots,\mu_{k-1}\}$. So, the LS linear estimator of any random vector w_k based on the observations $\{y_1,\ldots,y_L\}$, denoted as $\widehat{w}_{k/L}$, agrees with that based on the innovations $\{\mu_1,\ldots,\mu_L\}$, and, denoting $\Pi_h = E[\mu_h\mu_h^T]$, the following general expression for the LS linear estimators of w_k is obtained

$$\widehat{w}_{k/L} = \sum_{h=1}^{L} E[w_k\mu_h^T]\Pi_h^{-1}\mu_h. \tag{5}$$

One-stage observation predictor. To simplify future formulas and expressions, the observation model (3) will be equivalently written as follows:

$$y_k = (I-\Gamma_k)H_kx_k + \Gamma_k\overline{\Gamma}_{k-1}\overline{H}_{k-1}x_{k-1} + V_k, \quad k\geq 2,$$

where $V_k = (I-\Gamma_k)v_k + \Gamma_k\Gamma_{k-1}v_{k-1} + \Gamma_k(\Gamma_{k-1}H_{k-1} - \overline{\Gamma}_{k-1}\overline{H}_{k-1})x_{k-1}$.

From the general expression (5), denoting $\mathcal{V}_{k,h} \equiv E[V_k\mu_h^T]$, $h\leq k-1$, and since $\mathcal{V}_{k,h}=0$ for $h\leq k-2$, we obtain that $\widehat{V}_{k/k-1} = \mathcal{V}_{k,k-1}\Pi_{k-1}^{-1}\mu_{k-1}$, $k\geq 2$; hence, from the orthogonal projection lemma (OPL), the observation predictor is given by

$$\widehat{y}_{k/k-1} = (I-\overline{\Gamma}_k)\overline{H}_k\widehat{x}_{k/k-1} + \overline{\Gamma}_k\overline{\Gamma}_{k-1}\overline{H}_{k-1}\widehat{x}_{k-1/k-1} + \mathcal{V}_{k,k-1}\Pi_{k-1}^{-1}\mu_{k-1}, \quad k\geq 2 \tag{6}$$

and, consequently, the one-stage predictor and filter of the signal x_k are needed .

Centralized prediction and filtering recursive algorithm. The following theorem presents a recursive algorithm for the optimal LS linear centralized fusion estimators $\widehat{x}_{k/L}$, $L\leq k$, of the signal x_k based on the observations $\{y_1,\ldots,y_L\}$ given by (3).

Theorem 1. *The centralized predictor and filter, $\widehat{x}_{k/L}$, $L\leq k$, and the corresponding error covariance matrices, $\widehat{\Sigma}_{k/L} \equiv E[(x_k-\widehat{x}_{k/L})(x_k-\widehat{x}_{k/L}^T)]$, are obtained by*

$$\widehat{x}_{k/L} = A_ke_L, \quad L\leq k, \tag{7}$$

$$\widehat{\Sigma}_{k/L} = A_k\left(B_k - A_k\Sigma_L^e\right)^T, \quad k\geq 1, \tag{8}$$

where the vectors e_L and the matrices $\Sigma_L^e \equiv E[e_Le_L^T]$ are recursively obtained from

$$e_L = e_{L-1} + \mathcal{E}_L\Pi_L^{-1}\mu_L, \quad L\geq 1; \qquad e_0 = 0, \tag{9}$$

$$\Sigma_L^e = \Sigma_{L-1}^e + \mathcal{E}_L\Pi_L^{-1}\mathcal{E}_L^T, \quad L\geq 1; \quad \Sigma_0^e = 0. \tag{10}$$

The innovation, μ_L, satisfies

$$\mu_L = y_L - \overline{\mathcal{H}}_{A_L}e_{L-1} - \mathcal{V}_{L,L-1}\Pi_{L-1}^{-1}\mu_{L-1}, \quad L\geq 2; \quad \mu_1 = y_1, \tag{11}$$

 ISBN: 978-84-617-8694-7

where $\mathcal{V}_{L,L-1} = \Sigma^y_{L,L-1} - \mathcal{H}_{A_L}\mathcal{H}^T_{B_{L-1}}$, *and the innovation covariance,* Π_L, *is given by*

$$\Pi_L = \Sigma^y_L - \overline{\mathcal{H}}_{A_L}(\overline{\mathcal{H}}^T_{B_L} - \mathcal{E}_L) - \mathcal{V}_{L,L-1}\Pi^{-1}_{L-1}(\overline{\mathcal{H}}_{A_L}\mathcal{E}_{L-1} + \mathcal{V}_{L,L-1})^T, \quad L \geq 2; \quad \Pi_1 = \Sigma^y_1. \tag{12}$$

The matrices $\mathcal{E}_L$ *are given by*

$$\mathcal{E}_L = \overline{\mathcal{H}}^T_{B_L} - \Sigma^e_{L-1}\overline{\mathcal{H}}^T_{A_L} - \mathcal{E}_{L-1}\Pi^{-1}_{L-1}\mathcal{V}^T_{L,L-1}, \quad L \geq 2; \quad \mathcal{E}_1 = \overline{\mathcal{H}}^T_{B_1}. \tag{13}$$

Finally, the matrices Σ^y_L *and* $\Sigma^y_{L,L-1}$ *are given in (4), and the matrices* $\overline{\mathcal{H}}_{\Psi_L}$ *with* $\Psi_L = A_L,\ B_L$, *are defined by*

$$\overline{\mathcal{H}}_{\Psi_L} = (I - \overline{\Gamma}_L)\overline{H}_L\Psi_L + \overline{\Gamma}_L\overline{\Gamma}_{L-1}\overline{H}_{L-1}\Psi_{L-1}, \quad L \geq 2; \quad \overline{\mathcal{H}}_{\Psi_1} = (I - \overline{\Gamma}_1)\overline{H}_1\Psi_1. \tag{14}$$

Proof. From the general expression (5), to obtain the LS linear estimators $\widehat{x}_{k/L}$, $L \leq k$, it is necessary to calculate the coefficients $\mathcal{X}_{k,h} \equiv E[x_k\mu^T_h] = E[x_k y^T_h] - E[x_k\widehat{y}^T_{h/h-1}], \quad h \leq k$.

From *(H.1)* and the independence hypotheses, we have that $E[x_k y^T_h] = A_k\overline{\mathcal{H}}^T_{B_h}$, with $\overline{\mathcal{H}}_{B_h}$ given in (14). Now, using expression (6) for $\widehat{y}_{h/h-1}$, together with (5) for $\widehat{x}_{h/h-1}$ and $\widehat{x}_{h-1/h-1}$, we obtain that the filter coefficients are expressed as $\mathcal{X}_{k,h} = A_k\mathcal{E}_h,\ h \leq k$, where

$$\mathcal{E}_h = \overline{\mathcal{H}}^T_{B_h} - \sum_{j=1}^{h-1}\mathcal{E}_j\Pi^{-1}_j\mathcal{E}^T_j\overline{\mathcal{H}}^T_{A_h} - \mathcal{E}_{h-1}\Pi^{-1}_{h-1}\mathcal{V}^T_{h,h-1}, \quad h \geq 2; \quad \mathcal{E}_1 = \overline{\mathcal{H}}^T_{B_1}.$$

Then, by defining

$$e_L = \sum_{h=1}^{L}\mathcal{E}_h\Pi^{-1}_h\mu_h,\ L \geq 1; \quad e_0 = 0 \text{ and } \quad \Sigma^e_L = \sum_{h=1}^{L}\mathcal{E}_h\Pi^{-1}_h\mathcal{E}_h,\ L \geq 1; \quad \Sigma^e_0 = 0,$$

and taking into account that $E[e_L\mu^{(i)T}_h] = \mathcal{E}_h$, for $h \leq L$, and $E[e_L y^T_L] = \overline{\mathcal{H}}^T_{B_L}$, it is easy to obtain expressions (7)-(11) and (13) of Theorem 1.

Finally, expression (12) for Π_L is obtained taking into account that from the OPL, the innovation covariance matrix can be expressed as $\Pi_L = E[y_L y^T_L] - E[\widehat{y}_{L/L-1}\widehat{y}^T_{L/L-1}]$, and using that $\widehat{y}_{L/L-1} = \overline{\mathcal{H}}_{A_L}e_{L-1} + \mathcal{V}_{L,L-1}\Pi^{-1}_{L-1}\mu_{L-1}$. Then the proof is complete. □

4 Numerical simulation example

Consider a zero-mean scalar signal $\{x_k;\ k \geq 1\}$ with autocovariance function given by $E[x_k x_s] = 1.025641 \times 0.95^{k-s}, \quad s \leq k$, which is factorizable according to *(H1)* taking for example $A_k = 1.025641 \times 0.95^k$ and $B_k = 0.95^{-k}$. Measured outputs perturbed by white additive noises coming from two sensors are considered, and two different types of uncertainty are assumed in both sensors: missing measurements in sensor 1, and gain degradation in sensor 2. Specifically,

$$z^{(i)}_k = H^{(i)}_k x_k + v^{(i)}_k, \quad k \geq 1, \quad i = 1, 2,$$

 ISBN: 978-84-617-8694-7

with $H_k^{(i)} = 0.8\lambda_k^{(i)}$, where $\{\lambda_k^{(i)};\ k \geq 1\}$, $i = 1, 2$, are sequences of independent random variables, such that, for all $k \geq 1$, $\lambda_k^{(1)}$ a Bernoulli variable with $P[\lambda_k^{(1)} = 1] = p$, and $\lambda_k^{(2)}$ is uniformly distributed on the interval $[0.1, 0.9]$. The additive noises are defined as $v_k^{(i)} = c_i\eta_k$, $i = 1, 2$, where $c_1 = 0.5$, $c_2 = 0.75$, and $\{\eta_k;\ k \geq 1\}$ is a zero-mean Gaussian white process with unit variance. Also, we assume that the sequences $\{\eta_k;\ k \geq 1\}$ and $\{\lambda_k^{(i)};\ k \geq 1\}$, $i = 1, 2$, are mutually independent.

Now, according to the proposed observation model, it is assumed that, at any sampling time $k \geq 1$, the measured output from the i-th sensor, can be randomly delayed by one sampling period or lost during network transmission; that is,

$$y_k^{(i)} = (1 - \gamma_k^{(i)})z_k^{(i)} + \gamma_k^{(i)}\gamma_{k-1}^{(i)}z_{k-1}^{(i)}, \quad k \geq 2, \quad y_1^{(i)} = (1 - \gamma_1^{(i)})z_1^{(i)}; \qquad i = 1, 2,$$

where $\{\gamma_k^{(i)};\ k > 1\}$, $i = 1,\ 2$, are independent sequences of independent Bernoulli random variables with constant probabilities, $P[\gamma_k^{(i)} = 1] = \overline{\gamma}^{(i)}$.

To illustrate the effectiveness and applicability of the proposed estimators, the centralized prediction and filtering algorithm was implemented in MATLAB and a hundred iterations were performed.

Firstly, in order to compare the performance of the predictors, $\widehat{z}_{k/L}$, $L = k - 3,\ k - 2,\ k - 1$ and the filter, $\widehat{z}_{k/k}$, their error variances are calculated considering constant values $p = 0.5$ and $\overline{\gamma}^{(1)} = 0.2$, $\overline{\gamma}^{(2)} = 0.4$. The results are displayed in Figure 1, which shows that the filtering error variances are smaller than the prediction ones, thus confirming that the filter outperforms the predictor. Also, this figure shows that the predictor becomes more accurate as the number of available observations increases. Analogous results are obtained for other values of the probabilities p, $\overline{\gamma}^{(1)}$ and $\overline{\gamma}^{(2)}$.

Next, we analyze the sensitivity of the estimation performance to the variation of the probability p that the signal is present in the measurements of the first sensor. For this purpose, the filtering error variances are calculated for different values of p, when $\overline{\gamma}^{(1)} = 0.2$ and $\overline{\gamma}^{(2)} = 0.4$. The results are given in Figure 2, which shows that, as p increases, the filtering error variances become smaller and, hence, better estimations are obtained. Analogous conclusions are deduced for other values of $\overline{\gamma}^{(1)}$, $\overline{\gamma}^{(2)}$ and p.

Finally, considering a fixed value of p, namely $p = 0.5$, the filtering error variances have been calculated for different values of the delay probabilities $\overline{\gamma}^{(1)}$ and $\overline{\gamma}^{(2)}$. Specifically, the values $\overline{\gamma}^{(1)} = 0.1,\ 0.2,\ 0.3,\ 0.4,\ 0.5$, and $\overline{\gamma}^{(2)} = 0.1,\ 0.3,\ 0.5,\ 0.6$, have been used. The results are displayed in Figure 3, which shows that the filtering error variances become greater (and, consequently, worse estimations are obtained) as the delay probability $\overline{\gamma}^{(1)}$ or $\overline{\gamma}^{(2)}$ increases.

5 Concluding remark

In this paper, we have studied the recursive LS centralized fusion estimation problem for a class of multisensor uncertain systems with random parameter matrices, under the assumption that the sensor output transmissions to the processing center may experience random one-step delays and non-consecutive packet losses, when these transmission uncertainties occur with different rates at the different sensors. For the addressed model, we have derived an optimal recursive algorithm for the filtering and prediction problems, using the innovation technique. To measure the estimation accuracy, recursive formulas for the error covariance matrices have been also derived. The current results are applicable when the signal evolution model is not available, since the algorithm needs only the mean and covariance functions of the processes involved, but it can be also applied to the conventional state-space model formulation. The usefulness of the developed estimation algorithm has been illustrated by a numerical simulation example.

Future lines of research will attempt to: (i) Consider noise correlation, since many practical situations involve non-white measurement noises that can also be correlated among the sensors, and this correlation should not be ignored. (ii) Explore the design of distributed fusion estimators which, as it is known, despite being slightly less accurate than the centralized ones, are more robust and save time and storage resources in the fusion center.

Abstract

The distributed fusion filtering problem is addressed for discrete-time random signals from multi-sensor noisy measurements, which are transmitted to local processors through different communication channel links. Assume that, due to random transmission failures, some of the data packet processed for the estimation may either contain only noise (uncertain observations), be delayed (randomly delayed observations) or even be definitely lost (random packet dropouts). Using only covariance information, without requiring the evolution model of the signal process, local least-squares linear estimators based on the measurements received by the local processor of each individual sensor are obtained, and the distributed fusion method is then used to generate an optimal fusion filter by a matrix-weighted linear combination of such local estimators using the mean squared error as optimality criterion. The accuracy of the proposed estimators, which is measured by the estimation error covariances, is examined by a simulation example.

Key words: distributed fusion estimation, uncertain observations, random delays, packet dropouts

1 Introduction

Sensor networks are currently one of the most important technologies and information fusion has become a challenging issue within the study of the estimation problem in networked stochastic systems. Many of the existing fusion estimation algorithms are concerned with conventional systems, where each sensor transmits its outputs to the fusion center (FC) over perfect connections (see e.g. [1] and [2], and references therein).

However, usually the network characteristics may not be utterly reliable and, when the sensors send their measurements to the FC, some problems may arise as, for example, uncertain observations or missing measurements, random delays and/or packet dropouts, thus causing the deterioration of the quality of the fusion estimators designed without considering these drawbacks. For this reason, the design of new fusion estimation algorithms for systems featuring one of the aforementioned uncertainties (see e.g.[3]-[5] and references therein), or even several of them simultaneously (see e.g. [6]- [13] and references therein), has become an active research topic of growing interest.

There are two fundamental kinds of fusion filtering algorithms: (a) The centralized fusion filtering algorithms (see e.g. [6]), where the sensors simply forward all the measured data to the FC and then they are processed to provide optimal estimators; hence, when all the sensors work correctly, centralized fusion estimators have the best accuracy. (b) The distributed fusion filtering algorithms (see e.g. [12]), where local estimators are obtained from the measurements of each single sensor, and these local estimators are then combined according to a certain information fusion criterion; the distributed estimators, despite being slightly less accurate than the centralized ones, have better robustness and reliability.

In this paper, we address the distributed fusion estimation problem in networked systems with multiple uncertainties during transmission, which include random delays, packet dropouts and/or uncertain observations. To the best of the authors' knowledge, the simultaneous consideration of these uncertainties has not yet been investigated in the framework of covariance information and, therefore, it constitutes an interesting research challenge. The main contributions of the present paper include: (1) Our approach, based on covariance information, does not require the evolution model generating the signal process. (2) The estimators are obtained without the necessity of augmenting the state; so, the dimension of the designed estimators is the same as that of the original state, thus reducing the computational cost compared with the augmentation method.

The rest of the paper is structured as follows. In Section 2, we present the measurement model to be considered and the assumptions under which the distributed estimation problem is addressed. In Section 3, a local least-squares linear filtering algorithm is derived, and the proposed distributed estimators are generated by a matrix-weighted linear combination of the local estimators using the mean squared error as optimality criterion. A simulation example is given in Section 4 to show the performance of the proposed estimators. Finally, some conclusions are drawn in Section 5.

Notations. The notations used throughout the paper are standard. $\mathbb{R}^n$ denotes the n-dimensional Euclidean space. For a matrix A, A^T and A^{-1} denote its transpose and inverse, respectively. If a matrix dimension is not specified, it is assumed to be compatible with algebraic operations. $\delta_{k,s}$ denotes the Kronecker delta function. Finally, for any function $G_{k,s}$, depending on the instants k and s, we will write $G_k = G_{k,k}$ for simplicity; analogously, $K^{(i)} = K^{(ii)}$ will be written for any function $K^{(ij)}$, depending on sensors i and j.

 ISBN: 978-84-617-8694-7

2 Observation model

This paper deals with the fusion estimation problem of discrete-time random signals from multi-sensor noisy measurements transmitted through different channels using the distributed fusion method. Each sensor is assumed to transmit its outputs to a local processor over imperfect networks, which yield mixed uncertainties. Specifically, the observations processed for the estimation may either contain only noise, be one-step randomly delayed or dropped out, in which case the last observation that successfully arrived will be used for the estimation.

Signal process. The distributed fusion estimators will be obtained under the assumption that the evolution model of the signal to be estimated is unknown and only information about its mean and covariance functions is available; this information is specified in the following assumption: *The n_x-dimensional signal process $\{x_k;\ k \geq 1\}$ has zero mean and its autocovariance function is expressed in a separable form, $E[x_k x_s^T] = A_k B_s^T,\ s \leq k$, where A_k, B_s are known matrices.*

Multi-sensor measured outputs. Consider m sensors, whose measurements are described by the following equations:

$$z_k^{(i)} = H_k^{(i)} x_k + v_k^{(i)}, \quad k \geq 1, \quad i = 1, \ldots, m, \tag{1}$$

where $z_k^{(i)} \in \mathbb{R}^{n_z}$ is the measured output of the i-th sensor at time k, and $v_k^{(i)}$ is the noise vector. Assume that the measurement noises $\{v_k^{(i)};\ k \geq 1\}$, $i = 1, \ldots, m$, are zero-mean white processes with known covariances $E[v_k^{(i)} v_s^{(j)T}] = R_k^{(ij)} \delta_{k,s}$, for $i, j = 1, \ldots, m$.

From this assumption and the separable form of the signal autocovariance function, it is clear that, for $i, j = 1, \ldots, m$, the correlation matrices $\Sigma_{s,k}^{z^{(ij)}} \equiv E[z_s^{(i)} z_k^{(j)T}]$ are given by

$$\Sigma_{s,k}^{z^{(ij)}} = H_s^{(i)} B_s A_k^T H_k^{(j)T} + R_k^{(ij)} \delta_{s,k}, \quad s \leq k. \tag{2}$$

Observation model with mixed uncertainties. As it has been indicated, random one-step delays, packet dropouts and uncertain observations are supposed to exist in data transmissions from the individual sensors to the local processors. Namely, the following model is considered for the measurement of the i-th local processor, $y_k^{(i)}$, $i = 1, \ldots, m$:

$$\begin{array}{l} y_k^{(i)} = \gamma_{0,k}^{(i)} z_k^{(i)} + \gamma_{1,k}^{(i)} z_{k-1}^{(i)} + \gamma_{2,k}^{(i)} v_k^{(i)} + \gamma_{3,k}^{(i)} y_{k-1}^{(i)},\ k \geq 2; \\ y_1^{(i)} = \gamma_{0,1}^{(i)} z_1^{(i)} + \gamma_{2,1}^{(i)} v_1^{(i)}, \end{array} \tag{3}$$

where $\gamma_{3,k}^{(i)} = 1 - \sum_{d=0}^{2} \gamma_{d,k}^{(i)},\ k \geq 2$, and $\gamma_{2,1}^{(i)} = 1 - \gamma_{0,1}^{(i)}$. We denote $\gamma_{1,1}^{(i)} = \gamma_{3,1}^{(i)} = 0$, and we assume that, for $i = 1, \ldots, m$, and $d = 0, 1, 2, 3$, the process $\{\gamma_{d,k}^{(i)};\ k \geq 1\}$ is a sequence of

 ISBN: 978-84-617-8694-7

independent Bernoulli variables with known probabilities $P[\gamma_{d,k}^{(i)}=1]=\overline{\gamma}_{d,k}^{(i)}$, $\forall k\geq 1$. Also, we assume that $\{\gamma_{d,k}^{(i)};\ k\geq 1\}$ is independent of the sequences $\{\gamma_{d',k}^{(j)};\ k\geq 1\}$, $d'=0,1,2,3$, for any $j\neq i$.

Finally, the following independence hypothesis is also assumed: *For $i=1,\ldots,m$, and $d=0,1,2,3$, the signal, $\{x_k;\ k\geq 1\}$, and the processes $\{v_k^{(i)};\ k\geq 1\}$ and $\{\gamma_{d,k}^{(i)};\ k\geq 1\}$ are mutually independent.*

3 Distributed fusion filtering estimators

In this section a recursive filter is designed using the distributed fusion method. For this purpose, for each $i=1,\ldots,m$ a local least-squares (LS) linear estimator, $\widehat{x}_{k/k}^{(i)}$, $k\geq 1$, of the signal x_k, based on the measurements $\left\{y_1^{(i)},\ldots,y_k^{(i)}\right\}$, is obtained by a recursive algorithm and then a fusion distributed estimator, $\widehat{x}_{k/k}$, is generated by a matrix-weighted linear combination of the local estimators, $\widehat{x}_{k/k}^{(i)}$, $i=1,\ldots,m$, using the mean squared error as optimality criterion.

3.1 Local LS linear filtering recursive algorithm

For each $i=1,\ldots,m$, the following theorem presents a recursive algorithm for the optimal LS linear filtering estimators $\widehat{x}_{k/k}^{(i)}$, $k\geq 1$.

Theorem 1. *For $i=1,\ldots,m$, the local LS linear filtering estimators, $\widehat{x}_{k/k}^{(i)}$, $k\geq 1$, and their error covariance matrices, $P_{k/k}^{(i)}$, $k\geq 1$, are obtained by*

$$\widehat{x}_{k/k}^{(i)}=A_kO_k^{(i)},\quad k\geq 1;\qquad P_{k/k}^{(i)}=A_k\Big(B_k-A_kr_k^{(i)}\Big)^T,\quad k\geq 1. \tag{4}$$

where

$$O_k^{(i)}=O_{k-1}^{(i)}+J_k^{(i)}\Pi_k^{(i)-1}\mu_k^{(i)},\quad k\geq 1;\qquad O_0^{(i)}=0, \tag{5}$$

with

$$J_k^{(i)}=\mathcal{H}_{B_k}^{(i)T}-r_{k-1}^{(i)}\mathcal{H}_{A_k}^{(i)T}-J_{k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mathcal{R}_{k,k-1}^{(i)T},\quad k\geq 2;\quad J_1^{(i)}=\mathcal{H}_{B_1}^{(i)T}, \tag{6}$$

where $\mathcal{R}_{k,k-1}^{(i)}=\overline{\gamma}_{1,k}^{(i)}\left(\overline{\gamma}_{0,k-1}^{(i)}+\overline{\gamma}_{2,k-1}^{(i)}\right)R_{k-1}^{(i)}$, $k\geq 2$, and $r_k^{(i)}=E[O_k^{(i)}O_k^{(i)T}]$ is obtained from

$$r_k^{(i)}=r_{k-1}^{(i)}+J_k^{(i)}\Pi_k^{(i)-1}J_k^{(i)T},\quad k\geq 1;\qquad r_0^{(i)}=0. \tag{7}$$

The innovation, $\mu_k^{(i)}$, is calculated by

$$\mu_k^{(i)}=y_k^{(i)}-\mathcal{H}_{A_k}^{(i)}O_{k-1}^{(i)}-\mathcal{R}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\mu_{k-1}^{(i)}-\overline{\gamma}_{3,k}^{(i)}y_{k-1}^{(i)},\quad k\geq 2;\quad \mu_1=y_1^{(i)} \tag{8}$$

 ISBN: 978-84-617-8694-7

and its covariance matrix, $\Pi_k^{(i)}$*, is given by*

$$\begin{array}{l}\Pi_k^{(i)}=\Sigma_k^{y^{(i)}}-(\overline{\gamma}_{3,k}^{(i)})^2\Sigma_{k-1}^{y^{(i)}}-\overline{\mathcal{H}}_{A_k}^{(i)}\left(\mathcal{H}_{B_k}^{(i)T}-J_k^{(i)}\right)-\mathcal{R}_{k,k-1}^{(i)}\Pi_{k-1}^{(i)-1}\left(\mathcal{H}_{A_k}^{(i)}J_{k-1}^{(i)}+\mathcal{R}_{k,k-1}^{(i)}\right)^T,\ k\geq 2;\\ \Pi_1^{(i)}=\Sigma_1^{y^{(i)}}\end{array} \tag{9}$$

The matrices $\Sigma_k^{y^{(i)}}=E[y_k^{(i)}y_k^{(i)T}]$ *satisfy*

$$\Sigma_k^{y^{(i)}}=\overline{\gamma}_{0,k}^{(i)}\Sigma_k^{z^{(i)}}+\overline{\gamma}_{1,k}^{(i)}\Sigma_{k-1}^{z^{(i)}}+\overline{\gamma}_{2,k}^{(i)}R_k^{(i)}+\overline{\gamma}_{3,k}^{(i)}\Sigma_{k-1}^{y^{(i)}},\ k\geq 2;\quad \Sigma_1^{y^{(i)}}=\overline{\gamma}_{0,1}^{(i)}\Sigma_1^{z^{(i)}}+\overline{\gamma}_{2,1}^{(i)}R_1^{(i)},$$

where $\Sigma_k^{z^{(i)}}$ *is given in (2), and the matrices* $\mathcal{H}_{\Psi_k}^{(i)}$*, for* $\Psi_k=A_k,\ B_k$*, are defined by*

$$\mathcal{H}_{\Psi_k}^{(i)}=\overline{\gamma}_{0,k}^{(i)}H_k^{(i)}\Psi_k+\overline{\gamma}_{1,k}^{(i)}H_{k-1}^{(i)}\Upsilon_{k-1},\quad k\geq 2;\qquad \mathcal{H}_{\Psi_1}^{(i)}=\overline{\gamma}_{0,1}^{(i)}H_1^{(i)}\Psi_1.$$

Proof. Theorem 1 will be proved by an innovation approach. For the i-th sensor, the innovation at time h is defined as $\mu_h^{(i)}=y_h^{(i)}-\widehat{y}_{h/h-1}^{(i)}$, where $\widehat{y}_{h/h-1}^{(i)}$ is the LS one-stage linear predictor of $y_h^{(i)}$. To simplify the notation we write

$$\xi_h^{(i)}=\gamma_{0,h}^{(i)}z_h^{(i)}+\gamma_{1,h}^{(i)}z_{h-1}^{(i)}+\gamma_{2,h}^{(i)}v_h^{(i)},\quad h\geq 2;\quad \xi_1^{(i)}=y_1^{(i)}. \tag{10}$$

Then, from (3), the innovation process can be expressed by

$$\mu_h^{(i)}=\xi_h^{(i)}-\widehat{\xi}_{h/h-1}^{(i)}-(\gamma_{3,h}^{(i)}-\overline{\gamma}_{3,h}^{(i)})y_{h-1}^{(i)},\quad h\geq 2;\qquad \mu_1^{(i)}=\xi_1^{(i)}. \tag{11}$$

Now, by denoting $\mathcal{X}_{k,h}^{(i)}=E[x_k\mu_h^{(i)T}]$, the local LS linear estimators $\widehat{x}_{k/s}^{(i)},\ s\leq k$, are expressed as linear combination of the innovations as follows:

$$\widehat{x}_{k/s}^{(i)}=\sum_{h=1}^{s}\mathcal{X}_{k,h}^{(i)}\Pi_h^{(i)-1}\mu_h^{(i)},\quad s\leq k,$$

and we start by calculating the coefficients $\mathcal{X}_{k,h}^{(i)}$ which, from (11), are given by

$$\mathcal{X}_{k,h}^{(i)}=E[x_k\xi_h^{(i)T}]-E[x_k\widehat{\xi}_{h/h-1}^{(i)T}],\quad 2\leq h\leq k.$$

- From the model assumptions, we have that $E[x_k\xi_h^{(i)T}]=A_k\mathcal{H}_{B_h}^T,\quad 1\leq h\leq k.$
- Using that $\widehat{\xi}_{h/h-1}^{(i)}=\sum_{l=1}^{h-1}E[\xi_h^{(i)}\mu_l^{(i)T}]\Pi_l^{(i)-1}\mu_l^{(i)}$, the following identity holds

$$E[x_k\widehat{\xi}_{h/h-1}^{(i)T}]=\sum_{l=1}^{h-1}\mathcal{X}_{k,l}^{(i)}\Pi_l^{(i)-1}[\overline{\gamma}_{0,h}^{(i)}\mathcal{X}_{h,l}^{(i)T}H_h^{(i)T}+\overline{\gamma}_{1,h}^{(i)}\mathcal{X}_{h-1,l}^{(i)T}H_{h-1}^{(i)T}]-\mathcal{X}_{k,h-1}^{(i)}\Pi_{h-1}^{(i)-1}\mathcal{R}_{h,h-1}^{(i)T}.$$

 ISBN: 978-84-617-8694-7

Hence, $\mathcal{X}_{k,h}^{(i)} = A_k J_h^{(i)}$, $h \leq k$, where $J_h^{(i)}$ is a function satisfying

$$J_h^{(i)} = \mathcal{H}_{B_h}^{(i)T} - \sum_{l=1}^{h-1} J_l^{(i)} \Pi_l^{(i)-1} J_l^{(i)T} \mathcal{H}_{A_h}^{(i)T} - J_{h-1}^{(i)} \Pi_{h-1}^{(i)-1} \mathcal{R}_{h,h-1}^{(i)T}, \quad h \geq 2; \quad J_1^{(i)} = \mathcal{H}_{B_1}^{(i)T}.$$

Then, by defining

$$O_k^{(i)} = \sum_{h=1}^{k} J_h^{(i)} \Pi_h^{(i)-1} \mu_h^{(i)}, \ k \geq 1; \ \ O_0^{(i)} = 0, \text{ and } r_k^{(i)} = \sum_{h=1}^{k} J_h^{(i)} \Pi_h^{(i)-1} J_h^{(i)T}, \ k \geq 1; \ \ r_0^{(i)} = 0,$$

it is easy to obtain expressions (4)-(8) of Theorem 1.

Finally, expression (9) for $\Pi_k^{(i)}$ is obtained taking into account that the innovation covariance matrix can be expressed as

$$\Pi_k^{(i)} = E[(y_k^{(i)} - \overline{\gamma}_{3,k}^{(i)} y_{k-1}^{(i)})(y_k^{(i)} - \overline{\gamma}_{3,k}^{(i)} y_{k-1}^{(i)})^T] - E[\widehat{\xi}_{k/k-1}^{(i)} \widehat{\xi}_{k/k-1}^{(i)T}],$$

and using that $\widehat{\xi}_{k/k-1}^{(i)} = \mathcal{H}_{A_k}^{(i)} O_{k-1}^{(i)} + \mathcal{R}_{k,k-1}^{(i)} \Pi_{k-1}^{(i)-1} \mu_{k-1}^{(i)}$. Then the proof is complete. □

3.2 Matrix-weighted distributed fusion filtering estimators design

Once the local LS linear filters, $\widehat{x}_{k/k}^{(i)}$ for $i = 1, \ldots, m$, have been obtained, our goal is to design a distributed fusion filter, $\widehat{x}_{k/k}$, as the matrix-weighted linear combination of such local estimators that minimizes the mean squared estimation error. The assumptions and notation in this section are those of Theorem 1.

By denoting $\widehat{X}_{k/k} = \left(\widehat{x}_{k/k}^{(1)T}, \ldots, \widehat{x}_{k/k}^{(m)T}\right)^T$ and $\mathcal{F}_k = \left(F_k^{(1)}, \ldots, F_k^{(m)}\right)$, the aim is to find $\mathcal{F}_k$ such that the estimator $\mathcal{F}_k \widehat{X}_{k/k}$ minimizes $E\left[(x_k - \mathcal{F}_k \widehat{X}_{k/k})(x_k - \mathcal{F}_k \widehat{X}_{k/k})^T\right]$. As it is well known, the solution of this problem is given by the matrix

$$\mathcal{F}_k^{opt} = E\left[x_k \widehat{X}_{k/k}^T\right] \left(E\left[\widehat{X}_{k/k} \widehat{X}_{k/k}^T\right]\right)^{-1}, \quad k \geq 1. \tag{12}$$

The following theorem provides the proposed distributed fusion filtering estimators, $\widehat{x}_{k/k}$, and their error covariance matrices, $P_{k/k}$.

Theorem 2. *Let $\widehat{X}_{k/k} = \left(\widehat{x}_{k/k}^{(1)T}, \ldots, \widehat{x}_{k/k}^{(m)T}\right)^T$ be the vector formed by the local LS estimators calculated in Theorem 1. Then, the distributed fusion filtering estimators $\widehat{x}_{k/k}$, $k \geq 1$, and their error covariance matrices, $P_{k/k}$, $k \geq 1$, are given by*

$$\widehat{x}_{k/k} = \left(\Sigma_{k/k}^{\widehat{x}^{(1)}}, \ldots, \Sigma_{k/k}^{\widehat{x}^{(m)}}\right) \left(\Sigma_{k/k}^{\widehat{X}}\right)^{-1} \widehat{X}_{k/k}, \quad k \geq 1, \tag{13}$$

 ISBN: 978-84-617-8694-7

$$P_{k/k} = A_k B_k^T - \left(\Sigma_{k/k}^{\widehat{x}^{(1)}}, \ldots, \Sigma_{k/k}^{\widehat{x}^{(m)}}\right) \left(\Sigma_{k/k}^{\widehat{X}}\right)^{-1} \left(\Sigma_{k/k}^{\widehat{x}^{(1)}}, \ldots, \Sigma_{k/k}^{\widehat{x}^{(m)}}\right)^T, \quad k \geq 1. \tag{14}$$

where $\Sigma_{k/k}^{\widehat{X}} = \left(\Sigma_{k/k}^{\widehat{x}^{(ij)}}\right)_{i,j=1,\ldots,m}$, *and the cross-correlation matrices* $\Sigma_{k/k}^{\widehat{x}^{(ij)}} = E\left[\widehat{x}_{k/k}^{(i)} \widehat{x}_{k/k}^{(j)T}\right]$, $i, j = 1, \ldots, m$, *are obtained by*

$$\Sigma_{k/k}^{\widehat{x}^{(ij)}} = A_k r_k^{(ij)} A_k^T, \quad k \geq 1, \tag{15}$$

with $r_k^{(ij)} = E[O_k^{(i)} O_k^{(j)T}]$ *satisfying*

$$r_k^{(ij)} = r_{k-1}^{(ij)} + J_{k-1,k}^{(ij)} \Pi_k^{(j)-1} J_k^{(j)T} + J_k^{(i)} \Pi_k^{(i)-1} J_k^{(ji)T}, \quad k \geq 1; \quad r_0^{(ij)} = 0. \tag{16}$$

The matrices $J_k^{(ij)} = E[O_k^{(i)} \mu_k^{(j)T}]$ *are given by*

$$J_k^{(ij)} = J_{k-1,k}^{(ij)} + J_k^{(i)} \Pi_k^{(i)-1} \Pi_k^{(ij)}, \quad k \geq 1, \tag{17}$$

and $J_{k-1,k}^{(ij)} = E[O_{k-1}^{(i)} \mu_k^{(j)T}]$ *are calculated by*

$$\begin{array}{l} J_{k-1,k}^{(ij)} = \left(r_{k-1}^{(i)} - r_{k-1}^{(ij)}\right) \overline{\mathcal{H}}_{A_k}^{(j)T} + J_{k-1}^{(i)} \Pi_{k-1}^{(i)-1} \mathcal{R}_{k,k-1}^{(ji)T} - J_{k-1}^{(ij)} \Pi_{k-1}^{(j)-1} \mathcal{R}_{k,k-1}^{(j)T}, \quad k \geq 2; \\ J_{0,1}^{(ij)} = 0. \end{array} \tag{18}$$

The innovation cross-correlation matrices, $\Pi_k^{(ij)} = E[\mu_k^{(i)} \mu_k^{(j)T}]$, *are given by*

$$\begin{array}{l} \Pi_k^{(ij)} = \Sigma_k^{\xi^{(ij)}} - \overline{\mathcal{H}}_{A_k}^{(i)} \left(\overline{\mathcal{H}}_{B_k}^{(j)T} - J_k^{(j)} - J_{k-1,k}^{(ij)}\right) \\ \qquad\qquad - \mathcal{R}_{k,k-1}^{(ij)} \Pi_{k-1}^{(j)-1} \left(\overline{\mathcal{H}}_{A_k}^{(j)} J_{k-1}^{(j)} + \mathcal{R}_{k,k-1}^{(j)}\right)^T - \mathcal{R}_{k,k-1}^{(i)} \Pi_{k-1}^{(i)-1} \Pi_{k-1,k}^{(ij)}, \quad k \geq 2; \\ \Pi_1^{(ij)} = \Sigma_1^{\xi^{(ij)}}, \end{array} \tag{19}$$

where $\Sigma_k^{\xi^{(ij)}} = E[\xi_k^{(i)} \xi_k^{(j)T}]$ *satisfy*

$$\begin{array}{l} \Sigma_k^{\xi^{(ij)}} = \overline{\gamma}_{0,k}^{(i)} \Sigma_k^{z\xi^{(ij)}} + \overline{\gamma}_{1,k}^{(i)} \Sigma_{k-1,k}^{z\xi^{(ij)}} + \overline{\gamma}_{2,k}^{(i)} (\overline{\gamma}_{0,k}^{(j)} + \overline{\gamma}_{2,k}^{(j)}) R_k^{(ij)}, \quad k \geq 2; \\ \Sigma_1^{\xi^{(ij)}} = \overline{\gamma}_{0,1}^{(i)} \Sigma_1^{z\xi^{(ij)}} + \overline{\gamma}_{2,1}^{(i)} (\overline{\gamma}_{0,1}^{(j)} + \overline{\gamma}_{2,1}^{(j)}) R_1^{(ij)}, \end{array}$$

with $\Sigma_{s,k}^{z\xi^{(ij)}} = E[z_s^{(i)} \xi_k^{(j)T}]$, *for* $s = k-1,\ k$, *given by*

$$\Sigma_{s,k}^{z\xi^{(ij)}} = \overline{\gamma}_{0,k}^{(j)} \Sigma_{s,k}^{z^{(ij)}} + \overline{\gamma}_{1,k}^{(j)} \Sigma_{s,k-1}^{z^{(ij)}} + \overline{\gamma}_{2,k}^{(j)} R_k^{(ij)} \delta_{s,k}, \quad k \geq 2; \qquad \Sigma_1^{z\xi^{(ij)}} = \overline{\gamma}_{0,1}^{(j)} \Sigma_1^{z^{(ij)}} + \overline{\gamma}_{2,1}^{(j)} R_1^{(ij)}.$$

The matrices $\Pi_{k-1,k}^{(ij)} = E[\mu_{k-1}^{(i)} \mu_k^{(j)T}]$ *are calculated by*

$$\Pi_{k-1,k}^{(ij)} = \overline{\mathcal{H}}_{A_k}^{(i)} \left(J_{k-1}^{(j)} - J_{k-1}^{(ij)}\right) + \mathcal{R}_{k,k-1}^{(ij)} - \mathcal{R}_{k-1}^{(i)} \Pi_{k-1}^{(i)-1} \Pi_{k-1}^{(ij)}, \quad k \geq 2. \tag{20}$$

 ISBN: 978-84-617-8694-7

Finally, $\mathcal{R}_{k,k-1}^{(ij)} = \overline{\gamma}_{1,k}^{(i)}(\overline{\gamma}_{0,k-1}^{(j)} + \overline{\gamma}_{2,k-1}^{(j)})R_{k-1}^{(ij)},\ k \geq 2$, *and* $\Sigma_{k,s}^{z^{(ij)}}$ *are given in (2).*

Proof. From Theorem 1, it is not difficult to check that $\widehat{\xi}_{k/k-1}^{(i/j)}$, the estimator of $\xi_k^{(i)}$ based on the measurements $\left\{y_1^{(j)}, \ldots, y_{k-1}^{(j)}\right\}$, is given by

$$\widehat{\xi}_{k/k-1}^{(i/j)} = \mathcal{H}_{A_k}^{(i)} O_{k-1}^{(j)} + \mathcal{R}_{k,k-1}^{(ij)} \Pi_{k-1}^{(j)-1} \mu_{k-1}^{(j)}, \quad k \geq 2. \tag{21}$$

- Expressions (13) and (14) for the distributed estimators and their error covariance matrices, respectively, are immediately derived from (12).

- Expression (15) for the cross-correlation matrices between local estimators, $\Sigma_{k/k}^{\widehat{x}^{(ij)}}$, follows easily from (4), since $r_k^{(ij)} = E[O_k^{(i)} O_k^{(j)T}]$; moreover, using (5) and taking into account that $J_{s,k}^{(ij)} = E[O_s^{(i)} \mu_k^{(j)T}]$, for $s = k-1,\ k$, we get (16) for $r_k^{(ij)}$.

- Using (5) for $O_k^{(i)}$, expression (17) for $J_k^{(ij)} = E[O_k^{(i)} \mu_k^{(j)T}]$ is directly obtained.

- To derive (18) for $J_{k-1,k}^{(ij)} = E[O_{k-1}^{(i)} \mu_k^{(j)T}]$, we use (11) for $\mu_k^{(j)}$, which leads to $J_{k-1,k}^{(ij)} = E[O_{k-1}^{(i)} \xi_k^{(j)T}] - E[O_{k-1}^{(i)} \widehat{\xi}_{k/k-1}^{(j)T}]$. Now, from the Orthogonal Projection Lemma (OPL), we have $E[O_{k-1}^{(i)} \xi_k^{(j)T}] = E[O_{k-1}^{(i)} \widehat{\xi}_{k/k-1}^{(j/i)T}]$ and, using (21), it is easy to prove (18).

- If we use expression (11) in $\Pi_k^{(ij)} = E[\mu_k^{(i)} \mu_k^{(j)}]$, it is not difficult to see that

$$\Pi_k^{(ij)} = \Sigma_k^{\xi^{(ij)}} - E[\xi_k^{(i)} \widehat{\xi}_{k/k-1}^{(j)T}] - E[\widehat{\xi}_{k/k-1}^{(i)} \mu_k^{(j)T}], \quad k \geq 2. \tag{22}$$

  From the OPL, we have $E[\xi_k^{(i)} \widehat{\xi}_{k/k-1}^{(j)T}] = E[\widehat{\xi}_{k/k-1}^{(i/j)} \xi_k^{(j)T}]$ and, from (21) and (6), it follows that

$$E[\widehat{\xi}_{k/k-1}^{(i/j)} \xi_k^{(j)T}] = \overline{\mathcal{H}}_{A_k}^{(i)} \left(\overline{\mathcal{H}}_{B_k}^{(j)T} - J_k^{(j)}\right) + \mathcal{R}_{k,k-1}^{(ij)} \Pi_{k-1}^{(j)-1} \left(\overline{\mathcal{H}}_{A_k}^{(j)} J_{k-1}^{(j)} + \mathcal{R}_{k,k-1}^{(j)}\right)^T.$$

  Also from (21), the following identity holds

$$E[\widehat{\xi}_{k/k-1}^{(i)} \mu_k^{(j)T}] = \overline{\mathcal{H}}_{A_k}^{(i)} J_{k-1,k}^{(ij)} + \mathcal{R}_{k,k-1}^{(i)} \Pi_{k-1}^{(i)-1} \Pi_{k-1,k}^{(ij)}.$$

  Substituting the above expectations into (22), we immediately get (19).

- Using again expression (11) for $\mu_k^{(j)}$ in $\Pi_{k-1,k}^{(ij)} = E[\mu_{k-1}^{(i)} \mu_k^{(j)}]$, we have $\Pi_{k-1,k}^{(ij)} = E[\mu_{k-1}^{(i)} \xi_k^{(j)T}] - E[\mu_{k-1}^{(i)} \widehat{\xi}_{k/k-1}^{(j)T}]$, and applying the OPL and (21), we can show that expression (20) for $\Pi_{k-1,k}^{(ij)}$ holds true.

The proof of Theorem 3 is then complete. □

4 Numerical simulation example

Consider a zero-mean two-dimensional signal $\{x_k;\ k \geq 1\}$ whose autocovariance function is given by

$$E[x_k x_s^T] = \begin{pmatrix} 0.8^{k-s} & 1.02 \times 0.8^{k-s} \\ 0.9 \times 0.8^{k-s-1} & 0.918 \times 0.8^{k-s-1} \end{pmatrix}, \quad s < k,$$

which is factorizable just taking

$$A_k = \begin{pmatrix} 0.8^k & 1.02 \times 0.8^k \\ 0.9 \times 0.8^{k-1} & 0.918 \times 0.8^{k-1} \end{pmatrix} \text{ and } B_s = \begin{pmatrix} 0.8^{-s} & 0 \\ 0 & 0.8^{-s} \end{pmatrix}.$$

Consider four sensors which provide scalar measurements of the signal according to measured outputs model (1): $z_k^{(i)} = H_k^{(i)} x_k + v_k^{(i)}, \quad k \geq 1, \quad i = 1, 2, 3, 4$, where $H_k^{(1)} = (0.74,\ 0.75)$, $H_k^{(2)} = (0.65,\ 0.67)$, $H_k^{(3)} = (0.75,\ 0.7)$ and $H_k^{(4)} = (0.95,\ 0.9)$. The additive noise processes $\{v_k^{(i)};\ k \geq 1\}$, $i = 1, 2, 3, 4$, are defined as $v_k^{(i)} = c_i \eta_k$, where $c_1 = c_2 = 1$, $c_3 = 0.75$ and $c_4 = 1.5$, and $\{\eta_k; k \geq 1\}$ is a zero-mean Gaussian white process with unit variance. Clearly, these noises $\{v_k^{(i)}; k \geq 1\}$, $i = 1, 2, 3$, are correlated at any sampling time, with $R_k^{(ij)} = c_i c_j$.

Next, according to the theoretical observation model, suppose that random one-step delays, packet dropouts and uncertain observations, with different rates exist in the data transmissions from the individual sensors to the local processors. Specifically, let us consider the observation model (3):

$$\begin{aligned} y_k^{(i)} &= \gamma_{0,k}^{(i)} z_k^{(i)} + \gamma_{1,k}^{(i)} z_{k-1}^{(i)} + \gamma_{2,k}^{(i)} v_k^{(i)} + \gamma_{3,k}^{(i)} y_{k-1}^{(i)},\ k \geq 2; \\ y_1^{(i)} &= \gamma_{0,1}^{(i)} z_1^{(i)} + \gamma_{2,1}^{(i)} v_1^{(i)}, \end{aligned}$$

where, for $i = 1, 2, 3, 4$, and $d = 0, 1, 2, 3$, $\{\gamma_{d,k}^{(i)};\ k \geq 1\}$ are sequences of independent Bernoulli variables with the following probabilities:

$k = 1$

sensor	$\overline{\gamma}_{0,1}^{(i)}$	$\overline{\gamma}_{1,1}^{(i)}$	$\overline{\gamma}_{2,1}^{(i)}$	$\overline{\gamma}_{3,1}^{(i)}$
$i = 1$	0.8	0	0	0.2
$i = 2$	0.75	0	0	0.25
$i = 3$	0.75	0	0	0.25
$i = 4$	0.8	0	0	0.2

$k \geq 2$

sensor	$\overline{\gamma}_{0,k}^{(i)}$	$\overline{\gamma}_{1,k}^{(i)}$	$\overline{\gamma}_{2,k}^{(i)}$	$\overline{\gamma}_{3,k}^{(i)}$
$i = 1$	0.3	0.25	0.25	0.2
$i = 2$	0.25	0.3	0.2	0.25
$i = 3$	0.3	0.2	0.25	0.25
$i = 4$	0.25	0.25	0.3	0.2

To illustrate the feasibility and effectiveness of the estimators proposed in the current paper, the algorithms were implemented in MATLAB, and fifty iterations were run. Using simulated values, both the centralized and the proposed distributed fusion estimates were calculated, as well as the corresponding error covariance matrices in order to measure the

 ISBN: 978-84-617-8694-7

estimators accuracy. The derivation of the centralized filtering algorithm is omitted since it is totally analogous to that of the local filtering algorithm (Therorem 1).

For the first and second signal components, Figure 1 displays simulated trajectories along with the centralized and distributed fusion filtering estimations, and Figure 2 the error variances of the different filtering estimators (local, centralized and distributed).

From Figure 1, a satisfactory and efficient tracking performance of the proposed distributed fusion filtering estimators is observed. Figure 2 compares the filtering error variances of the local filters and the fusion filters and shows that the error variances of the distributed fusion filtering estimators are significantly smaller than those of every local estimators, but lightly greater than those of the centralized ones; nevertheless, this slight difference is compensated by the fact that the distributed fusion structure reduces the computational cost and has better robustness and fault tolerance. Consequently, agreeing with the theoretical results, the distributed fusion filter has better accuracy than the local filters and the centralized fusion filter outperforms them all, as it is the optimal one.

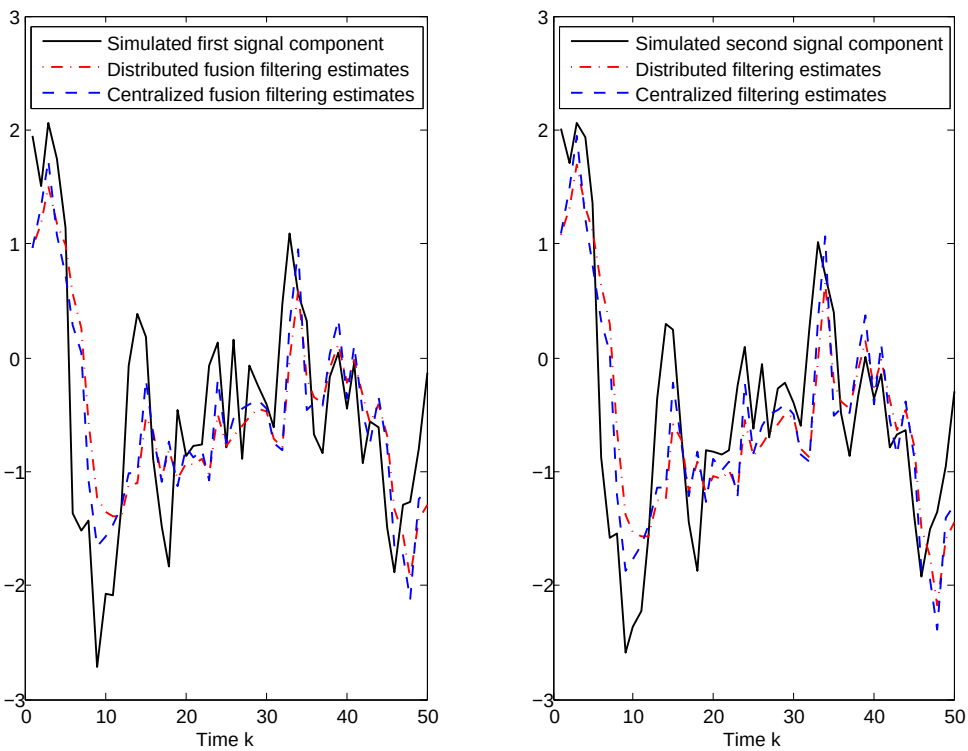

Figure 1: Simulated first and second signal components and centralized and distributed fusion filtering estimates.

 ISBN: 978-84-617-8694-7

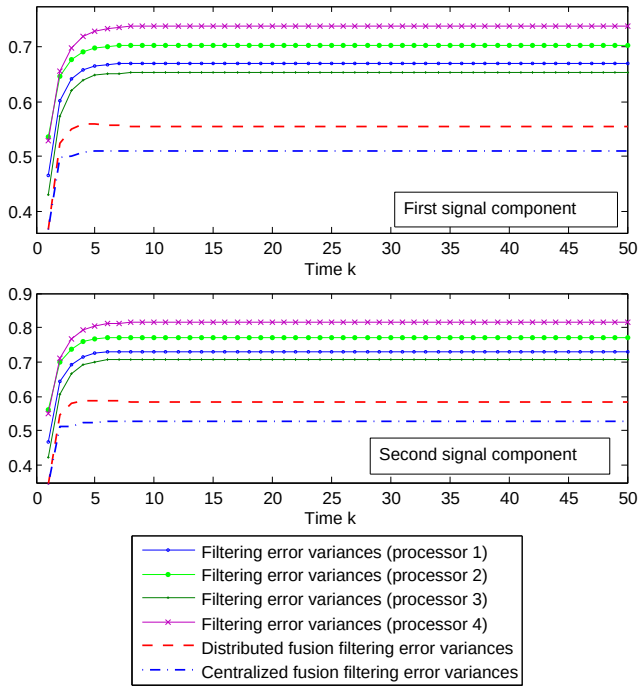

Figure 2: Error variance comparison of the centralized, distributed and local filters.

5 Conclusion

This paper makes valuable contributions to the estimation problem in networked stochastic systems featuring three types of random transmission uncertainties: missing measurements, one-step delays and packet dropouts. By an innovation approach, a recursive distributed filtering algorithm has been designed, which is easily implementable and does not require the signal evolution model, but only the mean and covariance functions of the system processes.

Relation-based Galois-connections: towards the residual of a relation

Inma P. Cabrera[1], Pablo Cordero[1] and Manuel Ojeda-Aciego[1]

[1] *Departamento de Matemática Aplicada, Universidad de Málaga. Spain*

emails: ipcabrera@uma.es, pcordero@uma.es, aciego@uma.es

Abstract

We explore a suitable generalization of the notion of Galois connection in which their components are binary relations. Many different approaches are possible depending both on the (pre-)order relation between subsets in the underlying powerdomain and the chosen type of relational composition.

Key words: Galois connection, relations

1 Introduction

Galois connections can be identified in lots of situations, and they have shown to be an interesting tool both for theory and for applications [6, 9]. Recent applications can still be found in different topics, specially in the realm of Formal Concept Analysis and the foundations of Fuzzy Set Theory, see for instance [1, 7].

In all the different notions of generalized Galois connection the problem of its construction is of capital importance: specifically, given a mapping $f\colon A \to B$ how can one obtain its residual (aka right adjoint). Freyd's adjoint theorem characterizes when such a residual exists when both A and B have the same structure. One of our recent research topics has been to study what happens if A and B are differently structured, and a number of results have been obtained considering different underlying settings. Namely, in [10] we worked with crisp functions between a poset (resp. preordered set) and an unstructured set; later, in [2] we entered in the fuzzy arena, considering the case in which A is a fuzzy preposet; then, in [3], we extended the previous results by allowing fuzzy equivalence relations as an adequate substitute to equality. In [4] we introduced the notion of relational fuzzy Galois connection, in which the components of the connection are not fuzzy functions but fuzzy

 ISBN: 978-84-617-8694-7

relations satisfying certain properties. Before proceeding to further generalizations, it is worth to start again from the crisp case and consider a more adequate notion of Galois connection whose components are crisp relations, and that is the topic of the present paper.

2 Preliminary definitions

A binary relation R between two sets A and B is a subset of the Cartesian product $A \times B$ and it can be also seen as a multivalued function R from the set A to the powerset $\mathcal{P}(B)$. For an element $(a, b) \in R$, it is said that a is related to b and denoted aRb.

Definition 1 *Given a binary relation $R \subseteq A \times B$,*

- *the* afterset *aR of an element $a \in A$ is defined as $\{b \in B \colon aRb\}$*
- *the* foreset *Rb of an element $b \in B$ is defined as $\{a \in A \colon aRb\}$*
- *the* domain *of R is the set* $\mathrm{Dom}(R) = \{a \in A \colon aR \neq \varnothing\}$
- *the* range *of R is the set* $\mathrm{Rng}(R) = \{b \in B \colon Rb \neq \varnothing\}$

Definition 2 *Given a binary relation $R \subseteq A \times B$ and a subset $X \subseteq A$,*

- *the* direct image *of X under R is*

$$R(X) = XR = \{b \in B \colon \text{ there exists } x \in X \text{ such that } xRb\} = \bigcup_{x \in X} xR$$

  The direct image of a subset X is the set of those elements of B that are related to at least *one element of X.*

- *the* subdirect image *of X under R is*

$$R^{\triangleleft}(X) = X^{\triangleleft}R = \{b \in B \colon xRb \text{ for all } x \in X\} = \bigcap_{x \in X} xR$$

  The subdirect image of a subset X is the set of those elements of B that are related to all *the elements of X.*

Observe that if $X = \{a\}$, the direct image and the subdirect image of X coincides with the afterset, thus aR coincides with $R(a)$ should we interpret R as a multivalued mapping.

In the realm of ordered structures, Ore [12] introduced in 1944 the so-called *Galois connections* as a pair of antitone mappings for which both possible compositions are inflationary. In order to extend this concept to binary relations it is necessary to fix the meaning of antitone and inflationary relation. One possibility is to consider the relation as a multivalued function and extend it naturally, but both the preordered structure in the powerset and the composition of relations admit different approaches.

 ISBN: 978-84-617-8694-7

Definition 3 *Given P an arbitrary set and $\leq$ a preorder (reflexive and transitive relation) defined over P, it is possible to lift the preorder structure to the powerset $\mathcal{P}(P)$ by defining*

$$X \ll Y \iff \text{for all } x \in X \text{ there exists } y \in Y \text{ such that } x \leq y \quad (1)$$

$$X \Subset Y \iff \text{for all } y \in Y \text{ there exists } x \in X \text{ such that } x \leq y \quad (2)$$

$$X \ltimes Y \iff \text{for all } x \in X \text{ there exists } y \in Y \text{ such that } x \leq y \text{ and} \quad (3)$$
$$\text{for all } y \in Y \text{ there exists } x \in X \text{ such that } x \leq y$$

Note that the relations defined above are the preorder relations used in the construction of the, respectively, Hoare, Smyth, and Plotkin powerdomains.

The concept of antitone multivalued function between two preordered sets depends on the preorder relation considered over the powerset. We explore three possibilities, being one approach more restrictive than the others:

Definition 4 *Let $\mathbb{A} = (A, \leq_A), \mathbb{B} = (B, \leq_B)$ be two preordered sets and $R \subseteq A \times B$ a binary relation between A and B.*

- *R is said to be* h-antitone *if $a_1 \leq_A a_2$ implies $a_2R \ll a_1R$, for all $a_1, a_2 \in A$.*
- *R is said to be* s-antitone *if $a_1 \leq_A a_2$ implies $a_2R \Subset a_1R$, for all $a_1, a_2 \in A$.*
- *R is said to be* p-antitone *if $a_1 \leq_A a_2$ implies $a_2R \ltimes a_1R$, for all $a_1, a_2 \in A$, equivalently, if it is h-antitone and s-antitone.*

Analogously, the definition of inflationary multivalued function also admits three possibilities.

Definition 5 *Let $\mathbb{A} = (A, \leq_A)$ be a preordered set and $R \subseteq A \times A$ a binary relation on A.*

- *R is said to be* h-inflationary *if $\{a\} \ll aR$, for all $a \in A$, that is, there exists (at least) $x \in aR$ such that $a \leq x$.*
- *R is said to be* s-inflationary *if $\{a\} \Subset aR$, for all $a \in A$, that is, $a \leq x$ for all $x \in aR$.*
- *R is said to be* p-inflationary *if it is h-inflationary and s-inflationary.*

Remark 1 *Notice that if a relation is s-inflationary, then it is also h-inflationary, therefore p-inflationary and s-inflationary are equivalent notions.*

The condition of the composition of two multivalued mappings being inflationary in some sense requires also to fix which definition of composition will be used.

Definition 6 *Let R be a binary relation between A and B and S be a binary relation between B and C.*

 ISBN: 978-84-617-8694-7

- *The* classical *composition of R and S is defined as follows*

$$\begin{aligned} R \circ S &= \{(x,z) \in A \times C\colon \text{ there exists } b \in B \text{ such that } xRb \text{ and } bSz\} \\ &= \{(x,z) \in A \times C\colon xR \cap Sz \neq \varnothing\} \end{aligned}$$

- *The $\triangleleft$ composition of R and S is defined as follows*

$$\begin{aligned} R \triangleleft S &= \{(x,z) \in A \times C\colon \text{ for all } b \in B \text{ such that } xRb \text{ it holds that } bSz\} \\ &= \{(x,z) \in A \times C\colon xR \subseteq Sz\} \end{aligned}$$

Observe that for an element $a \in A$, the afterset $a[R \circ S]$ coincides with the direct image of the afterset aR under S, that is

$$a[R \circ S] = (aR)S = \bigcup_{b \in aR} bS$$

Analogously, for an element $a \in A$, the afterset $a[R \triangleleft S]$ coincides with the subdirect image of the afterset aR under S, that is

$$a[R \triangleleft S] = (aR)^{\triangleleft}S = \bigcap_{b \in aR} bS$$

3 Two types of relational Galois connections

Definition 7 *Let $\mathbb{A} = (A, \leq_A), \mathbb{B} = (B, \leq_B)$ be two posets, $R \subseteq A \times B$ a binary relation between A and B and $S \subseteq B \times A$ a binary relation between B and A.*

The pair (R, S) is said to be an s-Galois connection *between $\mathbb{A}$ and $\mathbb{B}$ if*

i) R and S are s-antitone.

ii) $R \circ S$ and $S \circ R$ are s-inflationary.

Proposition 1 *Let $\mathbb{A} = (A, \leq_A), \mathbb{B} = (B, \leq_B)$ be two posets and (R, S) be an* s-Galois connection *between $\mathbb{A}$ and $\mathbb{B}$. Then if $b \in \mathrm{Rng}(R)$ then bS is at most a singleton, so, the restriction of S to $\mathrm{Rng}(R)$ is a (partial) single-valued function.*

Proof: If $b \in \mathrm{Rng}(R) \smallsetminus \mathrm{Dom}(S)$, then there is nothing to prove; therefore, let us assume that $b \in \mathrm{Rng}(R) \cap \mathrm{Dom}(S)$.

1. As $b \in \mathrm{Rng}(R)$, there exists $a \in A$ such that $b \in aR$ and, as $b \in \mathrm{Dom}(S)$, we have that bS is nonempty. We will now see that, $b \in xR$ for all $x \in bS$.

   Since $\{a\} \Subset a[R \circ S]$, taking into account that $b \in aR$, we have $a \leq x$ for all $x \in bS$. Now, as R is s-antitone, there exists $b' \in xR$ such that $b' \leq b$. The other inequality $b \leq b'$ follows because of $\{b\} \Subset b[S \circ R]$. As a result, $b = b' \in xR$.

 ISBN: 978-84-617-8694-7

2. Consider two elements $x, x^\star \in bS$, by definition of composition and the previous item, we have $x^\star \in x[R \circ S]$; since, by hypothesis, we have $\{x\} \Subset x[R \circ S]$, it turns out that $x \leq x^\star$. Applying that R is s-antitone, there exists $b^\star \in x^\star R$ such that $b^\star \leq b$. Again, the hypothesis $\{b\} \Subset b[S \circ R]$ implies $b \leq b^\star$, and we obtain $b = b^\star \in x^\star R$. This, together with $x \in bS$, proves that $x \in x^\star[R \circ S]$; finally, applying once again $x^\star \Subset x^\star[R \circ S]$, we obtain $x^\star \leq x$ and, therefore $x^\star = x$ and bS is a singleton. □

Notice that the previous result shows that the definition of s-Galois connection necessarily collapses the relations R and S to be (partial) functions in the case of posets. If we drop the antisymmetry and consider the more general case of preordered sets, we obtain a similar result in that the images of the relations are clusters.

As a result, it seems more convenient to consider alternative approaches either by changing the ordering between subsets and/or slightly modifying the notions of antitone or inflationary relation.

A promising definition seems to be the following:

Definition 8 *Let $\mathbb{A} = (A, \leq_A), \mathbb{B} = (B, \leq_B)$ be two preordered sets, $R \subseteq A \times B$ a binary relation between A and B and $S \subseteq B \times A$ a binary relation between B and A. The pair (R, S) is said to be an* h-Galois connection *between $\mathbb{A}$ and $\mathbb{B}$ if*

i) R and S are h-antitone.

ii) For all $a \in A$ and all $b \in B$ the following conditions hold:

$$\{a\} \ll yS \text{ for all } y \in aR \quad \text{and} \quad \{b\} \ll xR \text{ for all } x \in bS. \tag{4}$$

It is not difficult to check that condition (4) above is a consequence of the property of $R \triangleleft S$ and $S \triangleleft R$ being h-inflationary but, in general, are not equivalent.

The following result shows a necessary condition for a pair (R, S) to be an h-Galois connection.

Lemma 1 *If the pair (R, S) is an h-Galois connection between $\mathbb{A}$ and $\mathbb{B}$, then the following inclusions hold:* $\mathrm{Rng}(R) \subseteq \mathrm{Dom}(S)$ *and* $\mathrm{Rng}(S) \subseteq \mathrm{Dom}(R)$.

Proof: Given $b \in \mathrm{Rng}(R)$, there exists $a \in A$ such that $b \in aR$. Now, by condition (4) above, we obtain that $bS \neq \varnothing$ and, therefore, $b \in \mathrm{Dom}(S)$.

The other inclusion can be proved similarly. □

Notice that, in fact, the proof of the previous lemma does not use the antitonicity of either R or S.

With the condition of Lemma 1 in mind, we obtain an equivalence with the usual notion of Galois connection, as stated below:

 ISBN: 978-84-617-8694-7

Theorem 1 *Let $\mathbb{A} = (A, \leq_A), \mathbb{B} = (B, \leq_B)$ be two preordered sets, $R \subseteq A \times B$ a binary relation between A and B and $S \subseteq B \times A$ a binary relation between B and A. The pair (R, S) is an h-Galois connection between $\mathbb{A}$ and $\mathbb{B}$ if and only if the following holds:*

$$\mathrm{Rng}(R) \subseteq \mathrm{Dom}(S) \quad \text{and} \quad \mathrm{Rng}(S) \subseteq \mathrm{Dom}(R) \tag{5}$$

$$\{a\} \ll bS \iff \{b\} \ll aR \tag{6}$$

Proof: Given (R, S) an h-Galois connection between $\mathbb{A}$ and $\mathbb{B}$, condition (5) follows by Lemma 1. Now, for condition (6), assume that $\{a\} \ll bS$. Then, there exists $x \in bS$ such that $a \leq x$ and, by R h-antitone, we obtain $xR \ll aR$. On the other hand, by condition (4) we have $\{b\} \ll xR$. Now, by transitivity of $\ll$, we obtain that $\{b\} \ll aR$. The proof that $\{b\} \ll aR$ implies $\{a\} \ll bS$ is similar.

Conversely, assume that equivalence (6) holds, and let us prove that (R, S) is an h-Galois connection.

Firstly, we will show condition (4): Given $a \in A$ and $y \in aR$, since $y \leq y$, then $\{y\} \ll aR$ which by (6) implies that $\{a\} \ll yS$ for all $y \in aR$. The other part is similar.

Now, consider $a_1 \leq a_2$ in A. Then, since $\{a_2\} \ll yS$ for all $y \in a_2R$, it also holds that $\{a_1\} \ll yS$ for all $y \in a_2R$. Hence, by (6), we have $\{y\} \ll a_1R$, for all $y \in a_2R$ which means that $a_2R \ll a_1R$. The antitonicity of S follows analogously. □

4 Conclusions and further work

The problem of considering relations within the notion of Galois connection is not new, since it can be dated back to [8], nor outdated, since one can still find recent references dealing with different aspects of the integration of relations and Galois connections, see for instance [5, 11, 13].

We have obtained some prospective results on the notion of relational-based Galois connection, in which the components of the connection are relations between posets. There are several possibilities depending both on the (pre-)order relation between subsets in the underlying powerdomain and the chosen type of relational composition. We have just scratched the surface of the problem, and shown that one of the most reasonable approaches collapses in that the involved relations R and S should actually be functions. The second proposed definition uses a different approach in that, apart from considering an alternative ordering in the underlying powerdomain for the definition of antitonicity, it also generalizes the notion of being inflationary. This way, we have obtained a promising result in the form of Theorem 1.

As future work, we are planning to continue the line initiated in [2, 3] and attempt the construction of the residual, in the sense of relation-based (fuzzy) Galois connections, to a given mapping between differently structured domain and codomain, as stated in the introduction.

Abstract

We show how special well known matrices, namely, the creation and shift matrices play an important role on a matrix representation of orthogonal systems of polynomials with a hypercomplex variable and values in a Clifford algebra.

Key words: hypercomplex polynomials, matrix representation, creation matrix, shift matrix
MSC 2000: 30G35, 65F60, 11B83.

1 Introduction

In [7] the author constructs orthogonal bases of polynomials in the space of square integrable functions that are in the kernel of a generalized Cauchy-Riemann operator in the unit ball of $\mathbb{R}^{n+1}$. The construction process relies on building blocks that do not belong, in general, to the kernel of the referred operator. By using results established in [3] for these building blocks, we generalize the algebraic approach developed in [1] and stress the role of the well-known *creation matrix* and *shift matrix* in this representation. We recall that the so-called creation matrix H and the shift matrix J are defined by

$$(H)_{il} = \begin{cases} i, & i = l+1 \\ 0, & i \neq l+1 \end{cases} \qquad \text{and} \qquad (J)_{il} = \begin{cases} 1, & i = l+1 \\ 0, & i \neq l+1, \end{cases}$$

$i, l = 0, \ldots, m$, respectively. Although their simple structure, these matrices appear naturally in a matrix decomposition that represents polynomials in arbitrary dimension and in the framework of non-commutative algebras.

2 Basic concepts

Let $\{e_1, e_2, \ldots, e_n\}$ be an orthonormal basis of the Euclidean vector space $\mathbb{R}^n$ endowed with a non-commutative product according to the multiplication rules $e_k e_l + e_l e_k = -2\delta_{kl},\ k, l = 1, \ldots, n$, where δ_{kl} is the Kronecker symbol. The associative 2^n-dimensional Clifford algebra $\mathcal{C}\ell_{0,n}$ over $\mathbb{R}$ is the set of numbers of the form $a = \sum_A a_A e_A,\ a_A \in \mathbb{R}$, with $A \subseteq \{1, \cdots, n\}$, $e_A = e_{l_1} e_{l_2} \cdots e_{l_r}$, where $1 \leq l_1 < \cdots < l_r \leq n$ and $e_\emptyset =: e_0 =: 1$. The vector space $\mathbb{R}^{n+1}$ is embedded in $\mathcal{C}\ell_{0,n}$ by identifying $(x_0, x_1, \ldots, x_n) \in \mathbb{R}^{n+1}$ with the so-called *paravectors* $x = x_0 + \underline{x} \in \mathcal{A}_n := \mathrm{span}_{\mathbb{R}}\{1, e_1, \ldots, e_n\} \subset \mathcal{C}\ell_{0,n}$, where $\underline{x} = x_1 e_1 + \ldots + x_n e_n$ is called a *vector*. The conjugate $\bar{x}$ and the norm $|x|$ of x are given by $\bar{x} = x_0 - \underline{x}$ and $|x| = (x\bar{x})^{1/2} = (\bar{x}x)^{1/2} = \left(\sum_{k=0}^n x_k^2\right)^{1/2}$, respectively. The generalized Cauchy-Riemann operator and its conjugate are given, respectively, by $\overline{\partial} := \frac{1}{2}(\partial_0 + \partial_{\underline{x}})$ and $\partial := \frac{1}{2}(\partial_0 - \partial_{\underline{x}})$, where $\partial_0 := \frac{\partial}{\partial x_0}$ and $\partial_{\underline{x}} := e_1 \frac{\partial}{\partial x_1} + \cdots + e_n \frac{\partial}{\partial x_n}$.

We consider $\mathcal{C}\ell_{0,n}-$valued functions defined in an open subset $\Omega \subseteq \mathbb{R}^{n+1} \cong \mathcal{A}_n$, i.e. functions of the form $f(z) = \sum_A f_A(z) e_A$ with $f_A(z)$ real valued. Continuously differentiable functions f that satisfy the equation $\overline{\partial} f = 0$ (resp. $f\overline{\partial} = 0$) are called (left) *monogenic* (resp. right monogenic) and constitute the analogue of the class of holomorphic functions in higher dimensions. For more details, see [2, 5].

Let f be a monogenic function that is hypercomplex-differentiable in some domain $\Omega \subset \mathbb{R}^{n+1}$ in the sense of [6]. Then f is real-differentiable and its (hypercomplex) derivative is given by $f' = \partial f$ in Ω.

3 Matrix representation of orthogonal Clifford algebra-valued polynomials

Branching techniques combined with Gelfand-Tsetlin bases approach yield to the monogenic polynomials

$$f_{k,\mu} = X_{n+1,k_n}^{(k-k_n)} X_{n,k_{n-1}}^{(k_n - k_{n-1})} \cdots X_{3,k_2}^{(k_3-k_2)} \zeta^{k_2},$$

where $\zeta := x_1 - x_2\, e_1 e_2$ and μ is an arbitrary sequence of integers $(k_{n+1}, k_n, \ldots, k_3, k_2)$ such that $k = k_{n+1} \geq k_n \geq \ldots \geq k_3 \geq k_2 \geq 0$. These polynomials form an orthogonal basis with respect to a suitable Clifford algebra valued inner product of the space of monogenic polynomials of degree k (see [7]). The building blocks $X_{n+1,j}^{(k-j)}$, $j = 0, \ldots, k$, are, in general, non-monogenic polynomials and can be expressed as

$$X_{n+1,j}^{(k-j)}(x) = \sum_{s=0}^{k-j} \binom{k}{j+s} d_{j,s}(n)\, x_0^{k-j-s}\, \underline{x}^s, \quad x \in \mathcal{A}_n \tag{1}$$

 ISBN: 978-84-617-8694-7

where $d_{j,s}(n)$ are suitable real constants (cf. [3]). Given an arbitrary monogenic polynomial $P_j(\underline{x})$, in $\mathbb{R}^n$, of degree j, the system

$$\left\{\widetilde{X}^{(k)}_{n+1,j}(x) := X^{(k-j)}_{n+1,j}(x)\, P_j(\underline{x}), j = 0, \ldots, k,\ x \in \mathcal{A}_n\right\}_{k\in\mathbb{N}} \tag{2}$$

is formed by monogenic polynomials where again (1) appear as building blocks.

The matrix representation of the building blocks relies on the so-called *shifted generalized Pascal matrix* $S_r(t) = e^{(H+rJ)t}$, $t \in \mathbb{R}, r \in \mathbb{N}_0$, that combines in a single expression both H and J matrices.

For this representation we restrict ourselves to vectors of polynomials up to a certain degree $m \in \mathbb{N}_0$. Therefore, for each $j = 0, \ldots, k$, we consider the vectors $\xi(\underline{x}) = [1\ \underline{x}\ \cdots\ \underline{x}^m]^T$, $\boldsymbol{X}_j(x) = [X^{(0)}_{n+1,j}(x)\ X^{(1)}_{n+1,j}(x)\ \cdots\ X^{(m)}_{n+1,j}(x)]^T$ and the diagonal matrix $\mathcal{D}_j = \mathrm{diag}[d_{j,0}(n)\ d_{j,1}(n) \cdots d_{j,m}(n)]$.

Theorem 3.1. *For each fixed j, the vector $\boldsymbol{X}_j(x)$ can be decomposed in the form*

$$\boldsymbol{X}_j(x) = S_j(x_0)\ \mathcal{D}_j\ \xi(\underline{x}). \tag{3}$$

Proof. For each fixed j and considering $l = k - j$, it holds

$$\partial_0 X^{(0)}_{n+1,j}(x) = 0 \quad \text{and} \quad \partial_0 X^{(l)}_{n+1,j}(x) = (l + j)X^{(l-1)}_{n+1,j}(x), \ \ l > 0.$$

This property leads to the vector differential equation

$$\partial_0 \boldsymbol{X}_j(x) = (H + jJ)\boldsymbol{X}_j(x)$$

whose general solution is

$$\boldsymbol{X}_j(x) = e^{(H+jJ)x_0}\boldsymbol{X}_j(0, \underline{x}).$$

The result follows immediately noting that $X^{(l)}_{n+1,j}(0, \underline{x}) = d_{j,l}(n)\underline{x}^l$. □

The proposed decomposition (3) can be generalized for the whole orthogonal system (2) with the help of block matrices. The result highlights the role of the shift matrix J and its powers. Moreover, the generalized Pascal matrix $P(x_0) = S_0(x_0)$ comes into play as well (see [4]), connecting special simple matrices with real entries with hypercomplex entities.

Abstract

Ruscheweyh and Salinas showed in 2004 the relationship of a celebrated theorem of Vietoris (1958) about the positivity of certain sine and cosine sums with the function theoretic concept of stable holomorphic functions in the unit disc. The present paper reveals that the coefficient sequence in Vietoris' theorem is identical to a number sequence obtained by a new combinatorial identity which involves generators of quaternions. In this sense Vietoris' sequence of rational numbers combines seemingly disperse subjects in Real, Complex and Hypercomplex Analysis. Thereby we show that a non-standard application of Clifford algebra tools is able to reveal new insights in objects of combinatorial nature.

Key words: Vietoris' number sequence, quaternions, combinatorial identities
MSC 2000: 30G35; 11B83; 05A19.

1 Introduction

In the center of our attention lies the sequence of rational numbers

$$1,\ \tfrac{1}{2},\ \tfrac{1}{2},\ \tfrac{3}{8},\ \tfrac{3}{8},\ \tfrac{5}{16},\ \tfrac{5}{16}, \tfrac{35}{128}, \tfrac{35}{128}, \tfrac{63}{256}, \tfrac{63}{256}, \tfrac{231}{1024}, \tfrac{231}{1024}, \ldots. \tag{1}$$

which by means of the *generalized central binomial coefficient* $\binom{k}{\lfloor \frac{k}{2} \rfloor}$ can be written in compact form (cf. [4]) as

$$\mathcal{S} = (c_k)_{k\geq 0}\,, \quad \text{where } \ c_k = \frac{1}{2^k}\binom{k}{\lfloor \frac{k}{2} \rfloor}, \ \ k \geq 0. \tag{2}$$

 ISBN: 978-84-617-8694-7

Seemingly for the first time this sequence appeared in the context of positive trigonometric sums in a celebrated paper of L. Vietoris [17]. Askey's version ([2, p. 5]) of Vietoris' theorem is the following:

Theorem 1 (L. Vietoris)

$$\sum_{k=1}^{n} a_k \sin k\theta > 0, \;\; 0 < \theta < \pi, \;\; \textit{and} \;\; \sum_{k=0}^{n} a_k \cos k\theta > 0, \;\; 0 \leq \theta < \pi,$$

where

$$a_{2k} = a_{2k+1} = \frac{(\frac{1}{2})_k}{k!}, \qquad k = 0, 1, \ldots, \tag{3}$$

with $(\cdot)_k$ *as the raising factorial in the classical form of the Pochhammer symbol.*

We call attention to the fact that because of (3), the coefficients in the *sine* sum used in Askey's as well as in Vietoris' original version are exactly the elements of $\mathcal{S}$ in (2) or, explicitly, in (1). Obviously, demanding in (3) that a_{2k} and a_{2k+1} coincide, the sequence of coefficients in the *cosine* sum differs from (1) by the inclusion of $a_0 = 1$ and the shift of the indices by one to the left, i.e. $a_0 = 1 \quad \text{and} \quad a_{k+1} = c_k, \; k \geq 0$. Even though this small difference, we call $\mathcal{S}$ in the sequel simply *Vietoris' number sequence*. Compared with the traditional way of defining the coefficient sequence by (3), the use of the properties of the *generalized central binomial coefficient* allowed at least a unique representation (2) with consecutively running index k.

Before continuing with the specific task of the present paper, it seems worthwhile to mention the other areas in which Vietoris' theorem played an important role. Using the arsenal of real analysis methods in positivity theory, Askey and Steinig showed in [3] the embedding of Vietoris' results in general problems for Jacobi polynomials, including their relation to other subjects in Harmonic Analysis. Later on, Ruscheweyh and Salinas showed in [15] an interesting relationship of Vietoris' theorem with the function theoretic concept of stable holomorphic functions in the unit disc. The common origin of the present paper with others like, for example, [9, 5] where the sequence $\mathcal{S}$ was already mentioned in different contexts, is the field of Hypercomplex Analysis, particularly the study of monogenic (or Clifford-holomorphic) Appell polynomials [1, 8, 10]. Recently in [6], the authors obtained even some number theoretic results for a related to $\mathcal{S}$ integer number sequence (sequence A283208 in The On-Line Encyclopedia of Integer Sequences, published electronically at https://oeis.org).

The goal of the present paper concerns the surprising appearance of $\mathcal{S}$ in a relation between the generators of Hamilton's well known non-commutative algebra $\mathbb{H}$ of quaternions (see e.g. [10]), relying only on elementary properties of a adequately generalized binomial formula for the quaternions. Taking into account that $\mathbb{H}$ can be considered as a Clifford algebra $\mathcal{C}\ell_{0,n}$, for $n = 2$, the generalization of our results for an arbitrary $n \geq 2$ will be

 ISBN: 978-84-617-8694-7

treated in an extended version of this paper by applying intrinsic properties of monogenic Appell polynomials in terms of several hypercomplex variables.

2 Hamilton's quaternions come into the play

Consider a quaternion $q \in \mathbb{H}$ written as

$$q = x_0 + x_1\mathbf{i} + x_2\mathbf{j} + x_3\mathbf{k}, \text{ where } \mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1.$$

Due to non-commutativity the formal expansion of a binomial with two imaginary units (quaternion generators) $(\mathbf{i}+\mathbf{j})^k$, $k \geq 0$, will not directly lead to Pascal's triangle, as the case $k = 3$ shows:

$$(\mathbf{i}+\mathbf{j})^3 = \mathbf{i}^3 + (\mathbf{iij} + \mathbf{iji} + \mathbf{jii}) + (\mathbf{ijj} + \mathbf{jij} + \mathbf{jji}) + \mathbf{j}^3. \tag{4}$$

But that will happen if we try to embed the non-commutative multiplication into the concept of a $k-nary$ symmetric (or permutative) operation. Therefore let a_i stay for one of the generators $\mathbf{i}$ or $\mathbf{j}$ and write the quaternionic k-fold product of $k-s$ generators $\mathbf{i}$ and s generators $\mathbf{j}$, respectively, in the general form of a symmetric " $\times$ " product ([13]), i.e.

$$\mathbf{i}^{k-s} \times \mathbf{j}^s := \frac{1}{k!} \sum_{\pi(i_1,\ldots,i_n)} a_{i_1} a_{i_2} \cdots a_{i_k} \tag{5}$$

where the sum runs over ***all*** permutations of all $(i_1, \ldots, i_n)$. Then, by taking into account the repeated use of $\mathbf{i}$ and $\mathbf{j}$ on the right hand side of (5), we can write

$$\mathbf{i}^{k-s} \times \mathbf{j}^s = \frac{(k-s)!s!}{k!} \sum_{\pi(i_1,\ldots,i_n)} a_{i_1} a_{i_2} \cdots a_{i_k} = \left[\binom{k}{s}\right]^{-1} \sum_{\pi(i_1,\ldots,i_n)} a_{i_1} a_{i_2} \cdots a_{i_k}$$

where now the sum runs only over ***all distinguished*** permutations of all $(i_1, \ldots, i_n)$. Applying, for example, the convention (5) to (4) we obtain now, for $k = 3$ the expansion written with binomial coefficients in the form

$$(\mathbf{i}+\mathbf{j})^3 = \binom{3}{0}\mathbf{i}^3 + \binom{3}{1}\mathbf{i}^2 \times \mathbf{j} + \binom{3}{2}\mathbf{i} \times \mathbf{j}^2 + \binom{3}{3}\mathbf{j}^3. \tag{6}$$

Analogously, the expansion of $(\mathbf{i}+\mathbf{j})^k$ for any $k \geq 0$ follows now the rules of the ordinary binomial expansion in an evident way and leads to[1]

$$(\mathbf{i}+\mathbf{j})^k = \left[\sum_{s=0}^{k} \binom{k}{s} (\mathbf{i}^{k-s} \times \mathbf{j}^s)\right], \quad k \geq 0. \tag{7}$$

[1]An obvious generalization of (5) to the case of more than two generators used in the general case of $\mathcal{C}\ell_{0,n}$ for $n \geq 2$ leads to a polynomial formula.

 ISBN: 978-84-617-8694-7

Needless to say that the generalized binomial formula (7) is a key for studying combinatorial relations with quaternions in the following sections.

We will show now that another step towards our goal is the evaluation of expressions of the form $(\mathbf{i}^{k-s} \times \mathbf{j}^s)$ $k \geq 0,\ s = 0, 1, \ldots k$.

3 Evaluating symmetric products of quaternion generators

Notice that for $k \geq 2$ the influence of the non-commutativity of the ordinary quaternionic product is evident. This can be illustrated by the following examples:

$$\mathbf{i} \times \mathbf{j} = \frac{1!1!}{2!}(\mathbf{ij} + \mathbf{ij}) = 0,$$

$$\mathbf{i}^2 \times \mathbf{j} = \binom{3}{1}^{-1}(\mathbf{iij} + \mathbf{iji} + \mathbf{jii}) = -\frac{1}{3}\mathbf{j}, \tag{8}$$

$$\mathbf{i} \times \mathbf{j}^2 = \binom{3}{1}^{-1}(\mathbf{ijj} + \mathbf{jij} + \mathbf{jji}) = -\frac{1}{3}\mathbf{i}. \tag{9}$$

To obtain a general rule for those products we refer to an early version of the famous *Faá di Bruno formula* for the derivative of a composed function (see [11] and [12]) as it was used in [7].

T. Abadie's formula
If f and g are real functions of λ, with a sufficient number of derivatives, then

$$(g \circ f)^{(s)}(\lambda) = \sum_{l=0}^{s} \binom{s}{l} g^{(l)}\big(f(\lambda)\big)\Big\{\frac{d^{s-l}}{dh^{s-l}}\big(\Delta_h f(\lambda)\big)^l\Big\}_{h=0},$$

where $\Delta_h f(\lambda) := \frac{f(\lambda+h)-f(\lambda)}{h}$ is the difference quotient of f.

Consider now the polynomial $F_k(\lambda)$ of degree k in the real parameter λ,

$$F_k(\lambda) = (\mathbf{i} + \lambda\mathbf{j})^k = \sum_{s=0}^{k} \binom{k}{s} \lambda^s \mathbf{i}^{k-s} \times \mathbf{j}^s$$

and note that

$$\mathbf{i}^{k-s} \times \mathbf{j}^s = \frac{F_k^{(s)}(0)}{s!\binom{k}{s}}. \tag{10}$$

Since

$$F_k(\lambda) = \begin{cases} (-1-\lambda^2)^{\frac{k}{2}}, & \text{if} \quad k \text{ even;} \\ (-1-\lambda^2)^{\frac{k-1}{2}}(\mathbf{i} + \lambda\mathbf{j}), & \text{if} \quad k \text{ odd,} \end{cases} \tag{11}$$

 ISBN: 978-84-617-8694-7

it can be composed, for even k, in the form $F_k(\lambda) = (g \circ f)(\lambda)$ with suitably chosen functions

$$g(\lambda) = (-1-\lambda)^{\frac{k}{2}} \text{ and } f(\lambda) = \lambda^2.$$

whereas the case of an odd k can be reduced to the previous case by the relation

$$F_k(\lambda) = F_{k-1}(\lambda)(\mathbf{i} + \lambda\mathbf{j}).$$

Applying *T. Abadie's formula* and following the proof of *Proposition 1* in [7, p. 1730], about generalized powers of hypercomplex variables, one gets finally the values of (10) in the form:

$$\mathbf{i}^{k-s} \times \mathbf{j}^s = \begin{cases} (-1)^{\frac{k}{2}} \binom{\frac{k}{2}}{\frac{s}{2}} \binom{k}{s}^{-1}, & k \text{ even and } s \text{ even;} \\ 0, & k \text{ even and } s \text{ odd;} \\ (-1)^{\frac{k-1}{2}} \binom{\frac{k-1}{2}}{\frac{s}{2}} \binom{k}{s}^{-1} \mathbf{i}, & k \text{ odd and } s \text{ even;} \\ (-1)^{\frac{k-1}{2}} \binom{\frac{k-1}{2}}{\frac{s-1}{2}} \binom{k}{s}^{-1} \mathbf{j}, & k \text{ odd and } s \text{ odd.} \end{cases} \tag{12}$$

Remark 1 The examples in the beginning of this section, in particular relations (8) and (9), confirm very well the last three equalities in (12). It is evident, that there are, depending on the relative parities of k resp. s only four types of values of $\mathbf{i}^{k-s} \times \mathbf{j}^s$, namely (i) real and different from zero, (ii) equal to zero, (iii) a real multiple of $\mathbf{i}$ and (iv) a real multiple of $\mathbf{j}$. The reason for this, at first glance, surprising result is based on the following facts. Obviously, an integer power of the type of a so-called *reduced purely imaginary quaternion* $\underline{q} = \mathbf{i}+\mathbf{j}$, is either a real number (if k is even) or again a reduced purely imaginary quaternion (if k is odd; cf. (11)). Besides this, the symmetric products in which such a power (7) is additively decomposed avoid the appearance of ordinary mixed products like, for example, $\mathbf{i} \cdot \mathbf{j}$ as mutually annihilating summands. This becomes directly plausible if we look for example to the binomial expansion for even $k = 2$ or $k = 4$ where only entries of type (i) and type (ii) are present. An example for an odd k with $2 \times \frac{k+1}{2} = k+1$ alternating entries of type (iii) and (iv) is (6). In both cases we can recognize the symmetric structure of the corresponding lines in a Pascal triangle with quaternionic entries.

4 A combinatorial identity for Vietoris' number sequence

Before coming to our main result, let us still remember a well known combinatorial identity (cf. [14, p. 130] or [16, p. 44]) that we need for its proof, namely

$$\sum_{t=0}^{m} \binom{2t}{t} \binom{2m-2t}{m-t} = 4^m, \tag{13}$$

 ISBN: 978-84-617-8694-7

which in turn can be proved by evaluating the square of the generating function of the central binomial coefficients and its derivatives at $x = 0$.

Now we can prove

Theorem 2 *Let* $\mathbf{i}$ *and* $\mathbf{j}$ *be two generators of a reduced purely imaginary quaternion. Then the following combinatorial identity holds*

$$\binom{k}{\lfloor \frac{k}{2} \rfloor} \left[\sum_{s=0}^{k} \binom{k}{s} (\mathbf{i}^{k-s} \times \mathbf{j}^{s})^2 \right] = (-2)^k. \tag{14}$$

Taking into account the form of the elements of Vietoris' number sequence (2), formula (14) can be rewritten in order to obtain the representation of Vietoris' number sequence by symmetric products of the generators $\mathbf{i}$ and $\mathbf{j}$.

Corollary [*Representation of Vietoris' number sequence*]

$$c_k = (-1)^k \left[\sum_{s=0}^{k} \binom{k}{s} (\mathbf{i}^{k-s} \times \mathbf{j}^{s})^2 \right]^{-1}. \tag{15}$$

Proof of Theorem 2
As an auxiliary calculation we determine the square of the symmetric products in (12) multiplied by $\binom{k}{s}$ and distinguish between $k = 2m$ and $k = 2m + 1$ resp. $s = 2t$ and $s = 2t + 1$ for the different parities. We get immediately

$$\binom{k}{s} (\mathbf{i}^{k-s} \times \mathbf{j}^{s})^2 = \begin{cases} \dfrac{\binom{m}{t}^2}{\binom{2m}{2t}}, & k = 2m \quad \text{and } s = 2t; \\ 0, & k = 2m \quad \text{and } s = 2t + 1; \\ \dfrac{-\binom{m}{t}^2}{\binom{2m+1}{2t}}, & k = 2m + 1 \quad \text{and } s = 2t; \\ \dfrac{-\binom{m}{t}^2}{\binom{2m+1}{2t+1}}, & k = 2m + 1 \quad \text{and } s = 2t + 1. \end{cases} \tag{16}$$

Now we consider two cases corresponding to the parity of k.

I. k even

Denote by A_k the left-hand side of (14). The use of (16) (note that the second case

 ISBN: 978-84-617-8694-7

implies that the sum over odd values of s completely vanishes) together with (13) allows to write

$$\begin{aligned} A_{2m} &= \binom{2m}{m}\Big[\sum_{s=0}^{2m}\binom{2m}{s}(\mathbf{i}^{2m-s}\times\mathbf{j}^{s})^2\Big] = \binom{2m}{m}\Big[\sum_{t=0}^{m}\binom{2m}{2t}(\mathbf{i}^{2m-2t}\times\mathbf{j}^{2t})^2+0\Big] \\ &= \binom{2m}{m}\left[\sum_{t=0}^{m}\frac{\binom{m}{t}^2}{\binom{2m}{2t}}\right] = \sum_{t=0}^{m}\frac{(2t)!}{t!t!}\cdot\frac{(2m-2t)!}{(m-t)!(m-t)!} \\ &= 4^m = (-2)^{2m} \end{aligned}$$

II. k odd

In this case we apply the third and the fourth case of (16) and proceed analogously to the former case.

$$\begin{aligned} A_{2m+1} &= \binom{2m+1}{m}\Big[\sum_{s=0}^{2m+1}\binom{2m}{s}(\mathbf{i}^{2m+1-s}\times\mathbf{j}^{s})^2\Big] = \binom{2m+1}{m}\left[\sum_{t=0}^{m}\frac{-\binom{m}{t}^2}{\binom{2m+1}{2t}}-\sum_{t=0}^{m}\frac{\binom{m}{t}^2}{\binom{2m+1}{2t+1}}\right] \\ &= \binom{2m+1}{m}\sum_{t=0}^{m}\binom{m}{t}^2\left[\frac{(2t)!(2m-2t+1)!}{(2m+1)!}+\frac{(2m-2t)!(2t+1)!}{(2m+1)!}\right] \\ &= -2\sum_{t=0}^{m}\frac{(2t)!}{t!t!}\cdot\frac{(2m-2t)!}{(m-t)!(m-t)!} \\ &= -2\cdot 4^m = (-2)^{2m+1}. \end{aligned}$$

□

We finish with examples for the first values of c_k in (15) resp. (1),

$$\begin{aligned} c_0 &= 1 \\ c_1 &= (-1)^1\left[\mathbf{i}^2+\mathbf{j}^2\right]^{-1} = \frac{1}{2} \\ c_2 &= (-1)^2\left[(\mathbf{i}^2)^2+\binom{2}{1}(\mathbf{i}\times\mathbf{j})^2+(\mathbf{j}^2)^2\right]^{-1} = \frac{1}{2} \\ c_3 &= (-1)^3\left[(\mathbf{i}^3)^2+\binom{3}{1}(\mathbf{i}^2\times\mathbf{j})^2+\binom{3}{2}(\mathbf{i}\times\mathbf{j}^2)^2+(\mathbf{j}^3)^2\right]^{-1} = \frac{3}{8} \\ c_4 &= (-1)^4\left[(\mathbf{i}^4)^2+\binom{4}{1}(\mathbf{i}^3\times\mathbf{j})^2+\binom{4}{2}(\mathbf{i}^2\times\mathbf{j}^2)^2+\binom{4}{3}(\mathbf{i}\times\mathbf{j}^3)^2+(\mathbf{j}^4)^2\right]^{-1} = \frac{3}{8}. \end{aligned}$$

Abstract

The purpose of this paper is to study the problem of (S,T)-stability and convergence of the θ-modified Jungck-Ishikawa.

Key words: Coincidence point; Ishikawa iteration; stability.

1 Introduction and Preliminaries

Throughout this paper, we assume that E is a real Banach space.

An operator $T : E \to E$ is said to be Lipschizian if there exists a constant $L > 0$ such that

$$\| Tx - Ty \| \leq L \| x - y \|, \tag{1}$$

for all $x, y \in E$.

An operator $T : E \to E$ is said to be strongly pseudocontractive if there exists $t > 1$ such that

$$\| x - y \| \leq \| (1 + r)(x - y) - rt(Tx - Ty) \|, \tag{2}$$

for all $x, y \in E$ and $r > 0$.

Let $S, T : E \longrightarrow E$ be two non-self mappings such that $T(E) \subseteq S(E)$. Then the sequence $\{Sx_n\}_{n=0}^{\infty}$ defined by

$$Sx_{n+1} = Tx_n; \qquad n = 0, 1, 2, ... \tag{3}$$

 ISBN: 978-84-617-8694-7

is called Jungck-Picard iteration scheme [3].

Definition 1.1 *Let $T : E \to E$ be a self mapping. Then T has a fixed point if there is an $x \in E$ such that $Tx = x$. The point x is called a fixed point of T. The set of fixed point of T will be denoted by $F(T)$.*

Definition 1.2 *Let $S, T : E \longrightarrow E$. Then x is called a coincidence (common fixed) point of T and S, respectively, if there exists $x \in X$ such that*

$$(x =)Tx = Sx$$

The set of all coincidence points of T and S will be denoted by $C(T, S)$.

Let $S, T : E \longrightarrow E$ are two non-self mappings such that $T(E) \subseteq S(E)$. Then the sequence $\{Sx_n\}_{n=0}^{\infty}$ defined by

$$Sx_{n+1} = (1 - \alpha_n)Sx_n + \alpha_n Tx_n \qquad n = 0, 1, 2, ..., \tag{4}$$

where $\{\alpha_n\}$ is introduced by Singh et al. [7] to establish some stability results and it is called Jungck-Mann iteration scheme.

On the other hand, the sequence $\{Sx_n\}_{n=0}^{\infty}$ defined by

$$\begin{aligned} Sx_{n+1} &= (1 - \alpha_n)Sx_n + \alpha_n Tz_n \\ Sz_n &= (1 - \beta_n)Sx_n + \beta_n Tx_n, \qquad n = 0, 1, 2, ..., \end{aligned} \tag{5}$$

where $\{\alpha_n\}$ and $\{\beta_n\}$ are the sequences in [0, 1), is called Jungck Ishikawa iteration scheme [5]. If S is the identity mapping, then Jungck Picard, Jungck Mann and Jungck Ishikawa iteration schemes becomes Picard, Mann and Ishikawa iteration schemes.

The Ishikawa iterative process was first introduced by Ishikawa [2] in 1974, in order to approximate fixed point of Lipschitzian pseudocontractive operators, because in the case T is only pseudocontractive, the Mann iteration does not converge generally to the fixed point of T. In the literature, there are many convergence results on the Ishikawa iterations. For example, Chidume [1] proved the following result:

Theorem 1.1 *If E is a real Banach space with a uniformly convex dual E^*, and K is a nonempty closed convex and bounded subset of E, and $T : E \to E$ is a Lipschitz strongly pseudocontractive mapping, the Ishikawa iterative sequence $\{x_n\}$ converges strongly to the unique fixed point of T.*

 ISBN: 978-84-617-8694-7

Consider the nonlinear equation

$$f(x) = 0, \quad x \in \mathbb{R}. \tag{6}$$

Let $S, T : E \to E$, $T(E) \subset S(E)$, S is onto and T and S are differentiable. Suppose ξ is a simple zero of f and x_0 is an initial guess nearer ξ. The equation (6) can be written as

$$Sx = Tx. \tag{7}$$

Following the approach of [4] (see also [6]), if $T'x \neq 1$, we can modifify (7) by multiplying $\theta \neq -1$ on both sides as follows

$$\theta Sx = \theta Tx,$$

which implies that

$$Sx = \frac{\theta Tx + Sx}{\theta + 1} := T_\theta x, \tag{8}$$

where θ is an arbitrary number.

For a given x_0, we can find the approximate solution of x_{n+1} by using the iteration scheme named as modified Jungck iteration scheme

$$Sx_{n+1} = \frac{\theta Tx_x + Sx_x}{\theta + 1}, \quad \theta \neq -1, \tag{9}$$

or

$$Tx_{n+1} = \frac{\theta Tx_x + Sx_x}{\theta + 1}, \quad \theta \neq -1. \tag{10}$$

Using (9) in Jungck-Ishikawa iteration scheme, we develop a modified one scheme as follow:

Definition 1.3 *(See [6]). Let $T : E \longrightarrow E$ be a mapping. For given $\theta \neq -1$, $x_0 \in E$ and $\{\alpha_n\}$, $\{\beta_n\}$ sequences in [0,1], we denote $\{Sx_n\} \subset E$ the sequence defined by*

$$\begin{aligned} Sx_{n+1} =& (1 - \alpha_n)Sx_n + \alpha_n T_\theta z_n, \\ Sz_n =& (1 - \beta_n)Sx_n + \beta_n T_\theta x_n, \end{aligned} \tag{11}$$

where $T_\theta x = \frac{\theta Tx + Sx}{1+\theta}$. The iteration process (11) will be called modified Jungck-Ishikawa iteration.

The following lemma will be needed in proving our main results.

Lemma 1.1 *(See [8]). Let $\{\lambda_n\}$,$\{\mu_n\}$, $\{d_n\}$ be nonnegative real sequences satisfying*

$$\lambda_{n+1} \leq (1 + t_n)\lambda_n + \mu_n\lambda_n + c_n + d_n \qquad \forall n \geq 1$$

If $\{t_n\}$ is a sequence in [0,1] such that $\sum_{n=1}^{\infty} t_n = \infty$, $\sum_{n=1}^{\infty} \mu_n < \infty$, $\sum_{n=1}^{\infty} c_n < \infty$ and $d_n = o(t_n)$. Then $\lambda \longrightarrow 0$ as $n \longrightarrow \infty$

 ISBN: 978-84-617-8694-7

Using the following definition of the stability of an iteration process, Olantiwo [5] established some stability results as well as some strong convergence results for a pair of nonselfmappings using a Jungck-Ishikawa iteration process and some general contractive conditions.

Definition 1.4 *See ([5]). Let $S, T : E \to E$, $T(E) \subseteq S(E)$ and $l \in C(T, S)$. For any $x_0 \in E$, let the sequence $\{Sx_{n+1}\}_{n=0}^{\infty}$ generated by iteration $Sx_{n+1} = f(T, x_n)$, $n = 0, 1, 2, 3, ...$ converges to w. Let $\{Sy_n\}_{n=0}^{\infty} \subset E$ be an arbitrary sequence, and $\varepsilon_n = d(Sy_{n+1}, f(T, y_n))$, $n = 0, 1, 2, ...$ Then, the iteration $\{Sx_{n+1}\}_{n=0}^{\infty}$ will be called (S, T)-stable if only if $\lim_{n\to\infty} \varepsilon_n = 0$ implies that $\lim_{n\longrightarrow\infty} Sy_n = w$*

2 Main results

Definition 2.1 *Given $S : E \to E$ and $T : E \to E$.*

T is said to be S-Lipschitzian if there exists a constant $L > 0$ such that

$$\| Tx - Ty \| \leq L \| Sx - Sy \|, \tag{12}$$

for all $x, y \in E$.

T is S-strongly pseudocontractive is there exists $k > 0$ such that

$$\| Sx - Sy \| \leq \| Sx - Sy + q[(S - T - kS)x - (S - T - kS)y] \| \tag{13}$$

for all $x, y \in E$ and $q > 0$.

Let $S, T : E \to E$. Suppose $x_0 \in E$ and $x_{n+1} = f(x_n, \alpha_n, T, S)$ defines an iteration procedure which yields a sequence of points $\{Sx_n\} \subset E$ converging to a coincidence point w of T and S. Let $\{y_n\}$ and let $\varepsilon_n = \| Sy_{n+1} - f(x_n, \alpha_n, T, S) \|$ be a sequence in $[0, \infty)$.

Definition 2.2 *If $\sum_{n=1}^{\infty} \varepsilon_n < \infty$, implies that $\lim_{n\to\infty} Sy_n = w$, then the procedure defined by $x_{n+1} = f(x_n, \alpha_n, T, S)$ is said to be almost (S, T)-stable.*

If $\lim_{n\to\infty} \frac{\varepsilon_n}{\alpha_n} = 0$, implies that $\lim_{n\to\infty} Sy_n = w$, then the procedure defined by $x_{n+1} = f(x_n, \alpha_n, T, S)$ is said to be weakly (S, T)-stable.

Theorem 2.1 *Let $T, S : E \to E$ are two non-self mappings such that $T(E) \subseteq S(E)$, where $T_\theta = \frac{\theta Tx + Sx}{\theta + 1}$ is a S-Lipschitzian and S-strongly pseudocontractive mapping with $C(T, S) \neq \emptyset$. Let $\{x_n\}$ be defined by (11) and $\{\alpha_n\}, \{\beta_n\} \subset [0, 1]$ satisfying the conditions:*

i . $\sum_{k=1}^{\infty} \alpha_k = \infty$

ii . $\lim_{n\longrightarrow\infty} \sup \alpha_n < k/((L + 1)^3 + 2)$ *and* $\sum_{k=1}^{\infty} \alpha_k \beta_k < \infty$

 ISBN: 978-84-617-8694-7

Suppose $\{y_n\} \subset E$ *and define* $\{\varepsilon_n\}$ *by*

$$\begin{aligned} Ss_n =&(1-\beta_n)y_n + \beta_n T_\theta y_n \\ \varepsilon_n =& \parallel Sy_{n+1} - (1-\alpha_n)Sy_n - \alpha_n T_\theta s_n \parallel, \qquad n \geq 0 \end{aligned}$$

Then the following assertions hold:

1. $\{Sx_n\}_{n=0}^{\infty}$ *converges strongly to a coincidente point of* S *and* T.
2. $\{Sx_n\}_{n=0}^{\infty}$ *is both almost* (S,T)*-stable and weakly* (S,T)*-stable.*

Similarly to Theorem 2.2, we have the following

Theorem 2.2 *Let* $T, S : E \to E$ *are two non-self mappings such that* $T(E) \subseteq S(E)$*, where* $T_\theta = \frac{\theta Tx + Sx}{\theta+1}$ *is a* S*-Lipschitzian and* S*-strictly pseudocontractive mapping with* $C(T,S) \neq \emptyset$*. Let* $\{x_n\}$ *be defined by (11) and* $\{\alpha_n\}, \{\beta_n\} \subset [0,1]$ *satisfying the conditions:*

i . $\sum_{k=1}^{\infty} \alpha_k = \infty$

ii . *There exists* $\delta \in (0, 1-k)$ *such that* $\lim\limits_{n \longrightarrow \infty} \sup \alpha_n < \delta/((L+1)^3 + 2)$

iii. $\sum_{k=1}^{\infty} \alpha_k \beta_k < \infty$

Suppose $\{y_n\} \subset E$ *and define* $\{\varepsilon_n\}$ *by*

$$\begin{aligned} Ss_n =&(1-\beta_n)y_n + \beta_n T_\theta y_n \\ \varepsilon_n =& \parallel Sy_{n+1} - (1-\alpha_n)Sy_n - \alpha_n T_\theta s_n \parallel, \qquad n \geq 0 \end{aligned}$$

Then the following assertions hold:

1. $\{Sx_n\}_{n=0}^{\infty}$ *converges strongly to a coincidente point of* S *and* T.
2. $\{Sx_n\}_{n=0}^{\infty}$ *is both almost* (S,T)*-stable and weakly* (S,T)*-stable.*

On the effect of a polynomial field prescribed in an unbounded domain with an elliptical isolated inhomogeneity

Abstract

The Eshelby inhomogeneity or inclusion problem is known to play a crucial role in the micromechanical analysis of the mechanical behavior of composites [10] since leads to predict the overall behaviour of heterogeneous mediums. The so call inclusion problem has attracted the interest of several authors in the last two centuries. In particular, Poisson studied the perturbed field due to an isolated ellipsoid in the context of the Newtonian potential problem [1]. Later, Maxwell [12] obtained explicit uniform expressions for the induced electric field inside the ellipsoidal inclusion under an uniform electric polarization. Donnell [2] studied the problem of a homogeneous elliptical inclusion with the same elastic properties as the surrounding matrix and undergoes uniform stress-free transformation strains (also called *eigenstrains* in the literature). Afterward, Hardiman [3] considered the case of an elliptical inhomodeneity having elastic properties different from those of the matrix.

In the context of linear elasticity Eshelby [4], [5], [7] provided a systematic investigation of the corresponding three-dimensional problems. He introduced an interesting method known as the equivalent inclusion method for dealing with 3D inhomogeneity problems and showed that given an isolated ellipsoidal inclusion embedded into an infinitely homogeneous material, for any uniform loading imposed in the far field, the strain inside it is also uniform. This property, also called the *Eshelby uniformity property*, has been studied by many since then because it can model numerous phenomena in materials science, such as phase transformations in solids or the thermal expansion problem, as well as being useful as a simple modelling tool for inhomogeneous media [14].

In the case of non-uniform far field conditions, Eshelby showed that if the loading is a polynomial of order n, the interior field is characterized by a polynomial of the same

 ISBN: 978-84-617-8694-7

order. This is often called *Eshelby's polynomial conservation theorem*. Mura [10] gave further details of this theory and developed a method of solution based on multipole expansions in order to evaluate the induced strain field in an ellipsoidal inhomogeneity using the eigenstrain concept.

For ellipsoidal inhomogeneity problems the so-called Eshelby tensor arises naturally and it can be shown to be uniform for under uniform far fields conditions. However, for a *non-uniform* loading, Eshelby's solutions in general involve difficult integral expressions and then, the prediction of its influence is not a natural quantity to work with. Therefore, several methods based on complex variable [11] (due to uniform interior eigenstrain) or some circle theorems [6], [9], [8] have been developed in recent years for the study of interior fields. Recently, in [14] other one has been defined in order to determine such Eshelby tensors, even for general inclusion shapes. Despite these difficulties, it occurs that in many practical applications, e.g. permittivity, conductivity, elasticity, the influence on interior fields under *non-uniform* far field conditions also needs to be treated. As consequence, new better predictive methods are needed to be developed in order to characterize them in a direct manner. For these reasons, in this work for prescribed polynomial far field conditions, following the approximation to the Eshelby tensors developed in [14] and the integral operator method introduced in [13], and [15], we present a scheme to approximate interior fields inside isolated inhomogeneities of elliptical shape since many composites belong to this class (including layered and fiber reinforced composites). Moreover, we also verify that the obtained results ascertain the *Eshelby's polynomial conservation property* and are agree with some others provided by using complex conformal mapping [11] or the classical circle inclusion theorem ([6], [9], [8]). This result constitutes an useful scheme in the development of predictive material models that undergoes general non-uniform eigenstrains since they also can be uniformly approximated by Taylor series expansions, and even because they can be extended in forthcoming schemes to non elliptical shapes.

Key words: eigenstrains, elliptical inclusions, heterogeneities, conformal mapping, Eshelby's tensor, circle theorem, polynomial conservation property

Symmetry analysis for a generalized dissipative Dullin-Gottwald-Holm equation with arbitrary coefficients

J.C. Camacho[1], M. Rosa[1], M.L. Gandarias[1] and M.S. Bruzón[1]

[1] *Department of Mathematics, University of Cádiz*

emails: josecarlos.camacho@uca.es, maria.rosa@uca.es, marialuz.gandarias@uca.es, m.bruzon@uca.es

Abstract

In this work we study the classical Lie symmetries of a generalized Dullin-Gottwald-Holm equation with arbitrary coefficients. We consider the model (GDGH)

$$u_t - \alpha^2 u_{xxt} + (f(u))_x + \gamma u_{xxx} + \lambda(u - \alpha^2 u_{xx}) = \alpha^2(2u_x u_{xx} + u u_{xxx}). \qquad (1)$$

The equation GDGH is a nonlinear partial differential equation describing the unidirectional propagation of shallow water waves. The function $u(x,t)$ is the fluid velocity at time $t > 0$ in the direction x, γ is the coefficient of the linear dispersion term, $f(u)$ is a polynomial which derivative can be used to model the linear wave speed for undisturbed water at rest at spatial infinity, α^2 and $\frac{\gamma}{k}$ are squares of length scales where k is the coefficient of u in $f(u)$, this is, the linear wave speed for undisturbed water resting at spatial infinity, and λ is a coefficient of the weakly dissipative term $(u - \alpha^2 u_{xx})$.

When $f(u) = \frac{3}{2}u^2 + c_1 u + c_0$ and $\lambda > 0$ the GDGH equation is the disipate Dullin-Gottwald-Holm equation studied by Guo and Ni in [6], and later by Novruzov in [11].

When $f(u) = \frac{3}{2}u^2 + c_1 u + c_0$, $\lambda = 0$ and $\gamma \neq 0$ (1) becomes the Dullin-Gottwald-Holm equation (DGH) whith was orignally derived as an approximation to the incompressible Euler equations [4]. Also, when $\alpha = 0$ it becomes the Korteweg-de Vries (KdV) equation.

When $f(u) = \frac{3}{2}u^2 + c_1 u + c_0$, $\lambda = 0$, $\gamma = 0$ and $\alpha = 1$ (1) becomes the classical Camassa-Holm (CH) equation, introduced for Camassa and Holm in [3].

The GDGH equation when $\lambda = 0$ was proposed by Shaoyoung Lai and Meng We in [9]. This equation is also generalized as

$$u_t - u_{txx} + (h(u))_x + b u_{xxx} = a\left(\frac{g'(u)}{2}u_x^2 + g(u)u_{xx}\right)_x,$$

see [2].

 ISBN: 978-84-617-8694-7

By using the classical method of symmetry reductions of partial differential equations (PDEs) we obtain transformations under which differential equations are invariants, such transformations bring the GDGH (1) to itself.

When we have an invariant solution, which can be found by symmetry reduction, by using new variables, dependents and independents, we obtain a new differential equation considerably simpler. In the case of two independent variables and one dependent variable, we obtain ordinary differential equations (ODEs). The description of the method can be found in [12, 13].

There are several papers that study the symmetries of particular cases of equation GDGH [1, 2, 5, 7, 8, 10, 14]

The Lie symmetry group of the GDGH (1) will be generated by a vector field of the form

$$X = \xi(x,t,u)\partial_x + \tau(x,t,u)\partial_t + \phi(x,t,u)\partial_u.$$

When we require that the infinitesimal generator leaves invariant the set of solutions of the equation, we obtain, in the general case, the space and time translations, $\mathbf{v}_1 = \partial_x,\ \mathbf{v}_2 = \partial_t$.

The generators of an optimal system of one-dimensional symmetries in the general case are the set: $\{\mathbf{v}_1, \quad \lambda\mathbf{v}_1 + \mathbf{v}_2\}$. With the second generator, we have travelling waves, where the constant λ represents the speed of the wave. In order to reduce (1) to ODEs we obtain the similarity reductions by using the characteristic equations

$$\frac{dx}{\xi(x,t,u)} = \frac{dt}{\tau(x,t,u)} = \frac{du}{\phi(x,t,u)}.$$

The similarity reductions are

$$\left\{ \begin{array}{rcl} z & = & x + \mu\, t, \\ u & = & h(z), \end{array} \right.$$

and the reduced ODE is

$$\alpha^2\, h\, h''' + \mu\, \alpha^2\, h''' - \gamma\, h''' + 2\,\alpha^2\, h'\, h'' + \lambda\,\alpha^2\, h'' - f\, h' - \mu\, h' - \lambda\, h = 0. \tag{2}$$

If we considered h the independent variable, and $y = y(h)$, we can reduce the equation (2) to

$$\left(\alpha^2\, h + \mu\,\alpha^2 - \gamma\right)\, y\, \left(y\, y'' + (y')^2\right) + \alpha^2\, y\, \left(2\, y + \lambda\right)\, y' - \left(f + \mu\right)\, y - \lambda\, h = 0. \tag{3}$$

Solving (2) we obtain travelling waves solutions of the equation GDGH

For some special choices of the constants, other generators are admitted.

- Case 1. $f(u) = \frac{c_1}{2}u^2 - \frac{\gamma}{\alpha^2}u + c_2$.

$$\mathbf{v}_{31} = \gamma \mathrm{e}^{\lambda\, t}\partial_x - \alpha^2 \mathrm{e}^{\lambda\, t}\partial_t + \alpha^2 \lambda \mathrm{e}^{\lambda\, t} u \partial_u.$$

- Case 2. $f(u) = \frac{1}{2}u^2 + c_1 u + c_2$.

$$\mathbf{v}_{32} = \mathrm{e}^{-\lambda\, t}\partial_x - \lambda \mathrm{e}^{-\lambda\, t}\partial_u.$$

 ISBN: 978-84-617-8694-7

- Case 3. $f(u) = \frac{1}{2}u^2 - \frac{\gamma}{\alpha^2}u + c_1$.

$$\mathbf{v}_{32}\ ,\ \mathbf{v}_{43} = \gamma \mathrm{e}^{\lambda\, t}\partial_x - \alpha^2 \mathrm{e}^{\lambda\, t}\partial_t + \lambda\alpha^2 \mathrm{e}^{\lambda\, t} u\partial_u.$$

- Case 4. $f(u) = \frac{c_1}{2}u^2 + c_2 u + c_3$, $\lambda = 0$.

$$\mathbf{v}_{34} = \alpha^2 c_2 + c_1\gamma t\partial_x - \alpha^2(c_1 - 1)t\partial_t + \left(\alpha^2(c_1 - 1)u + \alpha^2 c_2 + \gamma\right)\partial_u.$$

- Case 5. $f(u) = c_2 + c_1\left(u - \frac{\gamma}{\alpha^2}\right)^2$, $\lambda = 0$.

$$\mathbf{v}_{35} = t\partial_t - \left(u - \frac{\gamma}{\alpha^2}\right)\partial_u.$$

- Case 6. $f(u) = \frac{1}{2}u^2 - \frac{\gamma}{\alpha^2}u + c_1$, $\lambda = 0$.

$$\mathbf{v}_{35}\ ,\ \mathbf{v}_{46} = t\partial_x + \partial_u.$$

we generate the optimal system in each case

- Case 1. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2,\ \mu\mathbf{v}_1 + \mathbf{v}_{31}\}$
- Case 2. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2,\ \mu\mathbf{v}_1 + \mathbf{v}_{32}\}$
- Case 3. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2,\ \mathbf{v}_{33},\ \mu\mathbf{v}_{33} + \mathbf{v}_{43}\}$
- Case 4. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2, \mu\mathbf{v}_2 + \mathbf{v}_{34}\}$
- Case 5. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2, \mu\mathbf{v}_1 + \mathbf{v}_{35}\}$
- Case 6. $\{\mathbf{v}_1,\ \mu\mathbf{v}_1 + \mathbf{v}_2, \mathbf{v}_{36}, \mathbf{v}_{46}\}$

From the other generators of the optimal system in the different cases we obtain the reduced equations.

Key words: partial differential equations, symmetries

A class of matrices having a set of block diagonal Lyapunov solutions satisfying $\mathcal{R}-$contractivity

A.C. Carapito[1]

[1] *Department of Mathematics, University of Beira Interior*

emails: carapito@ubi.pt

Abstract

We consider a set of square real matrices $\mathcal{A} = \{A_1, A_2, \cdots, A_N\}$, where each matrix is partitioned, in the same way, into blocks such that the diagonal ones are square matrices. Under the assumption that the block (1,1) in the same position have a common Lyapunov solution, a sufficient condition for the existence of a contractive set of block Lyapunov solutions for $\mathcal{A}$ is presented.

Key words: Block matrices, Common Lyapunov solution, Stability

1 Introduction

Consider a finite set $\mathcal{A} = \{A_1, \ldots, A_N\}$ of matrices in $\mathbb{R}^{n\times n}$, $\mathcal{A}$ is said to be *simultaneously stable* if there exists a positive definite and symmetric matrix P which is a Lyapunov solution for every $A_p \in \mathcal{A}$, i.e., if there exists P such that $-(A_p^T P + P A_p)$ is positive definite, for every $A_p \in \mathcal{A}$. The matrix P is called a *common Lyapunov solution* for $\mathcal{A}$, [9]. In practice, simultaneously stable sets of matrices play an important role, for instance, in the study of the stability of a class of hybrid dynamical systems, called linear switched systems where the state evolution is continuous, i.e., the state components are not subject to jumps during switching, see for instance [2, 1, 8]. However, when state discontinuities are allowed at the switching instants, see for instance [7], [5], [6], the stability of a switched system, for every switching law, can be assured by means of the existence of a $\mathcal{R}$-contractive set of Lyapunov solutions, [3], [4].
In this paper we address the problem of the existence of a $\mathcal{R}-$contractive set of Lyapunov solutions $\{P_p : p \in \mathcal{P}\}$ using an analysis in terms of block matrices such that the matrices P_p have a block diagonal structure.

 ISBN: 978-84-617-8694-7

2 Preliminaries

Let $\mathcal{A} = \{A_1, \dots A_N\}$ be a set of matrices in $\mathbb{R}^{n\times n}$. Consider that each matrix $A_p \in \mathcal{A}$ is similarly partitioned into 2×2 blocks as follows:

$$A_p = \begin{bmatrix} A_{11}^p & A_{12}^p \\ A_{21}^p & A_{22}^p \end{bmatrix}, p \in \mathcal{P} = \{1, \cdots, N\}, \tag{1}$$

where $A_{ii}^p \in \mathbb{R}^{n_i \times n_i}$, $i = 1, 2$, for each p and $n_1 + +n_2 = n$.

Let $\mathbb{S}$ a set of symmetric and definite matrices P_p, $p \in \mathcal{P}$ defined as follows

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix} \tag{2}$$

where the block P_{22} is an invertible matrix of order $z \in \{1, 2, \dots, n-1\}$.

Definition 1. *Let $\mathcal{A}$ be a set of matrices in $\mathbb{R}^{n\times n}$ defined as in (1). A set of symmetric matrices $\mathbb{S} = \{P_p, p \in \mathcal{P}\}$ is said a $\mathcal{R}-$contractive set of Lyapunov solutions for a switched system if, for the set of matrices $\mathcal{R} = \left\{ R_{(q,p)} = \begin{bmatrix} I_{n-z} & 0 \\ R_{21}^{(q,p)} & R_{22}^{(q,p)} \end{bmatrix} : p, q \in \mathcal{P} \right\}$, $\mathbb{S}$ satisfies:*

1. $A_p^T P_p + P_p A_p < 0$;
2. $R_{(q,p)}^T P_p R_{(q,p)} \leq P_p$, *for all* $p, q \in \mathcal{P}$

where I_{n-z} denotes the identity matrix of order $n - z$ and $R_{22}^{(q,p)}$, $p, q \in \mathcal{P}$,are invertible matrices.

A necessary condition for the $\mathcal{R}-$contractivity of a set of Lyapunov solutions can be establish in terms of Schur complement, [3].

Theorem 2. *If $\mathbb{S}$ is a $\mathcal{R}-$contractive set of Lyapunov solutions for $\mathcal{A}$, then P_p have comom Schur Complement of order $n - z$, i.e, $P_{11}^p - P_{12}^p (P_{22}^p)^{-1} P_{21}^p = C$ not depends on $p \in \mathcal{P}$.*

Notice that if $\mathbb{S}$ is a set of QLFs with common Shur complement of order n, C, then $P_p = C$, for all p. So, the problem of existence of a set of Lyapunov solutions with common Schur complement of order n reduces to the problem of existence of a common Lyapunov solution. The next theorem gives the relation between the contractivity and the common complement Schur property, [3].

Theorem 3. *Let $\mathcal{A}$ a set of matrices in $\mathbb{R}^{n\times n}$ and $\mathbb{S}$ be a set of symmetric and positive definite matrices of order n. The following statements are equivalent:*

1. *There exists a set of matrices $\mathcal{R} = \left\{ R_{(q,p)} = \begin{bmatrix} I_{n-z} & 0 \\ R_{21}^{(q,p)} & R_{22}^{(q,p)} \end{bmatrix} : p, q \in \mathcal{P} \right\}$ such that $\mathbb{S}$ is a $\mathcal{R}-$contractive set of Lyapunov solutions for $\mathcal{A}$.*
2. *$\mathbb{S}$ is a set of Lyapunov solutions for $\mathcal{A}$ with common Schur complement of order z.*

 ISBN: 978-84-617-8694-7

3 Existence of block diagonal Lyapunov solutions with common Schur complement

In this section, we identify a class of matrices $\mathcal{A} = A_p = \begin{bmatrix} A_{11}^p & A_{12}^p \\ A_{21}^p & A_{22}^p \end{bmatrix}$, $p \in \mathcal{P} = \{1, \cdots, N\}$, having a $\mathcal{R}-$contractive set of Lyapunov solutions, more precisely a set $\{P_p \colon p \in \mathcal{P}\}$ where the matrices P_p have a block diagonal structure with all blocks (1,1), P_{11}^p, equals to some matrix C, this is the same as saying that P_p share a common Schur complement, C. Next we present the following necessary condition,[3].

Theorem 4. *Let $\mathcal{A} = \{A_1, \dots A_N\}$ be a set of stable matrices in $\mathbb{R}^{n\times n}$ defined as in (1) where the blocks (2,2) are square matrices of order z. If there exists a set of block diagonal solutions for $\mathcal{A}$ with common Schur complement C, of order $n - z$, then C is a common Lyapunov solution for the blocks (1,1) and the blocks (2,2) are stable.*

In the sequel, we shall use the previous necessary condition and we suppose that C is a common Lyapunov solution for the blocks (1,1) of A_p and P_{22}^p are Lyapunov solutions for the blocks (2,2) of A_p, $p \in \mathcal{P}$, respectively. Then,

$$\begin{array}{ll} (A_{11}^p)^T C + C A_{11} & = -Q_1^p < \ 0, \text{ for all } p \in \mathcal{P}; \\ (A_{22}^p)^T P_{22}^p + P_{22}^p A_{22}^p & = -Q_2^p < \ 0, \ p \in \mathcal{P}, \end{array} , \tag{3}$$

respectively.

Theorem 5. *Let $\mathcal{A}$ a set of stable matrices partioned into 2×2 blocks satisfying (3). Then, $\{diag(P, P_{22}^p) : p \in \mathcal{P}\}$ is a set of Lyapunov solutions for $\mathcal{A}$ if, for each $p \in \mathcal{P}$, one of the following conditions is satisfied:*

(A) $16\lambda_{\max}\left((A_{12}^p)^T C (Q_1^p)^{-1} C A_{12}^p\right) \lambda_{\max}\left(P_{22}^p A_{21}^p (Q_1^p)^{-1} (A_{21}^p)^T P_{22}^p\right) < \lambda_{\min}^2 (Q_2^p)$

(B) $\lambda_{\min}(Q_1^p) > 4\|C A_{12}^p\|_s \|{A_{21}^p}^T P_{22}^p\| \|(Q_2^p)^{-1}\|$,

where $\|.\|$ denotes the spectral norm.

Proof. Suppose that for each $p \in \mathcal{P}$, (A) is satisfied. If $A_{12}^p = 0$ and $A_{21}^p = 0$ for all $p \in \mathcal{P}$, i.e, $\mathcal{A}$ is a set of block diagonal matrices, it is obvious that $\{\text{diag}(P, P_{22}^p) : p \in \mathcal{P}\}$ is a set of Lyapunov solutions for $\mathcal{A}$. If $A_{12}^p = 0$ or $A_{21}^p = 0$ for all $p \in \mathcal{P}$, i.e, $\mathcal{A}$ is a set of block triangular matrices, then easily we prove that $\{\text{diag}(P, \epsilon_p P_{22}^p) : p \in \mathcal{P}\}$ and $\{\text{diag}(P, \beta_p P_{22}^p) : p \in \mathcal{P}\}$, where

$$0 < \epsilon_p \ < \ \frac{\lambda_{\min}(Q_2^p)}{\lambda_{\max}(P_{22}^p A_{21}^p (Q_1^p)^{-1} (A_{21}^p)^T P_{22}^p)}.$$

and

$$\beta_p \ > \ \frac{\lambda_{\max}\left((A_{12}^p)^T C (Q_1^p)^{-1} C A_{12}^p\right)}{\lambda_{\min}(Q_2^p)},$$

 ISBN: 978-84-617-8694-7

are sets of Lyapunov solutions for $\mathcal{A}$ with respect to lower or upper case.

Otherwise, since each A_p is a sum of a lower block triangular T_p matrix with an upper block triangular matrix W_p

$$A_p = \begin{bmatrix} \frac{1}{2}A_{11}^p & 0 \\ A_{21}^p & \frac{1}{2}A_{22}^p \end{bmatrix} + \begin{bmatrix} \frac{1}{2}A_{11}^p & A_{12}^p \\ 0 & \frac{1}{2}A_{22}^p \end{bmatrix}, p \in \mathcal{P} \tag{4}$$

and the previous cases, we conclude that, for each p, diag $(C, t_p P_{22}^p)$ with

$$0 < t_p \quad < \quad \frac{\lambda_{\min}\left(Q_2^p\right)}{4\lambda_{\max}\left(P_{22}^p A_{21}^p (Q_1^p)^{-1} (A_{21}^p)^T P_{22}^p\right)}$$

is a Lyapunov solution for T_p and diag $(C, w_p P_{22}^p)$

$$w_p \quad > \quad \frac{4\lambda_{\max}\left((A_{12}^p)^T C (Q_1^p)^{-1} C A_{12}^p\right)}{\lambda_{\min}\left(Q_2^p\right)}.$$

is a Lyapunov solution for W_p. Therefore, taking account that (A) is verified, we can choose for each $p \in \mathcal{P}$, $t_p = w_p$. Taking $\alpha_p := t_p = w_p$ we conclude that $\{\text{diag}\,(C, \alpha_p P_{22}^p) : p \in \mathcal{P}\}$ is a set of block diagonal Lyapunov solutions for $\mathcal{A}$. □

Example 6. *The matrices*

$$A_1 = \left[\begin{array}{cc:cc} -2 & -1 & 1 & -1 \\ -0.5 & -2 & 0.5 & 2 \\ \hdashline -1 & 1 & -6 & -9 \\ -1 & -2 & 9 & -6 \end{array}\right] \quad \textit{and} \quad A_2 = \left[\begin{array}{cc:cc} -100 & 0 & -2 & 1 \\ 1 & -120 & -1 & 0 \\ \hdashline 1 & 0 & -10 & -11 \\ -1 & 1 & 150 & 0 \end{array}\right]$$

have a block diagonal Lyapunov solutions with common Schur complement of order 2.

Notice that the block (1,1) of both matrices share a common Lyapunov solution:

$$C = \begin{bmatrix} 1 & -0.2 \\ -0.2 & 1 \end{bmatrix}$$

and the blocks (2,2) are stable (but not admite a common Lyapunov solution). Considering the Lyapunov solutions

$$P_{22}^1 = \textit{diag}(0.08, 0.08) \ \textit{and} \ P_{22}^2 = \begin{bmatrix} 0.7 & 0.04 \\ 0.04 & 0.05 \end{bmatrix}$$

for the blocks (2,2), respectively, we obtain

$$Q_1^1 = \begin{bmatrix} 3.8 & 0.7 \\ 0.7 & 3.6 \end{bmatrix}; \qquad Q_1^2 = \begin{bmatrix} 200.4 & -45 \\ -45 & 240 \end{bmatrix}$$

$$Q_2^1 = \textit{diag}(0.96, 0.96) \qquad (\lambda_{\min}\left(Q_2^1\right))^2 \approx 0.9216;$$
$$Q_2^2 = \begin{bmatrix} 2 & 0.6 \\ 0.6 & 0.88 \end{bmatrix} \qquad (\lambda_{\min}\left(Q_2^2\right))^2 \approx 0.3835.$$

 ISBN: 978-84-617-8694-7

Easily we verify that Condition (A) of previous theorem is satisfied. So, we conclude that

$$\left\{ diag\left(\begin{bmatrix} 1 & -0.2 \\ -0.2 & 1 \end{bmatrix},\ diag(0.08, 0.08) \right), diag\left(\begin{bmatrix} 1 & -0.2 \\ -0.2 & 1 \end{bmatrix}, \begin{bmatrix} 0.7 & 0.04 \\ 0.04 & 0.05 \end{bmatrix} \right) \right\}$$

is a set of block diagonal Lyapunov solutions with common Schur complement of order 2.

Abstract

The purpose of this work is to study different kinds of stability for a class of integral equations defined on a finite interval. Sufficient conditions are derived in view to obtain Hyers-Ulam stability and Hyers-Ulam-Rassias stability by using fixed point techniques and the Bielecki metric.

Key words: Hyers-Ulam stability, Hyers-Ulam-Rassias stability, Banach fixed point theorem, integral equation
MSC 2000: 45M10, 34K20, 47H10

1 Introduction

During the last seven decades the concepts of Hyers-Ulam stability and Hyers-Ulam-Rassias stability for different kinds of functional equations, differential equations, integral equations and others has been studied in a quite extensive way due to their great number of applications e.g. in elasticity, semiconductors, heat conduction, fluid flow, scattering theory, chemical reactions and population dynamic, among others (see [1, 2, 3, 4, 5, 6, 7, 8]). Originated in 1940 from a famous question raised by S. M. Ulam, the first results of stability of this type were about to discover when a solution of an equation differing "slightly" from a given one must be somehow near to the solution of the given equation. A first parcial answer to this question was given by D. H. Hyers, introducing therefore the so-called Hyers-Ulam

 ISBN: 978-84-617-8694-7

stability. New directions were introduced by Th. M. Rassias, see [9], introducing therefore the so-called Hyers-Ulam-Rassias stability.

In this work, we will be devoted to analyse Hyers-Ulam and Hyers-Ulam-Rassias stability for the following class of integral equations:

$$y(x) = f\left(x, y(x), \int_a^b k(x, \tau, y(\tau), y(\alpha(\tau)))d\tau\right), \qquad x \in [a, b], \tag{1}$$

and

$$y(x) = f\left(x, y(x), \int_a^x k(x, \tau, y(\tau), y(\alpha(\tau)))d\tau\right), \qquad x \in [a, b], \tag{2}$$

where a and b are fixed real numbers, $f : [a, b] \times \mathbb{C} \times \mathbb{C} \to \mathbb{C}$ and $k : [a, b] \times [a, b] \times \mathbb{C} \times \mathbb{C} \to \mathbb{C}$ are continuous functions, and $\alpha : [a, b] \to [a, b]$ is a continuous delay function which therefore fulfills $\alpha(\tau) \leq \tau$ for all $\tau \in [a, b]$.

The formal definition of the above mentioned Hyers-Ulam-Rassias stability and Hyers-Ulam stability are now introduced for the integral equation (1).

If for each function y satisfying

$$\left|y(x) - f\left(x, y(x), \int_a^b k(x, \tau, y(\tau), y(\alpha(\tau)))d\tau\right)\right| \leq \sigma(x), \qquad x \in [a, b], \tag{3}$$

where σ is a non-negative function, there is a solution y_0 of the integral equation and a constant $C > 0$ independent of y and y_0 such that $|y(x) - y_0(x)| \leq C\sigma(x)$, for all $x \in [a, b]$, then we say that the integral equation (1) has the Hyers-Ulam-Rassias stability.

If for each function y satisfying

$$\left|y(x) - f\left(x, y(x), \int_a^b k(x, \tau, y(\tau), y(\alpha(\tau)))d\tau\right)\right| \leq \theta, \qquad x \in [a, b], \tag{4}$$

where $\theta \geq 0$, there is a solution y_0 of the integral equation and a constant $C > 0$ independent of y and y_0 such that $|y(x) - y_0(x)| \leq C\theta$, for all $x \in [a, b]$, then we say that the integral equation has the Hyers-Ulam stability.

Some of the present techniques to study the stability of functional equations use a combination of the following well-known Banach Fixed Point Theorem with a generalized metric in appropriate settings.

Theorem 1 *Let (X, d) be a generalized complete metric space and $T : X \to X$ a strictly contractive operator with a Lipschitz constant $L < 1$. If there exists a nonnegative integer k such that $d(T^{k+1}x, T^k x) < \infty$ for some $x \in X$, then the following three propositions hold true:*

i) the sequence $(T^n x)_{n\in\mathbb{N}}$ converges to a fixed point x^* of T;

 ISBN: 978-84-617-8694-7

ii) x^* *is the unique fixed point of* T *in*

$$X^* = \{y \in X : d(T^k x, y) < \infty\}; \tag{5}$$

iii) if $y \in X^*$*, then*

$$d(y, x^*) \leq \frac{1}{1-L}\, d(Ty, y). \tag{6}$$

Let $p > 0$ be a constant, we will be using the space $C_p([a,b])$ of continuous functions $u : [a,b] \to \mathbb{C}$ endowed with the generalized Bielecki metric

$$d_p(u,v) = \sup_{x\in[a,b]} \frac{|u(x) - v(x)|}{e^{p(x-a)}}. \tag{7}$$

We recall that $(C_p([a,b]), d_p)$ is a complete metric spaces (cf., [10]).

2 Hyers-Ulam-Rassias Stability

The present section is devoted to present sufficient conditions for the Hyers-Ulam-Rassias stability of the integral equations (1) and (2).

Theorem 2 *Let* $\alpha : [a,b] \to [a,b]$ *a continuous delay function with* $\alpha(t) \leq t$ *for all* $t \in [a,b]$ *and* $\sigma : [a,b] \to (0,\infty)$ *a non-negative function. Moreover, suppose that* $f : [a,b]\times\mathbb{C}\times\mathbb{C} \to \mathbb{C}$ *is a continuous function satisfying the Lipschitz condition*

$$|f(x,u(x),g(x)) - f(x,v(x),h(x))| \leq M\,(|u(x) - v(x)| + |g(x) - h(x)|) \tag{8}$$

with $M > 0$ *and the kernel* $k : [a,b] \times [a,b] \times \mathbb{C} \times \mathbb{C} \to \mathbb{C}$ *is a continuous kernel function satisfying the Lipschitz condition*

$$|k(x,t,u(t),u(\alpha(t))) - k(x,t,v(t),v(\alpha(t)))| \leq L|u(t) - v(t)| \tag{9}$$

with $L > 0$*.*

If $y \in C_p([a,b])$ *is such that*

$$\left| y(x) - f\left(x, y(x), \int_a^b k(x,\tau,y(\tau),y(\alpha(\tau)))d\tau\right)\right| \leq \sigma(x), \qquad x \in [a,b], \tag{10}$$

and $M\left(1 + \frac{L}{p}\left(e^{p(b-a)} - 1\right)\right) < 1$*, then there is a unique function* $y_0 \in C_p([a,b])$ *such that*

$$y_0(x) = f\left(x, y_0(x), \int_a^b k(x,\tau,y_0(\tau),y_0(\alpha(\tau)))d\tau\right) \tag{11}$$

 ISBN: 978-84-617-8694-7

and

$$|u(x)-y_0(x)| \leq \frac{p\sigma(x)}{p-Mp-ML(e^{p(b-a)}-1)} \tag{12}$$

for all $x \in [a,b]$.

This means that under the above conditions, the integral equation (1) has the Hyers-Ulam-Rassias stability.

Proof. We will consider the operator $T : C_p([a,b]) \to C_p([a,b])$, defined by

$$(Tu)(x) = f\left(x, u(x), \int_a^b k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau\right), \tag{13}$$

for all $x \in [a,b]$ and $u \in C_p([a,b])$.

Under the present conditions, we will deduce that the operator T is strictly contractive with respect to the metric (7). Indeed, for all $u, v \in C_p([a,b])$, we have,

$$\begin{aligned}
d_p(Tu,Tv) &= \sup_{x\in[a,b]} \frac{|(Tu)(x)-(Tv)(x)|}{e^{p(x-a)}} \\
&\leq M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \{|u(x)-v(x)| + \\
&\qquad \left|\int_a^b k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau - \int_a^b k(x,\tau,v(\tau),v(\alpha(\tau)))d\tau\right|\Big\} \\
&\leq M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \{|u(x)-v(x)| + \\
&\qquad \int_a^b |k(x,\tau,u(\tau),u(\alpha(\tau))) - k(x,\tau,v(\tau),v(\alpha(\tau)))|\, d\tau\Big\} \\
&\leq M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \left\{|u(x)-v(x)| + L\int_a^b |u(\tau)-v(\tau)|\, d\tau\right\} \\
&\leq M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^b |u(\tau)-v(\tau)|\, d\tau\right\} \\
&= M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^b e^{p(\tau-a)} \frac{|u(\tau)-v(\tau)|}{e^{p(\tau-a)}} d\tau\right\} \\
&\leq M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{\tau\in[a,b]} \frac{|u(\tau)-v(\tau)|}{e^{p(\tau-a)}} \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^b e^{p(\tau-a)} d\tau\right\} \\
&= M \left\{d_p(u,v) + L d_p(u,v) \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \frac{e^{p(b-a)}-1}{p}\right\}
\end{aligned}$$

 ISBN: 978-84-617-8694-7

$$= M\left(1+\frac{L}{p}\left(e^{p(b-a)}-1\right)\right)d_p(u,v). \tag{14}$$

Due to the fact that $M\left(1+\frac{L}{p}\left(e^{p(b-a)}-1\right)\right)<1$ it follows that T is strictly contractive. Thus, we can apply the above mentioned Banach Fixed Point Theorem, which ensures that we have the Hyers-Ulam-Rassias stability for the integral equation (1). Additionally, (12) follows from (6) and (10).

For the Volterra integral equation (2) we have the following result.

Theorem 3 *Let $\alpha:[a,b]\to[a,b]$ a continuous delay function with $\alpha(t)\leq t$ for all $t\in[a,b]$ and $\sigma:[a,b]\to(0,\infty)$ a non-negative function. Moreover, suppose that $f:[a,b]\times\mathbb{C}\times\mathbb{C}\to\mathbb{C}$ is a continuous function satisfying the Lipschitz condition*

$$|f(x,u(x),g(x))-f(x,v(x),h(x))|\leq M\left(|u(x)-v(x)|+|g(x)-h(x)|\right) \tag{15}$$

with $M>0$ and the kernel $k:[a,b]\times[a,b]\times\mathbb{C}\times\mathbb{C}\to\mathbb{C}$ is a continuous kernel function satisfying the Lipschitz condition

$$|k(x,t,u(t),u(\alpha(t)))-k(x,t,v(t),v(\alpha(t)))|\leq L|u(t)-v(t)| \tag{16}$$

with $L>0$.

If $y\in C_p([a,b])$ is such that

$$\left|y(x)-f\left(x,y(x),\int_a^x k(x,\tau,y(\tau),y(\alpha(\tau)))d\tau\right)\right|\leq\sigma(x),\qquad x\in[a,b], \tag{17}$$

and $M\left(1+\frac{L}{p}\left(\frac{e^{p(b-a)}-1}{e^{p(b-a)}}\right)\right)<1$, then there is a unique function $y_0\in C_p([a,b])$ such that

$$y_0(x)=f\left(x,y_0(x),\int_a^x k(x,\tau,y_0(\tau),y_0(\alpha(\tau)))d\tau\right) \tag{18}$$

and

$$|u(x)-y_0(x)|\leq\frac{pe^{p(b-a)}\sigma(x)}{e^{p(b-a)}(p-Mp)-ML(e^{p(b-a)}-1)} \tag{19}$$

for all $x\in[a,b]$.

This means that under the above conditions, the Volterra integral equation (2) has the Hyers-Ulam-Rassias stability.

 ISBN: 978-84-617-8694-7

Proof. We will consider the operator $T : C_p([a,b]) \to C_p([a,b])$, defined by

$$(Tu)(x) = f\left(x, u(x), \int_a^x k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau\right), \tag{20}$$

for all $x \in [a,b]$ and $u \in C_p([a,b])$.

Under the present conditions, we will deduce that the operator T is strictly contractive (with respect to the metric under consideration). Indeed, for all $u, v \in C_p([a,b])$, we have,

$$\begin{aligned}
d_p(Tu,Tv) &= \sup_{x\in[a,b]} \frac{|(Tu)(x)-(Tv)(x)|}{e^{p(x-a)}} \\
&\le M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \{|u(x)-v(x)| \\
&\qquad + \left|\int_a^x k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau - \int_a^x k(x,\tau,v(\tau),v(\alpha(\tau)))d\tau\right|\Big\} \\
&\le M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \{|u(x)-v(x)| \\
&\qquad + \int_a^x |k(x,\tau,u(\tau),u(\alpha(\tau))) - k(x,\tau,v(\tau),v(\alpha(\tau)))|\, d\tau\Big\} \\
&\le M \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \left\{|u(x)-v(x)| + L\int_a^x |u(\tau)-v(\tau)|\, d\tau\right\} \\
&\le M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^x |u(\tau)-v(\tau)|\, d\tau\right\} \\
&= M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^x e^{p(\tau-a)} \frac{|u(\tau)-v(\tau)|}{e^{p(\tau-a)}} d\tau\right\} \\
&\le M \left\{\sup_{x\in[a,b]} \frac{|u(x)-v(x)|}{e^{p(x-a)}} + L \sup_{\tau\in[a,b]} \frac{|u(\tau)-v(\tau)|}{e^{p(\tau-a)}} \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \int_a^x e^{p(\tau-a)} d\tau\right\} \\
&= M \left\{d_p(u,v) + L d_p(u,v) \sup_{x\in[a,b]} \frac{1}{e^{p(x-a)}} \frac{e^{p(b-a)}-1}{p}\right\} \\
&= M \left(1 + \frac{L}{p}\left(\frac{e^{p(b-a)}-1}{e^{p(b-a)}}\right)\right) d_p(u,v).
\end{aligned} \tag{21}$$

Due to the fact that $M\left(1+\frac{L}{p}\left(\frac{e^{p(b-a)}-1}{e^{p(b-a)}}\right)\right) < 1$ it follows that T is strictly contractive. Thus, we can apply the above mentioned Banach Fixed Point Theorem, which ensures that we have the Hyers-Ulam-Rassias stability for the Volterra integral equation (2). Additionally, (19) follows from (6) and (17).

 ISBN: 978-84-617-8694-7

3 Hyers-Ulam Stability

The present section is devoted to present sufficient conditions for the Hyers-Ulam stability of the integral equations (1) and (2).

Theorem 4 *Let $\alpha : [a,b] \to [a,b]$ a continuous delay function with $\alpha(t) \leq t$ for all $t \in [a,b]$. Moreover, suppose that $f : [a,b]\times\mathbb{C}\times\mathbb{C} \to \mathbb{C}$ is a continuous function satisfying the Lipschitz condition*

$$|f(x,u(x),g(x)) - f(x,v(x),h(x))| \leq M\left(|u(x)-v(x)| + |g(x)-h(x)|\right) \tag{22}$$

with $M > 0$ and the kernel $k : [a,b]\times[a,b]\times\mathbb{C}\times\mathbb{C} \to \mathbb{C}$ is a continuous kernel function satisfying the Lipschitz condition

$$|k(x,t,u(t),u(\alpha(t))) - k(x,t,v(t),v(\alpha(t)))| \leq L|u(t)-v(t)| \tag{23}$$

with $L > 0$.

If $y \in C_p([a,b])$ is such that

$$\left| y(x) - f\left(x, y(x), \int_a^b k(x,\tau,y(\tau),y(\alpha(\tau)))d\tau\right)\right| \leq \theta, \qquad x \in [a,b], \tag{24}$$

where $\theta > 0$ and $M\left(1+\frac{L}{p}\left(e^{p(b-a)}-1\right)\right) < 1$, then there is a unique function $y_0 \in C_p([a,b])$ such that

$$y_0(x) = f\left(x, y_0(x), \int_a^b k(x,t,y_0(t),y_0(\alpha(t)))dt\right) \tag{25}$$

and

$$|u(x) - y_0(x)| \leq \frac{p\theta}{p - Mp - ML(e^{p(b-a)}-1)} \tag{26}$$

for all $x \in [a,b]$

This means that under the above conditions, the integral equation (1) has the Hyers-Ulam stability.

Proof. We will consider the operator $T : C_p([a,b]) \to C_p([a,b])$, defined by

$$(Tu)(x) = f\left(x, u(x), \int_a^b k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau\right), \tag{27}$$

for all $x \in [a,b]$ and $u \in C_p([a,b])$.

By the same above procedure we have T strictly contractive with respect to the metric (7) due to the fact that $M\left(1+\frac{L}{p}\left(e^{p(b-a)}-1\right)\right) < 1$. Thus, we can again apply the Banach Fixed Point Theorem, which ensures that we have the Hyers-Ulam stability for the integral equation with (26) being obtained by using (6) and (24).

 ISBN: 978-84-617-8694-7

Now, we consider the Volterra integral equation (2).

Theorem 5 *Let $\alpha : [a,b] \to [a,b]$ a continuous delay function with $\alpha(t) \leq t$ for all $t \in [a,b]$. Moreover, suppose that $f : [a,b]\times\mathbb{C}\times\mathbb{C} \to \mathbb{C}$ is a continuous function satisfying the Lipschitz condition*

$$|f(x,u(x),g(x)) - f(x,v(x),h(x))| \leq M\left(|u(x)-v(x)| + |g(x)-h(x)|\right) \tag{28}$$

with $M > 0$ and the kernel $k : [a,b]\times[a,b]\times\mathbb{C}\times\mathbb{C} \to \mathbb{C}$ is a continuous kernel function satisfying the Lipschitz condition

$$|k(x,t,u(t),u(\alpha(t))) - k(x,t,v(t),v(\alpha(t)))| \leq L|u(t)-v(t)| \tag{29}$$

with $L > 0$.

If $y \in C_p([a,b])$ is such that

$$\left|y(x) - f\left(x, y(x), \int_a^x k(x,\tau,y(\tau),y(\alpha(\tau)))d\tau\right)\right| \leq \theta, \qquad x \in [a,b], \tag{30}$$

where $\theta > 0$ and $M\left(1+\frac{L}{p}\left(\frac{e^{p(b-a)}-1}{e^{p(b-a)}}\right)\right) < 1$, then there is a unique function $y_0 \in C_p([a,b])$ such that

$$y_0(x) = f\left(x, y_0(x), \int_a^x k(x,t,y_0(t),y_0(\alpha(t)))dt\right) \tag{31}$$

and

$$|u(x) - y_0(x)| \leq \frac{pe^{p(b-a)}\theta}{e^{p(b-a)}(p-Mp) - ML(e^{p(b-a)}-1)} \tag{32}$$

for all $x \in [a,b]$

This means that under the above conditions, the Volterra integral equation (2) has the Hyers-Ulam stability.

Proof. We will consider the operator $T : C_p([a,b]) \to C_p([a,b])$, defined by

$$(Tu)(x) = f\left(x, u(x), \int_a^x k(x,\tau,u(\tau),u(\alpha(\tau)))d\tau\right), \tag{33}$$

for all $x \in [a,b]$ and $u \in C_p([a,b])$.

By the same above procedure we have T strictly contractive (with respect to the metric under consideration) due to the fact that $M\left(1+\frac{L}{p}\left(\frac{e^{p(b-a)}-1}{e^{p(b-a)}}\right)\right) < 1$. Thus, we can again apply the Banach Fixed Point Theorem, which ensures that we have the Hyers-Ulam stability for the integral equation with (32) being obtained by using (6) and (30).

Remark 6 *Is possible analyse the Hyers-Ulam-Rassias stability of the integral equation but defined on infinite intervals. These results will be presented in a future work.*

Abstract

In this paper we present an efficient scheme for the computation of triangular Shepard method. More precisely, it is well known that the triangular Shepard method reaches an approximation order better than the Shepard one [4], but it needs to identify useful general triangulation of the node set. Here we propose a searching technique used to detect and select the nearest neighbor points in the interpolation scheme [2, 3]. It consists in determining the closest points belonging to the different neighborhoods and consequently applies to the triangulation-based approach. Numerical results show efficiency of the interpolation procedure.

Key words: scattered data interpolation, triangular Shepard method, fast computation, approximation algorithms
MSC 2000: 65D05, 65D15, 41A05

1 Introduction

Scattered data consists of a set of points $X_n = \{x_1, \ldots, x_n\}$ and corresponding functional values $f_1, \ldots, f_n$, where the points have no structure or order between their relative locations. Among the various approaches to interpolating scattered data, the Shepard method [8] is one of the earliest techniques. It defines an interpolating function as a convex combination of the functional values, that is a linear combination of them with non negative coefficients (or weight functions or basis functions) which are inverse distances to the scattered points and form a partition of unity. The main drawback of the Shepard method is

 ISBN: 978-84-617-8694-7

its low polynomial precision (only constants) that badly affects the reconstructed surface. Several variants of the Shepard method have been considered to overcome this drawback. Among them, the triangular Shepard method [7] is a convex combination of local linear interpolants with triangle-based weight functions, which are the product of inverse distances from the vertices of triangles and form a partition of unity. The main feature of the triangular Shepard method is its linear precision without using derivative data, although, for achieving a good accuracy of approximation, it needs to identify useful general triangulation of the node set.

An efficient organization of the scattered data, when local interpolation is used, turns out to be crucial. To this aim, in literature, techniques known as kd-trees, which are not specifically implemented for a specific interpolation scheme, have already been designed, [1, 6]. In this paper, we propose the use of a versatile partitioning structure, called the block-based partitioning structure, given in [3], which is suitably adapted to triangular Shepard interpolation.

The paper is organized as follows. In Section 2 we consider interpolation using the triangular Shepard method and the selection of the compact triangulation. Section 3 is devoted to present the searching technique used to detect and select the nearest neighbor points in our interpolation scheme. Finally, Section 4 shows some numerical results.

2 Interpolation on compact triangulations

2.1 Triangular Shepard method

In 1983 Little [7] introduced a variant of the Shepard method, called triangular Shepard, which is a Shepard-like convex combination of the linear interpolants of a set of triangles. More precisely, if we denote by $X_n = \{x_1, x_2, \ldots, x_n\}$ a set of nodes of $\mathbb{R}^2$ with associated function data $f_1, \ldots, f_n$ and by $T_m = \{t_1, t_2, \ldots, t_m\}$ a set of triangles which vertices are points of X_n, the triangular Shepard operator is defined by

$$K_\mu[f](x) = \sum_{j=1}^{m} B_{\mu,j}(x) L_j(x), \quad \mu > 0, \tag{1}$$

where $L_j(x)$ is the linear interpolant on the vertices of t_j, $j = 1, \ldots, m$, and the weight functions $B_{\mu,j}(x)$ are defined by

$$B_{\mu,j}(x) = \frac{\prod_{\ell=1}^{3} \frac{1}{\|x - x_{j_\ell}\|^\mu}}{\sum_{k=1}^{m} \prod_{\ell=1}^{3} \frac{1}{\|x - x_{k_\ell}\|^\mu}}, \qquad j = 1, \ldots, m. \tag{2}$$

 ISBN: 978-84-617-8694-7

As noticed by Little himself, the triangular Shepard operator (1) exceeds the Shepard method both in polynomial precision and esthetic behaviour. In fact, it has linear precision while Shepard method achieves only constant precision. The better polynomial precision of the triangular Shepard method reflects on a higher order of approximation. As shown in [4] the triangular Shepard method reaches quadratic approximation order while the Shepard method achieves at most linear approximation order [5]. We remark that the definition of the triangular Shepard operator (1) requires an appropriate list of triangles to be identified. However, these triangles can realize only a general triangulation of the node set X_n, that is a triangulation in which some triangles may overlap or be disjoint.

2.2 Selection of the compact triangulation

In order to identify useful general triangulation of the node set X_n we take into account theoretical results achieved in [4], which link the bound for the remainder term of the linear interpolant $L_j(x)$ with the bound for the remainder of the triangular Shepard operator (1). In particular, all triangles should have a rather regular form (as near as possible to equilateral triangles) and two quantities, denoted by h' and h'', play a key role in the choice of these triangles: the first one is the fill distance in the maximum norm and controls the uniformity of the triangle distribution, the second one excludes the presence of large triangles.

For each node x_i of the node set X_n we choose, among the 15 triangles with a vertex in x_i and other 2 vertices among its 6 nearest neighbors in X_n, the one which locally reduces the bound

$$2\|x - x_{j_1}\|^2 + 4h_j C_j \|x - x_{j_1}\| \tag{3}$$

for the error of the local linear interpolant, where x_{j_1} denotes the first vertex of t_j, h_j denotes the maximum edge length of t_j and C_j is a constant which depends only on the shape of t_j. We omit duplicate triangles and we get a triangulation T_m of the nodes with $m \leq n$ triangles, in which some of the triangles may overlap or be disjoint.

3 Localizing searching technique

In this section we present the searching technique used to detect and select the nearest neighbor points in our interpolation scheme [2, 3]. Though this procedure can be applied on a generic domain $R \subseteq \mathbb{R}^2$ and in higher dimensions, for our purpose we here pursue this description focusing on the unit square, i.e. $R = [0, 1] \times [0, 1]$.

Firstly, we define a circular neighborhood of radius

$$\delta = \frac{2}{d}, \tag{4}$$

 ISBN: 978-84-617-8694-7

with

$$d = \left\lfloor \frac{\sqrt{n}}{2} \right\rfloor, \tag{5}$$

where each neighborhood is centred at a data point belonging to R. To localize points in our method, we set $n/d^2 = 4$. Note that the larger (smaller) the value of d is, the more (less) localizing the scheme is.

In order to determine the closest points belonging to the different neighborhoods and consequently apply our triangulation-based approach, we propose a new structure that partitions the domain in blocks of square shape. Such technique results in an effective searching procedure which is quite efficient from a computational viewpoint. For this scope we partition the domain R with b^2 square blocks, b being the number of blocks along one side of the unit square defined as

$$b = \left\lceil \frac{1}{\delta} \right\rceil. \tag{6}$$

It follows that the side of each square block turns out to be equal to the neighborhood radius. Hence, such a choice (seemingly trivial) allows us to examine in the searching process only a small number of blocks, significantly reducing the computational effort compared to standard or more advanced searching procedures such kd-trees [1, 9]. In fact, our searching routine is performed in a constant time, independently from the initial number of nodes considered.

In our partitioning technique square blocks are numbered from 1 to b^2, following the lexicographic order "bottom to top, left to right". By a repeated use of a quicksort routine the set X_n is thus partitioned by the block-based partitioning structure into b^2 subsets X_{n_k}, $k = 1, \ldots, b^2$, where X_{n_k} are the points belonging to nine blocks: the k-th block and its eight neighboring blocks, see Figure 1. In such framework, we are able to get an optimal procedure to find the interpolation nodes closest to each of points.

4 Numerical results

In our numerical experiments we report results obtained by using the triangular Shepard interpolant (1). All the experiments are carried out by means of a grid of $n_e = 21 \times 21$ evaluation points on $R = [0, 1] \times [0, 1]$ by using several sets of Halton points [6]. The used test function is the Franke's one,

$$\begin{aligned} f(x,y) = 0.75 \exp\left(-\frac{(9x-2)^2 + (9y-2)^2}{4}\right) + 0.50 \exp\left(-\frac{(9x-7)^2 + (9y-3)^2}{4}\right) \\ +0.75 \exp\left(-\frac{(9x+1)^2}{49} - \frac{(9y+1)}{4}\right) - 0.20 \exp\left(-(9x-4)^2 - (9y-7)^2\right). \end{aligned}$$

 ISBN: 978-84-617-8694-7

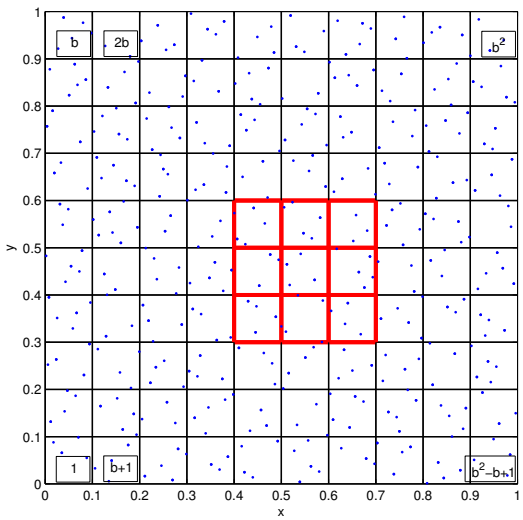

Figure 1: Example of 2D block-based partitioning structure with a data point set: in red the k-th block and its eight neighboring blocks, in blue a set of scattered points contained in the unit square R.

n	RMSE	t_{old}	t_{new}
10000	2.87e-4	27.3056	7.0784
20000	1.53e-4	242.5568	18.1962
40000	7.51e-5	–	49.3938
80000	3.59e-5	–	245.2871

Table 1: CPU times (in seconds) and RMSEs on a grid of $n_e = 21 \times 21$ evaluation points for the Franke's test function using different sets of n Halton points.

In Table 1 we show the CPU times computed in seconds and the root mean square error (RMSE)

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n_e} {e_i}^2}{n_e}}$$

with

$$e_i = |f(P_i) - K_2[f](P_i)|, \tag{7}$$

P_i being an evaluation point in R. In particular, we compare performance of the procedure which computes all the distances between the scattered points (t_{old}) with the one using the block-based searching technique (t_{new}).

Abstract

In this paper we present the problem of determining the so-called *basins of attraction* of dynamical systems. They are found out so that there exist manifolds partitioning the phase space into different regions. The reconstruction of such surfaces is carried out by means of meshfree interpolation tools and specifically we apply the Partition of Unity (PU) method with local Radial Basis Function (RBF) interpolants.

Key words: scattered data approximation, partition of unity method, radial basis functions, dynamical systems, competition population models, basins of attraction
MSC 2000: 65D05, 65D17, 92D25, 37M20

1 Introduction

Over the last years the topic of numerical approximation of multivariate data has gained popularity in various disciplines, such as numerical solution of PDEs, image registration, neural networks, optimization, statistics and finance. In what follows we investigate an application to population dynamics [1].

Nowadays, mathematical modeling is commonly applied to major disciplines and by these models the prediction of the temporal evolution of the considered quantities, i.e. populations, cancer, divorces, is sought [9]. This is obtained in general via dynamical systems. Here we present a reliable algorithm for the reconstruction of unknown manifolds partitioning the phase state of dynamical systems into disjoint sets. Indeed, in an initial value problem, involving a set of ordinary differential equations, a particular solution of the

system is completely determined by the Initial Condition (IC). Depending on the initial state of the system and on conditions involving the model parameters, the trajectories may in fact tend towards different equilibria.

The phase state of the dynamical system is thus partitioned into different regions, called the basins of attraction of each equilibrium, depending on where the trajectories originating in them will ultimately stabilize. In such cases, the final outcome of a mathematical model depends on the IC. If it lies in the basin of attraction of a certain equilibrium point, the system will finally settle to this specific steady state. To establish the ultimate system behavior, it is therefore important to assess for each possible attractor its domain of attraction.

Thus, we present a tool that allows to reconstruct the basin of attraction of each equilibrium, providing a graphical representation of the separatrix manifold [4, 5]. First, a suitable scheme is constructed for the generation of these manifolds. It provides points that, within a certain tolerance, lie on these sought manifolds. This is obtained via a suitable bisection-like routine that employs pairs of points belonging to two different sets of the partition. Then, since an attraction basin can be described by an implicit equation, we interpolate such points with the implicit PU method using local RBF approximants [6, 8, 10].

The model we consider throughout this paper, involving three populations P, Q and R, reads as follows

$$\begin{aligned}
\frac{dP}{dt} &= p\left(1-\frac{P}{u}\right)P - aPQ - bPR,\\
\frac{dQ}{dt} &= q\left(1-\frac{Q}{v}\right)Q - cPQ - eQR,\\
\frac{dR}{dt} &= r\left(1-\frac{R}{w}\right)R - fPR - gQR,
\end{aligned} \tag{1}$$

where p, q and r are the growth rates of P, Q and R, respectively, a, b, c, e, f and g are the competition rates, u, v and w are the carrying capacities of the three populations. The model describes the interaction of three competing populations within the same environment and has eight equilibria. For simplicity, we list here only those playing a role in this investigation, i.e. the origin $E_0 = (0, 0, 0)$, the points associated with the survival of only one population

$$E_1 = (u, 0, 0), \qquad E_2 = (0, v, 0), \qquad E_3 = (0, 0, w)$$

 ISBN: 978-84-617-8694-7

and the coexistence equilibrium

$$E_* = \left(\frac{u[p(gvwe - qr) - avr(we - q) - bwq(vg - r)]}{p(gvwe - qr) + uva(rc - fwe) + uwb(fq - gcv)}, \right.$$
$$\frac{v[q(fuwb - pr) - rcu(wb - p) - pew(fu - r)]}{q(fuwb - pr) + cuv(ra - gwb) + evw(gp - afu)},$$
$$\left. \frac{r[(cuva - pq) - gpv(cu - q) - ufq(va - p)]}{r(cuva - pq) + bwu(fq - vcg) + evw(gp - fua)} \right).$$

With the parameter setting $p = 1$, $q = 2$, $r = 2$, $a = 5$, $b = 4$, $c = 3$, $e = 7$, $f = 7$, $g = 10$, $u = 3$, $v = 2$, $w = 1$, the points associated with the survival of only one population are stable, the origin E_0 is an unstable equilibrium and the coexistence equilibrium E_* is a saddle point. The manifolds that partition the phase space into the different domains of attraction intersect only at the coexistence saddle point E_*.

2 Implicit RBF-PU approximation

In this section we present the method used to approximate the basins of attraction, i.e. the separatrix manifolds. Since they are often described by implicit surfaces, we consider the implicit PU approximation using locally radial kelnels or RBFs [2]. Such surfaces are defined by a point cloud data set $X_N = \{\boldsymbol{x}_i \in \mathbb{R}^3,\, i = 1, \ldots, N\}$, which belongs to a surface in $\mathbb{R}^3$.

2.1 Radial kernels

Generally, to recover a function $f : \Omega \to \mathbb{R}$ on a bounded domain $\Omega \subset \mathbb{R}^3$, we use a set of samples of f on N pairwise distinct data points or nodes $X_N \subset \Omega$, i.e. $\boldsymbol{f} = [f_1, \ldots, f_N]^T$, with $f_i = f(\boldsymbol{x}_i)$, $\boldsymbol{x}_i \in X_N$. For this aim, we define a positive definite and symmetric kernel $\Phi : \Omega \times \Omega \to \mathbb{R}$, obtaining the interpolant expressed as follows

$$u(\boldsymbol{x}) = \sum_{j=1}^{N} c_j \Phi(\boldsymbol{x}, \boldsymbol{x}_j), \qquad \boldsymbol{x} \in \Omega. \tag{2}$$

Here Φ is a radial kernel depending on a positive *shape parameter* ε for all $\boldsymbol{x}, \boldsymbol{z} \in \Omega$, i.e.

$$\Phi(\boldsymbol{x}, \boldsymbol{z}) = \phi_\varepsilon(||\boldsymbol{x} - \boldsymbol{z}||_2) = \phi(\varepsilon||\boldsymbol{x} - \boldsymbol{z}||_2),$$

where $\phi : \mathbb{R}_{\geq 0} \to \mathbb{R}$ defines a radial basis function. Table 1 shows a list of a few strictly positive definite radial kernels with their smoothness degrees [10].

The coefficients $\boldsymbol{c} = [c_1, \ldots, c_N]^T$ in (2) are found by solving the system of linear equations

$$A\boldsymbol{c} = \boldsymbol{f}, \tag{3}$$

RBF	$\phi_\varepsilon(r)$
Inverse MultiQuadric C^∞ (IMQ)	$(1+\varepsilon^2 r^2)^{-1/2}$
Matérn C^6 (M6)	$\mathrm{e}^{-\varepsilon r}(\varepsilon^3 r^3 + 6\varepsilon^2 r^2 + 15\varepsilon r + 15)$
Matérn C^4 (M4)	$\mathrm{e}^{-\varepsilon r}(\varepsilon^2 r^2 + 3\varepsilon r + 3)$
Wendland C^6 (W6)	$(1-\varepsilon r)_+^8\,(32\varepsilon^3 r^3 + 25\varepsilon^2 r^2 + 8\varepsilon r + 1)$
Wendland C^4 (W4)	$(1-\varepsilon r)_+^6\,(35\varepsilon^2 r^2 + 18\varepsilon r + 3)$

Table 1: Some examples of strictly positive definite radial kernels in $\mathbb{R}^3$.

where entries of the interpolation matrix are given by

$$A_{ij} = \Phi(\boldsymbol{x}_i, \boldsymbol{x}_j), \quad i,j = 1,\ldots,N.$$

The resulting solution u is a function of the *native Hilbert space* $\mathcal{N}_\Phi(\Omega)$ uniquely associated with the kernel, and, if $f \in \mathcal{N}_\Phi(\Omega)$, it is in particular the $\mathcal{N}_\Phi(\Omega)$-projection of f into the subspace

$$\mathcal{N}_\Phi(X_N) = \mathrm{span}\{\Phi(\boldsymbol{x}, \boldsymbol{x}_j), \boldsymbol{x}_j \in X_N\}$$

spanned by the standard basis of translates $\mathcal{T}_{X_N} = \{\Phi(\boldsymbol{x}, \boldsymbol{x}_j), 1 \le j \le N\}$, see [6, Ch. 14].

However, since in some situations the matrix A in (3) might turn out to be very ill-conditioned and, accordingly, the interpolant (2) unstable, many efforts have recently been made to derive more stable bases (see [7] for an overview).

2.2 Implicit PU interpolation

In order to determine the implicit PU interpolant, we consider additional interpolation conditions taking an extra set of off-surface points. Hence we generate the extra off-surface points referring to a small step away along the surface normals $\boldsymbol{n}_i$. This enables us to obtain for each node $\boldsymbol{x}_i$ two additional off-surface points: the former defined as $\boldsymbol{x}_{N+i} = \boldsymbol{x}_i + \delta \boldsymbol{n}_i$ is located outside the surface, the latter expressed in the form $\boldsymbol{x}_{2N+i} = \boldsymbol{x}_i - \delta \boldsymbol{n}_i$ is set inside, δ being the stepsize [6, Ch. 30].

After creating the data point set, we can construct the PU interpolant, whose zero contour or iso-surface interpolates three sets, i.e., X_N, $X_\delta^+ = \{\boldsymbol{x}_{N+1}, \ldots, \boldsymbol{x}_{2N}\}$ and $X_\delta^- = \{\boldsymbol{x}_{2N+1}, \ldots, \boldsymbol{x}_{3N}\}$.

The idea of the PU method is to decompose a (usually) large problem or domain $\Omega \subseteq \mathbb{R}^3$ into d small problems or subdomains Ω_j such that $\Omega \subseteq \bigcup_{j=1}^d \Omega_j$ with some mild overlap among the subdomains. Associated with these subdomains we construct a partition of

 ISBN: 978-84-617-8694-7

unity, i.e. a family of compactly supported, non-negative, continuous functions w_j with $\text{supp}(w_j) \subseteq \Omega_j$ such that

$$\sum_{j=1}^{d} w_j(\boldsymbol{x}) = 1, \qquad \boldsymbol{x} \in \Omega.$$

Therefore the global approximant may be expressed as follows

$$P(\boldsymbol{x}) = \sum_{j=1}^{d} u_j(\boldsymbol{x}) w_j(\boldsymbol{x}), \qquad \boldsymbol{x} \in \Omega, \tag{4}$$

where $w_j : \Omega_j \to \mathbb{R}$ defines the *Shepard weight*

$$w_j(\boldsymbol{x}) = \frac{\varphi_j(\boldsymbol{x})}{\sum_{k=1}^{d} \varphi_k(\boldsymbol{x})},$$

φ_j being the compactly supported Wendland C^{2k}, $k \geq 1$ functions [10]. The local RBF interpolant $u_j : \Omega_j \to \mathbb{R}$ in (4) assumes the form

$$u_j(\boldsymbol{x}) = \sum_{i=1}^{N_j} c_i^j \phi(||\boldsymbol{x} - \boldsymbol{x}_i^j||_2),$$

where N_j indicates the number of data points in Ω_j, i.e. the points $\boldsymbol{x}_i^j \in X_j = X_N \cap \Omega_j$.

The PU approach is thus a simple and effective computational method that allows us to decompose a large problem into many small subproblems, ensuring that the accuracy obtained for the local fits is carried over to the global one (for further details see [3, 10]).

3 Numerical experiments

In this numerical section we show how the implicit PU method can be applied to reconstruct the domains of attraction of dynamical systems presenting three stable equilibria.

Specifically, using the routine given in [5], we can approximate the basins of attraction of the system (1). In fact, considering n equispaced points on each edge of the cube $[0, \gamma]^3$, with $\gamma \in \mathbb{R}^+$, we can define a set of ICs, i.e.

$$\begin{array}{llll} P^1_{i_1,i_2} = (x_{i_1}, y_{i_2}, 0) & \text{and} & P^2_{i_1,i_2} = (x_{i_1}, y_{i_2}, \gamma), & i_1, i_2 = 1, \ldots, n, \\ P^3_{i_1,i_2} = (x_{i_1}, 0, z_{i_2}) & \text{and} & P^4_{i_1,i_2} = (x_{i_1}, \gamma, z_{i_2}), & i_1, i_2 = 1, \ldots, n, \\ P^5_{i_1,i_2} = (0, y_{i_1}, z_{i_2}) & \text{and} & P^6_{i_1,i_2} = (\gamma, y_{i_1}, z_{i_2}), & i_1, i_2 = 1, \ldots, n. \end{array}$$

Taking then such points in pairs and applying a bisection algorithm, we find a certain number of separatrix points that lie on the basins of attraction. As an example, the points

 ISBN: 978-84-617-8694-7

lying on the separatrix manifolds depicted in Figure 1 have been found assuming $n = 15$ and $\gamma = 6$.

In Figure 1 we report the plot of the three surfaces showing the domains of attraction. The latter have been approximated by using the method (4) described in Section 2. Such surfaces have been obtained by taking $d = 4$ subdomains and the W6 function in Table 1 with $\varepsilon = 0.1$. In this case the parameters used are $p = 1$, $q = 2$, $r = 2$, $a = 5$, $b = 4$, $c = 3$, $e = 7$, $f = 7$, $g = 10$, $u = 3$, $v = 2$ and $w = 1$.

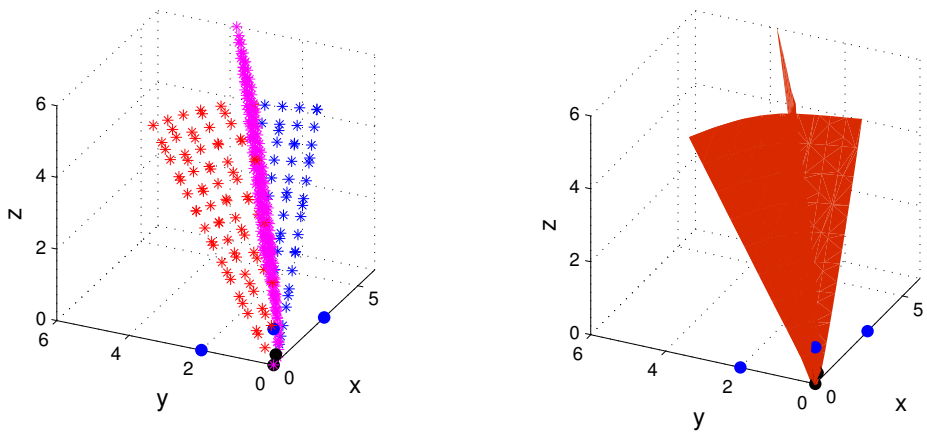

Figure 1: Detection of points on the surfaces determining the basins of attraction (left) and approximation of the domains of E_1, E_2 and E_3 (right). Stable equilibria are marked by a blue dot, unstable saddle points E_0 and E_* are represented by a black dot.

Abstract

In this paper we study the link between isomorphic digraphs and isomorphic Leibniz algebras, determining in detail this fact when using (pseudo)digraphs of 2 and 3 vertices associated with Leibniz algebras according to their isomorphism classes. Moreover, we introduce and implement an algorithmic procedure which allows us to decide if a given combinatorial structure is associated or not with a Leibniz algebra. Finally, and as application of this algorithm, we give the complete list with all the non-isomorphic combinatorial structures of 3 vertices associated with Leibniz algebras, studying the Leibniz-algebra structure associated with each configuration.

1 Introduction

Research on non-associative algebras is very extensive due to both its own theoretical relevance and its applications to many different fields, like Engineering, Physics or Applied Mathematics. Within these algebras, we will study Leibniz algebras. These algebras were introduced at the beginning of the 1990s by Loday [3] as a particular type of non-associative algebras providing a non-commutative generalization of Lie algebras. However, many general questions about them have not been solved at present by means of traditional techniques, such as obtaining their classification.

Nowadays, Graph Theory has become an essential tool to solve a wide range of problems in different research fields. In this way, we think that graphs and simplicial complexes (their generalization to higher dimensions) may be used to study non-associative algebras and solve open problems like the above-mentioned problem of classifying Leibniz algebras.

The main goal of this paper is to study the link between combinatorial structures and Leibniz algebras, taking into account some previous papers like [1, 2]. More concretely, we determine all the isomorphism classes of Leibniz algebras associated with combinatorial structures. We also introduce and implement an algorithm to decide if a given combinatorial structure is associated or not with a Leibniz algebra. Finally, we give a complete list with all non-isomorphic combinatorial structures of 3 vertices associated with each isomorphism class of Leibniz algebras, indicating the structure of each algebra.

2 Preliminaries

We recall some preliminary concepts on Leibniz algebras, bearing in mind that the reader can consult [3] as an introductory paper.

Definition 1 *A* Leibniz algebra $\mathcal{L}$ *over a field* $\mathbb{K}$ *is a vector space with a second inner bilinear composition law* $[\cdot,\cdot]$*, which verifies the so-called Leibniz identity*

$$[[X,Y],Z]-[[X,Z],Y]-[X,[Y,Z]]=0,\ \forall\, X,Y,Z\in\mathcal{L}$$

From now on, we will denote $L(X,Y,Z)=[[X,Y],Z]-[[X,Z],Y]-[X,[Y,Z]]$.

If, in addition, it is verified that $[X,X]=0$*, for all* $X\in\mathcal{L}$*, the Leibniz algebra is also a* Lie algebra*. In this case, it is satisfied that* $[X,Y]=-[Y,X]$ *and the Leibniz identity is equivalent to the Jacobi identity.*

Definition 2 *Given a basis* $\{e_i\}_{i=1}^n$ *of an* n*-dimensional Leibniz algebra* $\mathcal{L}$*, the* structure constants *of* $\mathcal{L}$ *are defined by* $[e_i,e_j]=\sum_{h=1}^n c_{i,j}^h e_h$*, for* $1\leq i,j\leq n$*.*

Definition 3 *The* derived *and* central series *of a finite-dimensional Leibniz algebra* $\mathcal{L}$ *are*

$\mathcal{L}_1=\mathcal{L},\ \mathcal{L}_2=[\mathcal{L},\mathcal{L}],\ \ldots,\ \mathcal{L}_k=[\mathcal{L}_{k-1},\mathcal{L}_{k-1}],\ \ldots$ and $\mathcal{L}^1=\mathcal{L},\ \mathcal{L}^2=[\mathcal{L},\mathcal{L}],\ \ldots,\ \mathcal{L}^k=[\mathcal{L}^{k-1},\mathcal{L}],\ \ldots$

So, $\mathcal{L}$ *is called* $(m-1)$*-step* solvable *(resp.* nilpotent*) if there exists* $m\in\mathbb{N}$ *such that* $\mathcal{L}_m=\{0\}$ *and* $\mathcal{L}_{m-1}\neq\{0\}$ *(resp.* $\mathcal{L}^m=\{0\}$ *and* $\mathcal{L}^{m-1}\neq\{0\}$*).*

3 Associating combinatorial structures with Leibniz algebras

Let $\mathcal{L}$ be a n-dimensional Leibniz algebra with basis $\mathcal{B}=\{e_i\}_{i=1}^n$. Its structure constants correspond to $[e_i,e_j]=\sum_{h=1}^n c_{i,j}^h e_h$ and, hence, the pair $(\mathcal{L},\mathcal{B})$ is associated with a combinatorial structure by the following procedure

 ISBN: 978-84-617-8694-7

a) For each $e_i \in \mathcal{B}$, we draw a vertex i.

b) For every vertex i verifying $[e_i, e_i] \neq 0$, we draw a loop such that its weight is an n-tuple given by $(c^1_{i,i}, c^2_{i,i}, \ldots, c^n_{i,i})$.

c) Given two vertices i, j verifying $(c^j_{i,j}, c^j_{j,i}) \neq (0,0)$, we draw a directed edge from vertex i to j whose weight is given by the pair $(c^j_{i,j}, c^j_{j,i})$.

d) Given three vertices $i < j < k$ such that $(c^k_{i,j}, c^k_{j,i}, c^i_{j,k}, c^i_{k,j}, c^j_{i,k}, c^j_{k,i}) \neq (0,0,0,0,0,0)$, we draw a full triangle ijk such that the edges ij, jk and ik have weights $(c^k_{i,j}, c^k_{j,i})$, $(c^i_{j,k}, c^i_{k,j})$ and $(c^j_{i,k}, c^j_{k,i})$, respectively. Moreover,

   d1) we use a discontinuous line (named *ghost edge*) for edges with weight $(0,0)$.

   d2) If two triangles ijk and ijl satisfy $(c^k_{i,j}, c^k_{j,i}) = (c^l_{i,j}, c^l_{j,i})$, draw only one edge between vertices i and j shared by both triangles.

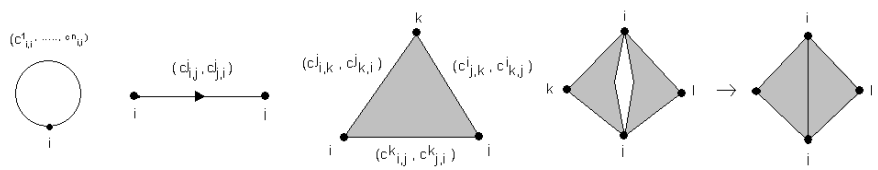

Figure 1: Loop, directed edge, full triangle and two triangles sharing an edge.

4 (Pseudo)digraphs associated with Leibniz algebras

This section is devoted to state some general results on the isomorphism classes of Leibniz algebras admitting configurations with 2 and 3 vertices, including the link of isomorphism between Leibniz algebras associated with different configurations. Throughout the paper we have used the results obtained in [2]. The main results that we have obtained are the following.

Theorem 1 *There exist only three isomorphism classes of 2-dimensional, non-abelian Leibniz algebras associated with (pseudo)digraphs, namely:* $\mathcal{L}^2_1 : [e_1, e_1] = e_2$, $\mathcal{L}^2_{2,1} : [e_2, e_1] = e_2$ *and* $\mathcal{L}^2_{2,2} : [e_1, e_2] = -[e_2, e_1] = e_2$.

 ISBN: 978-84-617-8694-7

Theorem 2 *There exist six isomorphism classes of 3-dimensional, non-abelian Leibniz algebras associated with non-connected (pseudo)digraphs. They are:* $\mathcal{L}_1^3 : [e_1, e_1] = e_2$, $\mathcal{L}_2^3 : [e_1, e_1] = e_2, [e_3, e_3] = e_2$, $\mathcal{L}_{3,1}^3 : [e_3, e_2] = e_3$, $\mathcal{L}_{3,2}^3 : [e_2, e_3] = -[e_3, e_2] = e_3$, $\mathcal{L}_{4,1}^3 : [e_2, e_2] = e_1, [e_3, e_2] = e_3$, $\mathcal{L}_{4,2}^3 : [e_2, e_2] = e_1, [e_2, e_3] = -[e_3, e_2] = e_3$.

5 Algorithmic procedure

In this section, we show an algorithmic method to determine if a given combinatorial structure is associated or not with a Leibniz algebra.

We have implemented this algorithm by using the symbolic computation package Maple, working the implementation in version 12 or higher. To do this, we have used the libraries `linalg` and `combinat` to activate commands related to Linear and Combinatorial Algebra. This algorithmic procedure consists of the following three steps

a) Defining the values of the structure constants according to the combinatorial structure.

b) Generating the law which should be satisfied by the Leibniz algebra, starting from the structure constants.

c) Checking if the Leibniz identities are satisfied for this law.

Abstract

The High Efficiency Video Coding (HEVC) standard has opened the door to high quality multimedia contents, enabling the advent of new formats such as Ultra High Definition (UHD), as a result of the unceasing demands of the market. This standard is able to outperform prior standards by up to 50% in terms of perceptual video quality, but at the cost of extremely large computational complexities. For this reason, the development of fast coding algorithms is now a requirement to make HEVC an adequate candidate for real-world scenarios. In this regard, this paper proposes a collaborative CPU+GPU coding architecture for this standard, in which the host performs a coarse-grained parallelization of the encoder using tile partitions, while the device carries out a fast motion estimation. As a result, an average speed-up of 8.41× can be obtained with 12 threads, at the cost of reasonable coding efficiency penalties.

Key words: HEVC, H.265, Heterogeneous, Parallel Encoding, GPU, Tiles

1 Introduction

Since its ratification more than a decade ago, the H.264/Advanced Video Coding (AVC) [1] standard established itself as the most widespread video compression standard for many types of applications and scenarios, including Blu-ray and various high-definition (HD)

 ISBN: 978-84-617-8694-7

television broadcasts. Nevertheless, the consumption pattern of video contents has changed in recent years, with higher preference for larger resolutions such as ultra high definition (UHD), and higher quality of contents. This, however, has led to an increase in bit rate that could become a relevant problem from the point of view of communication networks and storage services. For these reasons, the Joint Collaborative Team on Video Coding (JCT-VC) defined the High Efficiency Video Coding (HEVC) standard in early 2013 [2]. This standard has been designed to support very large resolutions and formats while improving the coding efficiency of previous standards. In fact, HEVC roughly doubles the rate-distortion (R-D) performance of H.264/AVC. In other words, it is able to reduce nearly 50% bit rate for the same perceptual video quality [3]. This notable improvement in coding efficiency comes, however, at the expense of extremely high computational complexities [4].

The HEVC standard is based on the same block-based scheme as its predecessors. The improved efficiency is derived from the enhancement of many existing coding tools, as well as the introduction of new ones. Among others, these tools include a highly flexible quadtree partitioning scheme that divides the picture into square blocks named coding tree units (CTU). While these tools enable good coding efficiency, they imply a huge increase in encoding time. To reduce the processing time, HEVC introduces some high-level tools, such as tiles and wavefronts, with the aim of allowing the parallel encoding and decoding of a video sequence. These parallelization techniques rely on creating partitions that are processed concurrently. However, some dependencies are broken to achieve this concurrency.

The parallel techniques defined in the standard operate at a coarse-grained level, while the rest of encoding operations are sequential. In fact, some of these operations can involve large computation times. In particular, the inter prediction module can take more than 60% of the encoding time in Random Access configurations [5]. This module is responsible for determining the motion vectors (MV) that minimize the rate-distortion (R-D) cost of matching each of the blocks in which the picture is divided with respect to temporal neighbors. Given the nature of this operation and the large number of repetitive operations performed, an auxiliary device such as a graphic processing unit (GPU) could help reduce the time devoted to the inter prediction. In this regard, this paper proposes a GPU-based heterogeneous coding architecture in which several picture partitions are processed in parallel in the CPU, and the integer motion estimation (ME) algorithm of the inter prediction module is performed in a single GPU, creating a collaborative framework between both devices. The main aim of the proposed architecture is to reduce the total processing time of the encoder, which is achieved at the cost of minimal coding efficiency losses.

The rest of this paper is organized as follows. Section 2 presents a short summary of HEVC. Section 3 covers some of the most relevant related works in the topic. Then, Section 4 provides an overview of the proposed GPU-based heterogeneous coding architecture. An experimental evaluation is carried out in Section 5, showing the results of this architecture in terms of time reduction and coding efficiency. Finally, conclusions are drawn in Section 6.

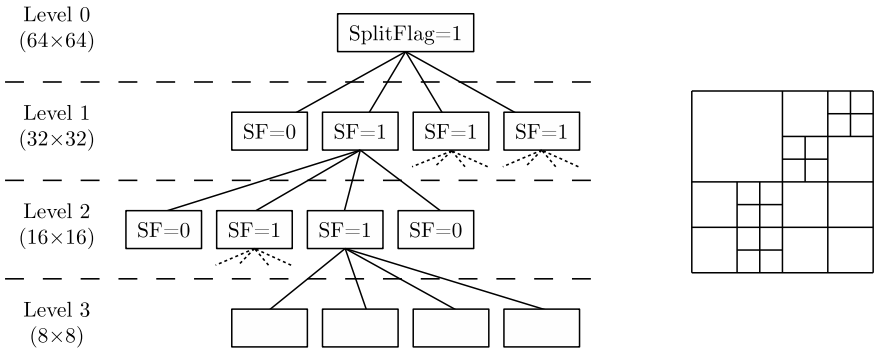

Figure 1: Example of CTU quadtree structure defined in HEVC

2 Technical Background

As mentioned in the introduction of this paper, HEVC achieves considerably higher coding efficiency compared to previous standards by enhancing existing coding tools and introducing new ones. In this regard, one of the most important novelties introduced by HEVC is the new picture partitioning scheme, which is now based on a quadtree structure as shown in Fig. 1. Each input picture is partitioned into square regions called coding tree units (CTU), whose size is typically 64×64 pixels. These structures can be partitioned, in turn, into coding units (CU), prediction units (PU) and transform units (TU). PUs store prediction information such as MVs, and can range from 64×64 to 8×8 using either symmetrical or asymmetrical sizes. TUs, in turn, contain residual information and range from 32×32 to 4×4, adopting a tree structure named residual quadtree (RQT). Other new features in HEVC include a total of 35 different intra coding modes, or the new in-loop filters.

With regard to the prediction, HEVC defines eight possible partitions for each CU size: 2N×2N, 2N×N, N×2N, N×N, 2N×nU, 2N×nD, nL×2N and nR×2N. The last four PU types correspond to the asymmetric motion partitioning (AMP) introduced as a novelty in this standard. These new sizes involve a large increase in the complexity of the encoder, but it also enables larger adaptability for edges, especially with larger CU sizes. To get more accurate motion vector predictors (MVP), the standard defines the advanced motion vector prediction (AMVP) algorithm, which enables to derive several most probable candidates based on data from adjacent PUs. As a result, less bits are necessary to encode the MVs, which enables the use of the merge mode more often, omitting the transmission of MVs.

All these new coding tools introduced in HEVC enable a very flexible encoding. Nevertheless, they also involve a notable increase in the computational complexity of both the encoder and the decoder. With the aim of reducing this complexity, the standard defines two different parallelization strategies known as tiles [6] and wavefront parallel processing (WPP) [7]. On the one hand, tiles are rectangular partitions where dependencies are par-

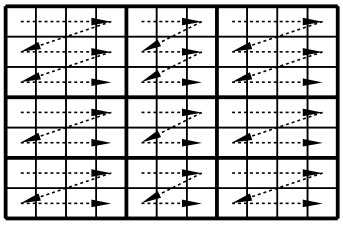

Figure 2: Example of picture partitioned in tiles, and coding order

tially broken across boundaries, making it possible to process them independently. The in-loop filters can still cross these boundaries, however, to improve the overall coding efficiency. An example of tile-based processing can be seen in Fig. 2, in which the input picture has been divided into 9 tiles. On the other hand, WPP enables the creation of rows that can be processed in parallel. In this case, unlike tiles, the entropy coding is allowed to cross partitions with the aim of minimizing coding losses, but at the cost of introducing a delay of two CTUs between consecutive rows, which limits the parallelism of the algorithm. As a design decision, both techniques cannot coexist at the same time.

3 Related Work

Provided the need for parallel techniques in HEVC, several state-of-art works address the complexity analysis and parallelization strategies of this standard [5, 8]. As for other parallelization techniques, authors in [9] present a variation of WPP called Overlapped Wavefront (OWF), which enables processing two consecutive pictures at the same time to avoid ramping inefficiencies. In this way, when a thread finishes processing a CTU row and there is no more available rows in the current frame, it can begin processing the next picture instead of idling. However, this paper applies this technique to the decoder side. With regard to the encoder, authors in [10] propose a fine-grained parallel optimization of the ME module for multi-core and many-core platforms, allowing to perform the MV prediction of all PUs available in a CU at the same time. Therefore, the maximum parallelism will be dependent of the platform. In a similar way to this work, a ME algorithm for many-core platforms is presented in [11].

Other works make use of GPU devices in the encoding process, especially to perform inter prediction. Authors in [12] propose a scheme designed for GPU plus multi-core CPU platforms, in a similar way to this paper. However, the encoder used in the tests does not include all the coding tools, and thus results are not comparable. In [13], authors propose a GPU-based ME algorithm that makes use of a diamond search pattern, which might not obtain the best candidate in some cases. This work was later extended for bi-prediction in [14], but still used the same search pattern. Additionally, the achieved speed-up is

limited due to the portion of time devoted to the ME, which could be solved with the use of a coarse-grained algorithm.

4 CPU Plus GPU Tile-Based Coding Architecture

As detailed in the previous sections, it is possible to parallelize both the encoder and the decoder using the techniques defined in the standard: tiles and WPP. While this is an effective way to reduce the total encoding time, some modules still involve large computation times, which should be reduced to achieve reasonable processing times. The module in which it is devoted the largest amount of time is the inter prediction module, which basically consists in subtracting the current PU to different positions in the reference frame, in order to reduce the R-D cost generated by a given MV. The nature of this operation makes the GPU a very adequate auxiliary device to perform the whole processing in little time. For this reason, in this paper we propose a GPU-based heterogeneous coding architecture in which the CPU performs a coarse-grained parallelization of the encoding, while the GPU carries out a fine-grained parallelization of the ME algorithm of the inter prediction module. In this way, it is possible to archive much larger speed-ups than using a homogeneous parallel architecture, i.e. with each of the algorithms separately. In this regard, the tile-based algorithm defined in the standard has been selected to perform the coarse-grained parallelization provided that it results in larger speed-ups. The next subsections will show the approach followed by the proposed architecture.

4.1 Coarse-Grained Parallelization Algorithm: Tiles

As mentioned in Section 2, a tile is a partition that can be independently encoded or decoded with regard to the other tiles in the same frame. As an exception, the filtering operation needs to be performed after all the tiles in a frame have been encoded or decoded, and thus cannot be parallelized. Consequently, a synchronization point is required at the end of the frame. Despite this, tiles offer huge parallelism that can be exploited so that every tile is encoded by a different processing unit, which in our case corresponds to a thread.

Our proposed approach is to divide each frame into as many tiles as available processing units. In this way, if a hardware platform is composed of an octa-core CPU, each frame would be divided into eight different tiles. While tiles can be assigned any rectangular shape defined by parameter, the approach followed in this paper is to utilize only horizontal tiles. The reason for this is to improve the data locality in the device, as frames are usually stored in raster scan order. Additionally, in order to maximize the parallel efficiency of the algorithm, each partition is assigned the same number of CTUs, if possible.

Apart from the filtering operation mentioned before, the synchronization point located at the end of the frame also enables to update the decoded picture buffer (DPB), which stores the reconstructed version of the frames after their encoding. In order to avoid costly

memory transfers, a shared memory scheme has been utilized, so that the DPB is shared across processing units.

4.2 GPU-Based Inter Prediction Algorithm

Whereas the tile-based algorithm is able to achieve coarse-grained parallelism of the encoding process, it is still possible to further parallelize the encoding with the proposed heterogeneous architecture. As already mentioned, one of the most computationally expensive operations of the encoder is the inter prediction, and the ME algorithm in particular. This operation consists in estimating the MVs that perform the transformation of the PUs in the current frame with regard to the reference frames with the lowest R-D cost. It is performed by subtracting the corresponding partitions from the reference pictures, which involves a large number of repetitive operations. Considering the nature of this algorithm, it should be noted the convenience of the GPU architecture.

CPU and GPU can work together in a synchronous or an asynchronous way. However, to avoid delays caused by data transfers and kernel executions, the GPU needs to perform its operations asynchronously. The way in which this asynchronism is achieved by the proposed algorithm is shown in Fig. 3. As can be seen, the original frames are copied to the device as soon as a group of pictures (GOP) starts being processed. In this way, they are always available for prediction in the device. Given that the ME requires the reconstructed version of the frames to perform the prediction, these are copied and replaced in the device once they are encoded. With regard to the assignation of workload to the device, the host queues the ME of the following CTU to the one that is currently being processed. In other words, the device is always processing a CTU ahead of the host. This is possible thanks to a double buffer that holds the motion information of the current CTU, while it allocates the space necessary for next one. For this reason, the host might need to wait for the device to finish processing the first CTU as an exceptional case.

In a similar way to how the encoder would perform the ME in the host, the device calculates the MVs for all the possible PUs in which a CTU is divided, and their associated distortion costs. However, the device is capable of evaluating all the possible MVs in the search area, while the host requires to use fast algorithms in order to perform the estimation in an assumable period of time. The ME is performed in two steps, which corresponds to two different GPU kernels. On the one hand, the first kernel executes the operations required to calculate the distortion costs, i.e. the sum of absolute difference (SAD) residuals across a search area in the reference frame. On the other hand, the second one consists in a reduction algorithm that determines the best MV in terms of SAD cost.

The first kernel relies on the fact that the dimensions of every PU defined by the standard are divisible by four, and thus it is possible to calculate the SAD residual information of a PU from the composition of its 4×4 partitions. Under this assumption, the previously mentioned kernel distributes a device thread to each sample in the reference search area,

 ISBN: 978-84-617-8694-7

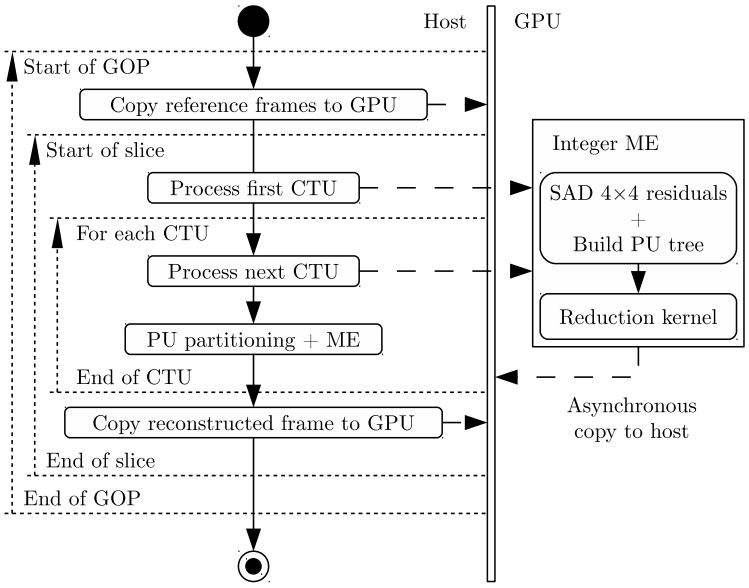

Figure 3: GPU-based inter prediction algorithm diagram

which is equivalent to a MV. Each thread is responsible for calculating all the 4×4 SAD blocks in a CTU. After all the threads have finished calculating these costs, each of them puts them together to calculate the distortion of the PUs into which a CTU might be divided. At this point, the device has at its disposal the distortion cost of each PU in each position in the search area. Therefore, the second kernel consists in a reduction algorithm that selects the best MV in terms of SAD. The result of this step is the optimal MV from the point of view of the distortion for each PU and reference frame. This information is sent to the host.

With the information calculated in the GPU, the encoder is able to skip the integer motion estimation process, which is the first part of the inter prediction algorithm. Instead of performing this estimation, the host only needs to obtain the MV that the device asynchronously copied beforehand. As a result, the computational complexity of the inter prediction module is reduced.

4.3 Joint GPU-Based Heterogeneous Architecture

While the tile-based algorithm defined in the standard performs a coarse-grained parallelization of the encoding, the GPU-based ME algorithm is able to speed up one of the most computationally expensive modules of the encoder. As they both work at different levels, they can cooperate simultaneously. The way in which this collaboration takes place

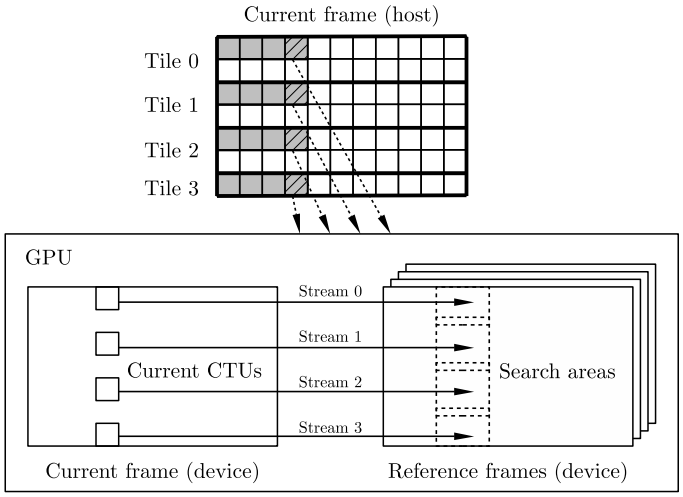

Figure 4: Combination of the tile-based algorithm and the GPU-based proposal (4 threads)

is shown in Fig. 4. As can be seen, the input pictures are partitioned into horizontal tiles as described in Section 4.1. Each of these tiles is assigned to a processing unit, which is equivalent to a thread in our model. Every processing unit queues, in turn, the GPU-based ME algorithm into different streams of the same device, making it possible to execute the kernels concurrently with respect to the host. As a result, the device utilization increases, and the total power consumption decreases.

The scalability of the proposed architecture depends on two different factors. The first one is inherent to the design of the tiles algorithm, and limits the maximum parallelism to the number of rows in a frame. However, this issue becomes less important the larger the frame is. For example, a UHD sequence could hold 34 different horizontal tiles. The second factor that might limit the parallelism is the hardware platform itself, as the device could limit the amount of parallelism if is not able to process all the required CTUs simultaneously. Nevertheless, this has not happened in our experimental evaluation of the architecture.

5 Performance Evaluation

The experiments have been executed on the HEVC Test Model (HM-16.3) reference software [15], following the guidelines and coding conditions provided by the JCT-VC in [16]. In this regard, Random Access has been the selected configuration, and the QP values are 22, 27, 32 and 37. The encodings have been carried out using the Main profile and 8-bit depth. Sequences of classes A to D according to the JCT-VC classification have been used,

Table 1: Per-sequence results of the proposed GPU-based heterogeneous architecture varying number of threads

Class	Video sequence	BD-rate (%)					Speed-up				
		1	2	4	8	12	1	2	4	8	12

D	BasketballPass	0.38	2.47	5.25			1.11	2.05	3.38		
	BQSquare	0.06	1.23	2.93			1.05	1.85	3.35		
	BlowingBubbles	−0.26	0.65	2.33			1.05	1.89	3.34		
	RaceHorses	−0.30	1.30	4.05			1.11	1.89	3.49		
Mean values (A & B)		0.59	0.97	1.73	3.12	4.41	1.09	2.04	3.82	6.82	8.41
Mean values (all)		0.33	1.11	2.48	3.96	4.41	1.09	2.01	3.68	6.87	8.41

which include the following resolutions: 2560×1600 (A), 1920×1080 (B), 832×480 (C), and 416×240 (D).

The hardware platform used in the experiments is composed of an Intel® Xeon® E5-2650 v2 CPU running at 2.60 GHz and an NVIDIA® Tesla® K40 GPU. The encoder has been compiled with GCC 4.8.5 and NVIDIA® CUDA 7.0, and executed on CentOS 7. Turbo Boost was disabled to achieve the reproducibility of the results.

With regard to the parametrization of the encoder, the sample adaptive offset (SAO) filter has been disabled, as well as the *LFCrossSliceBoundary* flag. The reason for this decision is to achieve full independence between tiles, as the SAO filter might introduce some dependencies in the encoding. The executions have been performed using 1, 2, 4, 8 and 12 threads.

The results will be provided in terms of speed-up and Bjøntegaard delta rate (BD-rate). The latter represents the percentage of bit rate variation between two sequences with the same objective quality [17]. Therefore, a negative value implies that the proposal improves the coding efficiency of the baseline encoder.

 ISBN: 978-84-617-8694-7

Table 1 shows the results obtained by the proposed architecture when different number of threads are used for the execution. The results in which only one thread is used correspond to the case in which only the GPU is enabled, but no tile-based parallelization is performed. Also, it can be seen that the tests were not carried out for class D when 8 and 12 threads were used, and also for class C with 12 threads. This is caused by the fact that the maximum parallelism of the tile-based coarse-grained algorithm is limited by the total number of rows in the frame. As these classes are composed of low resolution sequences, they do not admit as many threads as used in the tests, so the obtained results would be the same as using a lower number of processing units: 4 threads for class D and 8 threads for class C. Considering that the average values shown in the table might not comprise the same set of results, the mean values for classes A and B are also shown to better reflect the effect of the proposed architecture.

First, it is worth detailing the results obtained by the GPU-based ME algorithm itself. It can be seen that the achieved speed-up is limited to 1.09×, which is derived from the fact that this is the portion of time devoted by the encoder to the integer ME in the inter prediction module. Nevertheless, this time reduction is achieved at the expense of very low coding efficiency losses of 0.33% on average. In fact, it can be seen that in some sequences the coding efficiency improved with respect to the baseline encoder, which is caused by the fact that the GPU-based algorithm performs a full search that covers all the possible MVs in the search area, while the baseline algorithm carries out a simplified search. Additionally, it has to be taken into account that this speed-up will perform as a multiplier factor for the tile-based parallelization algorithm.

With regard to the joint algorithm, it can be seen that the coding efficiency experiences larger losses when the number of processing units increases. This is the expected behavior of the algorithm, as more dependencies are broken. In fact, it is inherent to the design of the tile-based scheme defined in the standard. The table also displays the speed-up obtained by the proposed joint algorithm, which can reach a factor of up to 8.41× with 12 threads. This means that the proposed architecture does not fully utilize the hardware platform. At first, it might seem that this is caused by a bottleneck in the device, but in fact, the real cause is that the pictures cannot be evenly partitioned, which causes that some tiles might be larger than others. Also, it might happen that two tiles with the same number of CTUs take different times to process depending on the complexity of the picture. Nevertheless, the achieved speed-up is notable, and denotes that the proposed architecture is scalable as long as the frames are divided adequately. Regarding the contribution of the GPU in the joint algorithm, the benefits of the device can be observed in the results obtained for 2 threads, in which it can be seen that the achieved speed-up can be larger than 2×, which would not be feasible with only the host. The same behavior is displayed for the sequence PeopleOnStreet for 4 threads. As for the rest, the multiplying factor of the GPU is occluded by the inefficiencies derived from the tile-based algorithm.

 ISBN: 978-84-617-8694-7

6 Conclusions and Future Work

The HEVC standard has enabled the advent of a great number of applications and video formats such as UHD, as a result of the demands of the market for higher quality of video contents. Nevertheless, the improved coding efficiency of HEVC has also led to a relevant increase in computational complexity of both the encoder and the decoder. The research community is making large efforts to develop algorithms and techniques that enable to reduce this complexity with the aim of making this standard feasible for real-world scenarios. Accordingly, this paper proposes a CPU+GPU collaborative framework for HEVC in which the CPU performs a coarse-grained parallelization of the encoding, while the GPU aids in carrying out the ME. Having into consideration the intrinsic limitations of tiles, the experimental evaluation of the algorithm showed that the algorithm is scalable, reaching a speed-up of 8.41% with 12 threads for reasonable coding efficiency losses.

As future work, the most immediate step would be to extend the GPU algorithm to perform the fractional ME as well, so larger time reductions would be obtained. Additionally, it would be also of interest to analyze other coarse-grained algorithms that solve the limitations of horizontal tiles.

Abstract

In this paper we present a method for computing sparse preconditioners for solving rank deficient least squares (LS) arising from practical problems. The main idea of the method proposed is updating an incomplete factorization computed for a regularized problem to recover the solution of the original one. The numerical experiments show that the preconditioner proposed can be successfully applied to accelerate the convergence of iterative Krylov subspace methods.

Key words: Iterative methods, preconditioners, least squares.

1 Introduction

Linear least squares (LS) problems arise in many large-scale applications of the science and engineering as neural networks, linear programming, exploration seismology or image processing to name a few. The LS problem considered is formulated as

$$\min_x \|b - Ax\|_2, \tag{1}$$

where $A \in \mathbb{R}^{m\times n}$ $(m \geq n)$ is large and sparse and $b \in \mathbb{R}^m$. This problem can be solved iteratively using the conjugate gradient like methods [1]. Basically, this methods implicitly apply the conjugate gradient or minimal residual method to the normal equations

$$A^T Ax = A^T b. \tag{2}$$

 ISBN: 978-84-617-8694-7

When the system matrix is large and sparse iterative methods may be preferred because they often require much less storage than their direct counterparts. Their successful application often needs a good preconditioner in order to achieve fast convergence rates. When the matrix A has full rank, the preferred method of choice is computing an incomplete Cholesky factorization (IC) of the symmetric and positive definite matrix $C = A^T A$, see [2]. If the matrix A is rank deficient then, the matrix C is a semidefinite positive matrix and the Cholesky factorization suffers breakdown because negative or zero pivots are encountered. Thus, rank deficient LS problems are in general much more harder to solve. Basically, the are two types of approaches for solving this case iteratively. The first one consists of computing an incomplete factorization of a regularized matrix which can be used as a preconditioner for the original LS problem [6]. The second type is solving a mathematically equivalen augmented linear system of order $m+n$ [1]. The technique proposed in this work belongs to the first type.

The idea is to compute an IC factorization of the normal equations associated to the regularized matrix

$$\begin{bmatrix} A \\ \alpha^{1/2} I \end{bmatrix}. \tag{3}$$

Thouse are given by

$$C_\alpha = A^T A + \alpha I. \tag{4}$$

The shift α is known as Tikhonov regularization parameter. If α is choosen large enough the computation of an IC for the matrix C_α can be done easily. On the other hand, since the final purpose is to use this incomplete factorization as a preconditioner for the original (unregularized) linear system, the parameter α should be chosen as small as possible. Both requirements make difficult the choice of the appropriate α. In practice, the factorization is restarted more than once, increasing α on each restart until breakdown is avoided.

We propose a method that simplifies the choice of the regularization parameter. It is based on the work presented in [3] in which the authors study how to update a preconditioner for LS problems when the linear system is modified by adding or removing equations. Consider the matrix

$$(C_\alpha - \beta I) \tag{5}$$

which is an update of the shifted matrix C_α in (3). Clearly, the closer β is to α, the closer this update is to the normal equations of the original system. Our technique consists of updating an incomplete Cholesky factorization obtained for C_α using the augmented matrix

$$\begin{bmatrix} C_\alpha & \beta^{1/2} I \\ \beta^{1/2} I & I \end{bmatrix}. \tag{6}$$

Observe that between equations (5) and (6) one can establish the relations

$$C_\alpha - \beta I = \begin{bmatrix} I & O \end{bmatrix} \begin{bmatrix} C_\alpha & \beta^{1/2} I \\ \beta^{1/2} I & I \end{bmatrix} \begin{bmatrix} I \\ \beta^{1/2} I \end{bmatrix}, \tag{7}$$

 ISBN: 978-84-617-8694-7

and

$$(C_\alpha - \beta I)^{-1} = \begin{bmatrix} I & O \end{bmatrix} \begin{bmatrix} C_\alpha & \beta^{1/2} I \\ \beta^{1/2} I & I \end{bmatrix}^{-1} \begin{bmatrix} I \\ O \end{bmatrix}. \quad (8)$$

Thus, an IC factorization computed for (6) can be used as a preconditioner for the original normal equations using these relations. Also note that the modification of the shifted matrix in equation (5) allows for the choice of shift α values large enough to avoid breakdown during the IC of the matrix C_α. The subsequent update of the computed IC factorization should keep the updated preconditioner close to the original system.

2 Preconditioner computation

A block IC factorization of the augmented matrix (6) can be computed as follows. Since

$$\begin{pmatrix} C_\alpha & \beta^{1/2} I \\ \beta^{1/2} I & I \end{pmatrix} = \begin{pmatrix} L_\alpha & 0 \\ \beta^{1/2} L_\alpha^{-T} & I \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & R \end{pmatrix} \begin{pmatrix} L_\alpha^T & \beta^{1/2} L_\alpha^{-1} \\ 0 & I \end{pmatrix}$$

where $R = I - \beta L_\alpha^{-T} L_\alpha^{-1})$, the preconditioner is computed in four steps:

1. Compute $C_\alpha \approx L_\alpha L_\alpha^T$.
2. Compute $T = \beta^{1/2} L_\alpha^{-1}$.
3. Compute $R = I - T^T T$.
4. Compute $L_R L_R^T \approx R$.

3 Preconditioner application

The preconditioning step for a Krylov subspace iterative method typically consists of obtaining the preconditioned vector $s = M^{-1} r$ where M^{-1} is the preconditioner and r is the residual. Thus, the preconditioning strategy proposed computes the preconditioned residual by applying equation (8) with an incomplete factorization of the augmented matrix. That is,

$$\begin{pmatrix} L_\alpha & 0 \\ \beta^{1/2} L_\alpha^{-T} & I \end{pmatrix} \begin{pmatrix} I & 0 \\ 0 & R \end{pmatrix} \begin{pmatrix} L_\alpha^T & \beta^{1/2} L_\alpha^{-1} \\ 0 & I \end{pmatrix} \begin{pmatrix} s \\ s_1 \end{pmatrix} = \begin{pmatrix} r \\ 0 \end{pmatrix}.$$

The preconditioning step is done as follows:

1. Solve $L_\alpha r_1 = r$.
2. Solve $L_R (L_R^T r_2) = -T^T r_1$.
3. Solve $L_\alpha^T s = r_1 - T r_2$.

These three steps will be referenced as updated preconditioned method.

 ISBN: 978-84-617-8694-7

4 Numerical experiments

In this section we study the numerical performance of the preconditioner update method proposed. We present results obtained with matrices arising in different areas of scientific computing from the Florida Sparse Matrix Collection [4].

The technique proposed was used as preconditioner for the conjugate gradient method applied to the normal equations. It was compared with the IC factorization of C_α used as preconditioner for the LSMR method [5].

Table 1 shows the set of matrices tested. The matrices were cleaned by removing the null rows and columns before solving the LS problem. The number of rows and columns after removing the null ones, number of nonzeros, nnz, and nullity of the matrix (estimated null space rank) are reported.

Table 1: Set of tested matrices

 ISBN: 978-84-617-8694-7

The matrices with $m < n$ were transposed. Moreover, the Dulmage-Mendelson permutation was applied to A. The columns of the matrix corresponding to the normal equations $C = A^T A$ were normalised by their 2-norm. As result, an IC factorization $L_\alpha L_\alpha^T$ was computed for the shifted matrix,

$$C_\alpha = SPCP^T S^T + \alpha I.$$

For the updated preconditioner, a value of $\alpha = \beta = 1$ was used for all the matrices, except for the matrix BEAFLW for which a value of $\alpha = 10^{-3}$ was needed. The right-hand side b provided with the problem was used. Otherwise, the vector of all ones was used.

Table 2 show the results. In this table, $time_t$, $||r||_2$ and itn represent the total time (in seconds), residual norm ($||b-Ax||_2$) of the original LS problem and the number of iterations needed to converge the iterative method. As mentioned above, LSMR correspond to the results obtained with the IC factorization of C_α while PCG correspond to ones obtained with the proposed updated preconditioning technique. The iterative methods were stopped when the relative initial residual, i.e., $||b - Ax||_2/||b||$, was reduced to 10^{-6}. L_α was calculated with drop tolerance equal to 0.1, except for the matrices MRI1 and MRI2 for which a value of 0.2 was used. The experiments were performed using MATLAB.

The results show that the updated preconditioner method is competitive and robust for solving rank deficient least square problems. There are some problem for which the total solution time is reduced considerably. Thus, we think that the preconditioner proposed can be successfully applied to accelerate the convergence of iterative Krylov subspace methods.

Abstract

In this paper, we discuss a higher order convergent numerical method for two-parameter singularly perturbed problem having boundary and interior layers due to a discontinuous convection coefficient and discontinuous source term. A hybrid monotone scheme which provides almost second order uniform convergent solution, is constructed on a piecewise uniform mesh. The current scheme is compared with the standard upwind scheme, used at the point of discontinuity. Numerical experiments show that the hybrid scheme provides a higher order (almost second order) accuracy compared to the standard upwind scheme which is almost first order accurate.

Key words: singular perturbation, boundary and interior layers, hybrid scheme
MSC 2000: 65N12, 65N30 and 65N06

1 Introduction

Singularly perturbed problems (SPPs) can be characterized by the presence of a (or few) small positive parameter(s) which follows the boundary or interior layers. Adaptive mesh

generation [3, 4] is necessary to identify these layers. The simplest adaptive mesh on this context is due to Shishkin [1], who proposed a piecewise uniform mesh to capture the layer behavior. In today's literature, numerical methods for SPPs (involving only diffusion parameter) with smooth data [1], and non-smooth data [2, 5, 6, 7] are available on Shishkin meshes. Two-parameter problems, involving convection (ε_c) and diffusion (ε_d) parameters, extend the convection and reaction dominated model. In recent years, several numerical methods are observed for two-parameter problems with smooth data [8, 9, 10, 13] and non-smooth [11]. The papers [2, 6, 7] are dedicated to the numerical analysis of interior layers due to the discontinuous convection coefficient. Motivated by the works, we consider the following two-parameter singularly perturbed problem with discontinuous convection coefficient and source term:

$$Lu(x) \equiv \varepsilon_d u''(x) + \varepsilon_c a(x)u'(x) - b(x)u(x) = f(x),\ \forall\ x \in (\Gamma^- \cup \Gamma^+), \tag{1}$$

$$u(0) = u_0, \quad u(1) = u_1, \tag{2}$$

$$\text{where } a(x) \leq -\alpha_1 < 0,\ \text{for } x \in \Gamma^- \text{ and } a(x) \geq \alpha_2 > 0,\ \text{for } x \in \Gamma^+, \tag{3}$$

$$|\ [a](d)\ | \leq C,\ \ |\ [f](d)\ | \leq C. \tag{4}$$

Here ε_d and ε_c are known as singular perturbation parameters, where $0 < \varepsilon_d \ll 1$, $0 \leq \varepsilon_c \leq 1$. For simplicity, we consider the domain as $\overline{\Gamma} = [0, 1]$ with $\Gamma = (0, 1)$ and $\Gamma^- = (0, d)$, $\Gamma^+ = (d, 1)$. Here $b(x)$ is assumed to be sufficiently smooth function in $\overline{\Gamma}$ and satisfies $b(x) \geq \beta > 0$ and $a(x)$, $f(x)$ are sufficiently smooth in $(\Gamma^- \cup \Gamma^+) \cup \{0, 1\}$. Also $a(x), f(x)$ and its derivatives have a jump discontinuity at $d \in \Gamma$, where the jump of $\omega(x)$ at $x = d$ is denoted as $[\omega](d) = \omega(d+) - \omega(d-)$. These assumptions ensure that the SPP (1)-(2) has a solution $u(x) \in C^0(\overline{\Gamma}) \cap C^1(\Gamma) \cap C^2(\Gamma^- \cup \Gamma^+)$.

Note that $\varepsilon_c = 0$ reduces (1) to a reaction diffusion problem [5] and $\varepsilon_c = 1$ reduces (1) to a convection diffusion problem [6]. The solution behaves similar to dissipative form, when $\varepsilon_d/\varepsilon_c^2 \to 0$ as $\varepsilon_c \to 0$ and it acts in the dispersive form, when $\varepsilon_c^2/\varepsilon_d \to 0$ as $\varepsilon_d \to 0$ [9]. Hence, we consider the following two cases for the numerical discretization:
Case (i): $\sqrt{\alpha}\varepsilon_c \leq \sqrt{\gamma\varepsilon_d}$,
Case (ii): $\sqrt{\alpha}\varepsilon_c \geq \sqrt{\gamma\varepsilon_d}$,
where $\gamma = \min_{\overline{\Gamma}}\{b(x)/\alpha(x)\}$ with $\alpha(x) = -\alpha_1,\ x < d$ and $\alpha(x) = \alpha_2,\ x > d$.

For two-parameter problems with smooth data, the upwind scheme leads to $O(N^{-1}\ln^2 N)$ accuracy on Shishkin mesh [10], where N defines the number of partitions in the domain. Later in [8], the authors established a higher order numerical method by combining the upwind, central difference and mid-point schemes in various partitions of the domain. Their numerical method provides $O(N^{-2}\ln^3 N)$ accuracy, if $\sqrt{\alpha}\varepsilon_c \leq \sqrt{\gamma\varepsilon_d}$ and $O(N^{-2}\ln^2 N)$, if $\sqrt{\alpha}\varepsilon_c \geq \sqrt{\gamma\varepsilon_d}$ on Shishkin mesh. In [11]a discontinuity in source term is introduced and obtained $O(N^{-1}\ln^2 N)$, for $\sqrt{\alpha}\varepsilon_c \leq \sqrt{\gamma\varepsilon_d}$ and $O(N^{-1}\ln^3 N)$, for $\sqrt{\alpha}\varepsilon_c \geq \sqrt{\gamma\varepsilon_d}$ on the Shishkin mesh. Several other adaptive meshes, based on equidistribution principle [4] can be observed for two-parameter problems which leads to first order accuracy.

 ISBN: 978-84-617-8694-7

The above articles motivate us to consider the higher order numerical analysis for two-parameter problems with discontinuous convection and source term which lead to boundary and interior layers.

Throughout this article, C denotes a generic positive constant independent of mesh points, N (assumed to be divisible by 2) and ε_d, ε_c. The infinity norm is denoted as $\|u\|_{\overline{\Omega}} = \max_{x\in\overline{\Omega}} |u(x)|$ for a function $u(x)$ defined on a general domain $\overline{\Omega}$. We denote it by $\|.\| = \|.\|_{\overline{\Omega}}$. Accordingly, the corresponding discrete norm is denoted as $\|.\| = \|.\|_{\overline{\Omega}^N}$.

The paper is arranged as follows. Section 2 presents a discrete problem based on hybrid finite difference scheme corresponding to the continuous problem. Numerical examples in Section 3, validates these theoretical findings. The conclusion is drawn in Section 4.

2 Numerical Approximation

This section introduces the discretization of (1)-(2). The discrete problem will be defined on an *a priori* adaptive piecewise uniform mesh, which is dense inside the boundary and interior layer regions. To construct this mesh, we first divide the domain $\overline{\Gamma}$ into six subintervals:

$$\overline{\Gamma} = [0,\tau_1] \cup [\tau_1, d-\tau_2] \cup [d-\tau_2, d] \cup [d, d+\tau_3] \cup [d+\tau_3, 1-\tau_4] \cup [1-\tau_4, 1],$$

for some τ_1, τ_2, τ_3 and τ_4. The mesh points are denoted as $\overline{\Gamma}^N = \{x_i\}_0^N$ where $x_{N/2}$ denotes the point of discontinuity $x_{N/2} = d$. On these mesh points, we define the discrete solution as U_i. The transitions parameters τ_1, τ_2, τ_3 and τ_4 in $\overline{\Gamma}$ are chosen as follows:

$$\left\{\begin{array}{l} \tau_1 = \min\left\{\dfrac{d}{4}, \dfrac{2}{\theta_2}\ln N\right\}, \quad \tau_2 = \min\left\{\dfrac{d}{4}, \dfrac{2}{\theta_1}\ln N\right\}, \\ \tau_3 = \min\left\{\dfrac{1-d}{4}, \dfrac{2}{\theta_1}\ln N\right\}, \quad \tau_4 = \min\left\{\dfrac{1-d}{4}, \dfrac{2}{\theta_2}\ln N\right\}, \end{array}\right. \tag{5}$$

where

$$\theta_1 = \left\{\begin{array}{ll} \dfrac{\sqrt{\rho\alpha}}{2\sqrt{\varepsilon}}, & \text{if } \sqrt{\alpha}\mu \le \sqrt{\rho\varepsilon}, \\ \dfrac{\alpha\mu}{2\varepsilon}, & \text{if } \sqrt{\alpha}\mu \ge \sqrt{\rho\varepsilon}, \end{array}\right. \text{and } \theta_2 = \left\{\begin{array}{ll} \dfrac{\sqrt{\rho\alpha}}{2\sqrt{\varepsilon}}, & \text{if } \sqrt{\alpha}\mu \le \sqrt{\rho\varepsilon}, \\ \dfrac{\rho}{2\mu}, & \text{if } \sqrt{\alpha}\mu \ge \sqrt{\rho\varepsilon}. \end{array}\right.$$

Now we construct a uniform mesh on each subintervals $[0,\tau_1]$, $[d-\tau_2, d]$, $[d, d+\tau_3]$ and $[1-\tau_4, 1]$, so that each subintervals contains $N/8+1$ uniform mesh points and the subintervals $[\tau_1, d-\tau_2]$ and $[d+\tau_3, 1-\tau_4]$ contains $N/4+1$ uniform mesh points respectively. The mesh sizes in each of the subintervals from left to right of $\overline{\Gamma}$ are denoted as $h_1 = 8\tau_1/N$, $h_2 = 4(d-\tau_2-\tau_1)/N$, $h_3 = 8\tau_2/N$, $h_4 = 8\tau_3/N$, $h_5 = 4(1-d-\tau_3-\tau_4)/N$ and $h_6 = 8\tau_4/N$. On the above adaptive mesh $\overline{\Gamma}^N$, we discretize the BVP (1)-(2) as

$$\begin{array}{l} L^N U_i \equiv \varepsilon_d \delta^2 U_i + \varepsilon_c a_i D^* U_i - b_i U_i = f_i, \quad \text{for } i = 1, 2, ..., N-1, \\ D^+ U_{N/2} - D^- U_{N/2} = 0 \ \text{ with } \ U_0 = u(0), \ U_N = u(1). \end{array} \tag{6}$$

 ISBN: 978-84-617-8694-7

The upwind discretization (6) is almost first order accurate [11] (see the numerical Section 3). Now, we construct an almost second order accurate hybrid scheme for (1)-(2) by combining the following central, upwind and mid-point difference schemes with a five-point scheme:

$$\begin{aligned} L_c^N U_i &\equiv \varepsilon_d \delta^2 U_i + \varepsilon_c a_i D^0 U_i - b_i U_i = f_i, \\ L_u^N U_i &\equiv \varepsilon_d \delta^2 U_i + \varepsilon_c a_i D^* U_i - b_i U_i = f_i, \\ L_m^N U_i &\equiv \varepsilon_d \delta^2 U_i + \varepsilon_c \overline{a}_i D^* U_i - \overline{b_i U_i} = \overline{f}_i, \end{aligned}$$

where, $D^0 U_i = \dfrac{U_{i+1} - U_{i-1}}{h_i + h_{i+1}}$, $D^+ U_i = \dfrac{U_{i+1} - U_i}{h_{i+1}}$, $D^- U_i = \dfrac{U_i - U_{i-1}}{h_i}$,
$\delta^2 U_i = \dfrac{1}{\overline{h}_i}\left(D^+ U_i - D^- U_i\right)$, $\overline{z}_i = \dfrac{z_i + z_{i+1}}{2}$ and $D^* = \begin{cases} D^-, & \text{if } i < N/2, \\ D^+, & \text{if } i > N/2. \end{cases}$

At $x_{N/2} = d$, we use a five-point difference scheme by combining the second order accurate one sided difference approximation $u'(x) \approx (-3U(x)+4U(x+h_3)-U(x+2h_3))/2h_3$, based on forward difference operator and $u'(x) \approx (3U(x) - 4U(x-h_4) + U(x-2h_4))/2h_4$, based on backward difference operator. At the point of discontinuity, we define the scheme

$$L_t^N U_{N/2} \equiv \frac{-U_{N/2+2} + 4U_{N/2+1} - 3U_{N/2}}{2h_4} - \frac{U_{N/2-2} - 4U_{N/2-1} + 3U_{N/2}}{2h_3} = 0, \qquad (7)$$

Now, we define the finite difference scheme (L^N), which involves the central, upwind, mid-point and a five-point scheme on the piecewise uniform mesh which is as follows:
when $\sqrt{\alpha}\varepsilon_c \le \sqrt{\gamma\varepsilon_d}$

$$L^N \equiv \begin{cases} L_c^N, \text{ if } x_i \in (0,\tau_1) \cup (d-\tau_2, d) \cup (d, d+\tau_3) \cup (1-\tau_4, 1), \\ L_c^N, \text{ if } x_i \in (\tau_1, d-\tau_2) \cup (d+\tau_3, 1-\tau_4), \text{ with } 2\varepsilon_c \|a\| h_k < \varepsilon_d, \ k = 2, 5, \\ L_t^N, \text{ if } x_i = d, \end{cases}$$

and for $\sqrt{\alpha}\varepsilon_c \ge \sqrt{\gamma\varepsilon_d}$

$$L^N \equiv \begin{cases} L_m^N, \text{ if } x_i \in (0,\tau_1) \cup (1-\tau_4, 1), \\ L_m^N, \text{ if } x_i \in (\tau_1, d-\tau_2) \cup (d+\tau_3, 1-\tau_4), \text{ with } \begin{cases} 2\varepsilon_c \|a\| h_k \ge \varepsilon_d, \\ 2\|b\| h_k < \varepsilon_c \alpha, \ k = 2, 5, \end{cases} \\ L_u^N, \text{ if } x_i \in (\tau_1, d-\tau_2) \cup (d+\tau_3, 1-\tau_4), \text{ with } \begin{cases} 2\varepsilon_c \|a\| h_k \ge \varepsilon_d, \\ 2\|b\| h_k \ge \varepsilon_c \alpha, \ k = 2, 5, \end{cases} \\ L_c^N, \text{ if } x_i \in (d-\tau_2, d) \cup (d, d+\tau_3), \\ L_t^N, \text{ if } x_i = d. \end{cases}$$

 ISBN: 978-84-617-8694-7

At the transition points τ_1 and $(d+\tau_3)$, the scheme is defined as

$$L^N \equiv \begin{cases} L_c^N, \text{ if } x_i = \begin{cases} \tau_1 = \dfrac{1}{8}, \\ d+\tau_3 = d+\dfrac{1}{8}, \end{cases} \\ L_m^N, \text{ if } x_i = \begin{cases} \tau_1, \text{ where } \tau_1 < \dfrac{1}{8}, \text{ for } 2\|b\|h_2 < \varepsilon_c\alpha, \\ d+\tau_3, \text{ where } d+\tau_3 < d+\dfrac{1}{8}, \text{ for } 2\|b\|h_5 < \varepsilon_c\alpha, \end{cases} \\ L_u^N, \text{ otherwise.} \end{cases}$$

At the transition points $(d-\tau_2)$ and $(1-\tau_4)$, we define the scheme as

$$L^N \equiv \begin{cases} L_c^N, \text{ if } x_i = \begin{cases} d-\tau_2 = d-\dfrac{1}{8}, \text{ for } 2\varepsilon_c\|a\|h_3 < \varepsilon_d, \\ 1-\tau_4 = 1-\dfrac{1}{8}, \text{ for } 2\varepsilon_c\|a\|h_6 < \varepsilon_d, \end{cases} \\ L_m^N, \text{ if } x_i = \begin{cases} d-\tau_2 = d-\dfrac{1}{8}, \text{ for } 2\varepsilon_c\|a\|h_3 \ \geq \varepsilon_d, \\ 1-\tau_4 = 1-\dfrac{1}{8}, \text{ for } 2\varepsilon_c\|a\|h_6 \geq \varepsilon_d, \end{cases} \\ L_m^N, \text{ if } x_i = \begin{cases} d-\tau_2, \text{ where } d-\tau_2 > d-\dfrac{1}{8}, \text{ for } 2\|b\|h_3 < \varepsilon_c\alpha, \\ 1-\tau_4, \text{ where } 1-\tau_4 > 1-\dfrac{1}{8}, \text{ for } 2\|b\|h_6 < \varepsilon_c\alpha, \end{cases} \\ L_u^N, \text{ otherwise.} \end{cases}$$

Now, we define the discrete problem as

$$\begin{aligned} & L^N U_i = Q^N f_i, \text{ for } i = 1, ..., N-1, \text{ with } U_0 = u(0),\ U_N = u(1), \\ & \text{where} \qquad Q^N f_i = \begin{cases} f_i, & \text{if } L^N \equiv L_c^N \text{ or } L_u^N, \\ \overline{f}_i, & \text{if } L^N \equiv L_m^N, \\ 0, & \text{if } L^N \equiv L_t^N. \end{cases} \end{aligned} \tag{8}$$

The matrix associated with (8) does not satisfy M-matrix condition at the point of discontinuity $x_i = d$. But, (without loss of generality) we can convert this five-point difference scheme into a three-point difference scheme (say, $L_T^N U_i$) by estimating $U_{N/2-2}$, $U_{N/2+2}$ from $L_c^N U_i$, so that the new equations do have the monotonicity property. To do this, note

$$\begin{aligned} U_{N/2-2} \ = & \frac{2h_3}{2\varepsilon_d - h_3\varepsilon_c a_{N/2-1}} \left[h_3 f_{N/2-1} + \left(\frac{2\varepsilon_d}{h_3} + h_3 b_{N/2-1} \right) U_{N/2-1} \right. \\ & \left. - \left(\frac{2\varepsilon_d + h_3\varepsilon_c a_{N/2-1}}{2h_3} \right) U_{N/2} \right], \end{aligned}$$

 ISBN: 978-84-617-8694-7

$$U_{N/2+2} = \frac{2h_4}{2\varepsilon_d + h_4\varepsilon_c a_{N/2+1}}\left[h_4 f_{N/2+1} + \left(\frac{2\varepsilon_d}{h_4} + h_4 b_{N/2+1}\right)U_{N/2+1} - \left(\frac{2\varepsilon_d - h_4\varepsilon_c a_{N/2+1}}{2h_4}\right)U_{N/2}\right].$$

Now we replace the above expressions of $U_{N/2-2}$, $U_{N/2+2}$ of five-point difference scheme $(L_t^N U_{N/2})$ to construct a three point scheme $(L_T^N U_{N/2})$ which preserves the monotonicity property and leads to an higher order accuracy at the point of discontinuity.

$$\begin{aligned} L_T^N U_{N/2} \equiv & \left(\frac{2\varepsilon_d - h_4\varepsilon_c a_{N/2+1}}{2\varepsilon_d + h_4\varepsilon_c a_{N/2+1}} - 6 + \frac{2\varepsilon_d - h_3\varepsilon_c a_{N/2-1}}{2\varepsilon_d + h_3\varepsilon_c a_{N/2-1}}\right)U_{N/2} \\ & + \left(\frac{-4\varepsilon_d - 2h_4^2 b_{N/2+1}}{2\varepsilon_d + h_4\varepsilon_c a_{N/2+1}} + 4\right)U_{N/2+1} + \left(\frac{-4\varepsilon_d - 2h_3^2 b_{N/2-1}}{2\varepsilon_d + h_3\varepsilon_c a_{N/2-1}} + 4\right)U_{N/2-1} \\ = & \frac{2h_3^2 f_{N/2-1}}{2\varepsilon_d + h_3\varepsilon_c a_{N/2-1}} + \frac{2h_4^2 f_{N/2+1}}{2\varepsilon_d + h_4\varepsilon_c a_{N/2+1}}. \end{aligned}$$

So, the reformulated discrete operator (say $L_*^N U_i$) of (8) can be written as

$$L_*^N U_i = Q_*^N f_i, \text{ for } i = 1, 2, ..., N-1, \tag{9}$$

$$U_0 = u(0),\ U_N = u(1), \tag{10}$$

where

$$L_*^N U_i = \begin{cases} L_T^N U_i, & \text{for } i = N/2, \\ L^N U_i, & \text{for } i \neq N/2, \end{cases}$$

and

$$Q_*^N f_i = \begin{cases} \dfrac{2h_3^2 f_{N/2-1}}{2\varepsilon_d + h_3\varepsilon_c a_{N/2-1}} + \dfrac{2h_4^2 f_{N/2+1}}{2\varepsilon_d + h_4\varepsilon_c a_{N/2+1}}, & \text{if } i = N/2, \\ Q^N f_i, & \text{if } i \neq N/2. \end{cases}$$

Finally the discrete problem (9)-(10) form a traditional system of equation which will be solved using a TDMA Solver to obtain the numerical solution. The parameter uniform higher order error estimate of the computed solution for sufficiently large N satisfy the following bound

$$\|U - u\| \leq \begin{cases} C(N^{-1}\ln N)^2, & \text{if } \sqrt{\alpha}\varepsilon_c \leq \sqrt{\gamma\varepsilon_d}, \\ CN^{-2}(\ln N)^3, & \text{if } \sqrt{\alpha}\varepsilon_c \geq \sqrt{\gamma\varepsilon_d}, \end{cases} \quad \forall\ 0 \leq i \leq N.$$

where $u(x_i)$ be the solution of the continuous problem (1)-(2) and $U(x_i)$ be the solution of the discrete problem (9)-(10). Further a study on stability and error analysis of the proposed scheme will be presented in nearest future.

 ISBN: 978-84-617-8694-7

3 Numerical Examples

This section experimentally demonstrates the applicability of the hybrid scheme (9)-(10) and compare it with the existed upwind scheme (6).

Example 1 *Consider the two-parameter problem (1)-(2) with the following discontinuous convection coefficient and source term:*

$$a(x) = \begin{cases} -(1+x(1-x)), & for \quad 0 \le x \le 0.5, \\ (1+x(1-x)), & for \quad 0.5 < x \le 1, \end{cases} \quad b(x) = 1,$$

$$f(x) = \begin{cases} -2(1+x^2), & for \quad 0 \le x \le 0.5, \\ 3(1+x^2), & for \quad 0.5 < x \le 1, \end{cases} \quad and\ u(0) = u(1) = 0.$$

As the exact solution of Example 1 is unknown, we use the double mesh principle [1, 3, 4, 12] to calculate the maximum pointwise error $E^N_{\varepsilon_d,\varepsilon_c}$ and corresponding order of convergence $\rho^N_{\varepsilon_d,\varepsilon_c}$ of the numerical solution provided by the scheme (9) which is as follows:

$$E^N_{\varepsilon_d,\varepsilon_c} = \max_{0\le i\le N} |U^N_i - U^{2N}_i| \quad \text{and} \quad \rho^N_{\varepsilon_d,\varepsilon_c} = \log_2 \left(E^N_{\varepsilon_d,\varepsilon_c} / E^{2N}_{\varepsilon_d,\varepsilon_c} \right).$$

Here U^N_i denotes the numerical solution obtained with N number of mesh intervals and U^{2N}_i denotes the solution on $2N$ number of mesh intervals obtained by bisecting the previous original mesh. Similarly, we find the uniform error E^N and order of convergence ρ^N of (6) for a fixed ε_c and various values of ε_d, taken from the set $S = \{\varepsilon_d | \varepsilon_d = 10^{-2}, 10^{-4}, \cdots, 10^{-14}\}$:

$$E^N = \max_{\varepsilon_d \in S} E^N_{\varepsilon_d,\varepsilon_c} \quad \text{and} \quad \rho^N = \log_2 \left(E^N / E^{2N} \right).$$

Here, the numerical experiment is performed by choosing the constant values α=2.5, β=1.0 and γ=0.2 for Example 1.

We present $E^N_{\varepsilon_d,\varepsilon_c}$ and $\rho^N_{\varepsilon_d,\varepsilon_c}$ in Tables 1 and 2 respectively for Example 1. Table 2 shows that the order of convergence is almost second order $O(N^{-2}\ln^2 N)$ when $\sqrt{\alpha}\varepsilon_c \le \sqrt{\gamma\varepsilon_d}$ and $O(N^{-2}\ln^3 N)$ when $\sqrt{\alpha}\varepsilon_c \ge \sqrt{\gamma\varepsilon_d}$ for the above example. Table 3 presents the maximum error E^N and order of convergence ρ^N using the standard upwind scheme (6). This table shows that the existing scheme gives first order parameter uniform convergence, while the Table 2 shows almost second order convergence using the hybrid difference scheme. Note that the errors are also lower in Table 1 compared to Table 3.

Loglog error plot in Figure 1 also demonstrates that the predicted order of convergence, i.e., $O(N^{-2}\ln^3 N)$, if $\sqrt{\alpha}\varepsilon_c \le \sqrt{\gamma\varepsilon_d}$ and $O(N^{-2}\ln^2 N)$, if $\sqrt{\alpha}\varepsilon_c \ge \sqrt{\gamma\varepsilon_d}$ are correct.

4 Conclusion

In this paper, an almost second order uniformly convergent numerical solution is obtained for a two-parameter singularly perturbed problem where the convection coefficient and source

term have a jump discontinuity at an interior point of the domain. The present hybrid difference scheme is a combination of upwind, midpoint and central difference schemes with a five point scheme at the point of discontinuity which preserves the monotonicity property on Shishkin mesh. The computational result shows that the proposed scheme is uniformly convergent and provides better accuracy than standard upwind difference. Therefore, looking towards the better numerical performance of the proposed scheme, it can be concluded that one can take the above computational analysis as a motivation for further theoretical analysis of the proposed scheme.

Accelerated POD least-squares approach for missing data reconstruction

Saifon Chaturantabut[1]

[1] *Department of Mathematics and Statistics, Faculty of Science and Technology, Thammasat University, Thailand*

emails: saifon@mathstat.sci.tu.ac.th

Abstract

This work introduces a technique that reduces the computational complexity, and therefore decreases the simulation time, for approximating missing data components through the least-squares (LS) approximation with the basis from proper orthogonal decomposition (POD). In the existing standard approach, POD basis is first computed to extract dominant trends of data from existing set of complete samples. Then, the approximation of each missing data is obtained optimally in the least-squares sense. However, in the case of high-dimensional data, the reconstruction process might require high-complexity computation. To accelerate this approximation process, this work employs certain *important* and *relevant* available data components, which are selected through a greedy iterative procedure, called discrete empirical interpolation method (DEIM). This work introduces two different variants of the acceleration, which are tested on the subsurface flow data. The numerical results demonstrate that the proposed technique can be as accurate as the standard POD-LS method with much less computational time.

Key words: Data reconstruction, Proper orthogonal decomposition, Least-squares method

1 Introduction

Missing data estimation has been an important problem in many engineering applications, such as in the reconstruction of unavailable experimental data or in image processing research. A popular approach for solving this problem is based on proper orthogonal decomposition(POD). The approach using POD for the purpose of data reconstruction is often called gappy POD (GPOD). GPOD method essentially uses POD basis in the least-squares

 ISBN: 978-84-617-8694-7

approximation, and it will be also called *POD-LS* method in this work. In the application of aerodynamic flow fields, GPOD was formally introduced in [7] and it was later used to calibrate and illustrate air flow past a wing [22]. GPOD has been recently used in many other engineering applications, such as in chemical engineering [5, 11], in mechanical engineering [6, 27], in image processing [19], and in optimization of water flooding reservoir [15].

Proper orthogonal decomposition (POD) was introduced in 1937 by Lumley in the context of inhomogeneous structure turbulent flows [21] and stochastic tools in turbulence [20]. POD is also known as, for example, Karhunen-Love decomposition (KLD), principal component analysis (PCA), or singular value decomposition(SVD). POD has been successfully used in many applications, e.g. [4, 14, 18, 24], since it can provide an approximation from the basis that extracts the dominant characteristic of the existing data. Discrete empirical interpolation method (DEIM) [10], a variant of [3], was originally introduced to estimate nonlinear term in dynamical systems by selecting the interpolation indices using a greedy algorithm. The index selection process in this algorithm is based on trying to capture most variation of the sample set heuristically. It has been used in many applications, such as morphological structure spiking neurons [17], 2-D shallow-water equations [12], Navier-Stokes equations [1], four-dimensional variational data assimilation [26], three-dimensional nonlinear aeroelasticity model [13], electrical, thermal, and microelectromechanical models [16].

To derive the accelerated POD-LS method for decreasing computational time in reconstructing missing data components, this work first reviews some background of POD and GPOD in Section 2. Then, DEIM approximation and the corresponding greedy process for selecting components are discussed in Section 3.1. The combination of DEIM with the POD-LS method or Gappy POD to accelerate the approximation procedure is presented in Section 3.2. The numerical results in Section 4 demonstrate the accuracy of the proposed method through the reconstruction of missing components in concentration flow data with much less computational time. Finally, the conclusion and future extension are discussed in Section 5.

2 Standard POD-LS method (Gappy POD)

This section reviews some relevant background for constructing missing data based on proper orthogonal decomposition (POD) and least-squares (LS) approximations. The combination of these approaches is also known as gappy POD (GPOD) method.

2.1 Proper Orthogonal Decomposition (POD)

Let $\{\mathbf{y}_j\}_{j=1}^{n_s} \subset \mathbb{R}^n$ be the set of snapshots or samples. Proper orthogonal decomposition (POD) can be used to extract important features of the sample sets. In particular, consider an approximation of $\mathbf{y}_j$ by using orthogonal projection onto the space spanned by the set of vectors $\{\mathbf{v}_i\}_{i=1}^{k} \subset \mathbb{R}^n$ in the form $\mathbf{y}_j \approx \sum_{i=1}^{k} \mathbf{v}_i(\mathbf{v}_i^T\mathbf{y}_j) = \mathbf{V}\mathbf{V}^T\mathbf{y}_j$. Then, if $\{\mathbf{v}_i\}_{i=1}^{k}$ is the

 ISBN: 978-84-617-8694-7

POD basis, it is an orthonormal basis that minimizes the approximation error in $2-$norm for a given fixed basis rank $k < n$, i.e. $\{\mathbf{v}_i\}_{i=1}^k$ solves the following minimization problem:

$$\min_{\{\phi_i\}_{i=1}^k} \sum_{j=1}^{n_s} \|\mathbf{y}_j - \sum_{i=1}^{k} \phi_i(\phi_i^T \mathbf{y}_j)\|_2^2, \qquad \phi_i^T \phi_j = \delta_{ij},$$

where $\delta_{ij} = 0$ if $i \neq j$ and $\delta_{ij} = 1$ if $i = j$. Singular value decomposition (SVD) turns out to be corresponding to this solution of POD basis. That is, POD basis of rank k consists of the first k *left* singular vectors from SVD of the snapshot matrix: $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_{n_s}] \in \mathbb{R}^{n \times n_s}$. Suppose the SVD of a rectangular matrix $\mathbf{Y} \in \mathbb{R}^{n \times n_s}$ is given by $\mathbf{Y} = \hat{\mathbf{V}} \Sigma \mathbf{Z}^T$, where r is the rank of $\mathbf{Y}$, $\hat{\mathbf{V}} = [\mathbf{v}_1, \ldots, \mathbf{v}_r] \in \mathbb{R}^{n \times r}$ and $\mathbf{Z} \in \mathbb{R}^{n_s \times r}$ are orthogonal matrices and $\Sigma = diag(\sigma_1, \ldots, \sigma_r) \in \mathbb{R}^{r \times r}$ with singular values in decreasing order: $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$.

It can be shown [23] that the minimum error of the approximation by using POD basis is given by the sum of the neglected singular values $\sigma_{k+1}, \ldots, \sigma_r$. I.e.,

$$\sum_{j=1}^{n_s} \|\mathbf{y}_j - \mathbf{V}\mathbf{V}^T \mathbf{y}_j\|_2^2 = \sum_{\ell=k+1}^{r} \sigma_\ell^2. \tag{2.1}$$

Note that, besides using SVD, the POD basis can be computed by using the method of snapshots based on eigenvalue decomposition of correlation matrix of the snapshots [25]. The procedure for computing POD basis is shown in Algorithm 1.

Algorithm 1 Algorithm for constructing POD basis

INPUT: Snapshots $\{\mathbf{y}_j\}_{j=1}^{n_s} \subset \mathbb{R}^n$

OUTPUT: POD basis $\mathbf{V}_k$.

1: Create snapshot matrix : $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_{n_s}] \in \mathbb{R}^{n \times n_s}$and let $r = rank(\mathbf{Y})$
2: Compute SVD: $\mathbf{Y} = \hat{\mathbf{V}} \Sigma \mathbf{Z}^T$ and choose dimension $k \leq r$
3: POD basis of rank k : $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_k] = \hat{\mathbf{V}}(:, 1:k)$

2.2 Gappy POD

Gappy POD (GPOD) can be used to approximate or reconstruct missing data from the available partial data, that obtained, e.g. from experimental measurements or numerical simulations.

Define $\mathcal{Y} := \{\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_{n_s}\} \subset \mathbb{R}^n$. Let $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_{n_s}] \in \mathbb{R}^{n \times n_s}$. Suppose $\widehat{\mathbf{y}}$ is an incomplete sample which consists of n_c known components and $n_g = n - n_c$ unknown components. Let $\mathcal{C} := \{\wp_1, \wp_2, \ldots, c_{n_c}\} \subset \{1, 2, \ldots, n\}$ be the indices of the *known* components in $\widehat{\mathbf{y}}$ and define $\mathbf{C} = [\mathbf{e}_{c_1}, \ldots, \mathbf{e}_{c_{n_c}}] \in \mathbb{R}^{n \times n_c}$, where $\mathbf{e}_{c_i} = [0, \ldots, 0, 1, 0, \ldots, 0]^T \in \mathbb{R}^n$ is the c_i-th column of the identity matrix $\mathbf{I}_n \in \mathbb{R}^{n \times n}$, for $i = 1, \ldots, m$. Note that, pre-multiplying

 ISBN: 978-84-617-8694-7

$\mathbf{C}^T$ is equivalent to extracting the n_c rows corresponding to the indices $c_1, \ldots, c_{n_c},$. Similarly, let $\mathcal{G} = \{g_1, g_2, \ldots, g_{n_g}\} \subset \{1, 2, \ldots, n\}$ be the indices of the *unknown* components in $\widehat{\mathbf{y}}$ and define $\mathbf{G} = [\mathbf{e}_{g_1}, \ldots, \mathbf{e}_{g_{n_g}}] \in \mathbb{R}^{n \times n_g}$. I.e. the known components and the unknown components are given in the following two vectors $\widehat{\mathbf{y}}_c \in \mathbb{R}^{n_c}$ and $\widehat{\mathbf{y}}_g \in \mathbb{R}^{n_g}$, respectively. The missing components contained in $\widehat{\mathbf{y}}_g$ will be approximated by first performing a projection onto the column span of POD basis matrix $\mathbf{V}$ with rank k from Algorithm 1, i.e.

$$\widehat{\mathbf{y}} \;\approx\; \mathbf{V}\mathbf{a}, \qquad \text{or} \qquad \widehat{\mathbf{y}}_c \approx \mathbf{V}_c\mathbf{a} \;\text{ and }\; \widehat{\mathbf{y}}_g \approx \mathbf{V}_g\mathbf{a},$$

for some coefficient vector $\mathbf{a} \in \mathbb{R}^k$, and where $\mathbf{V}_c := \mathbf{C}^T\mathbf{V} \in \mathbb{R}^{n_c \times k}$, $\mathbf{V}_g := \mathbf{G}^T\mathbf{V} \in \mathbb{R}^{n_g \times k}$.

The known components contained in $\widehat{\mathbf{y}}_c = \mathbf{C}^T\widehat{\mathbf{y}}$ are then used to determine the coefficient vector $\mathbf{a}$ through the approximation $\widehat{\mathbf{y}}_c \approx \mathbf{V}_c\mathbf{a}$ from the following least-squares problem:

$$\min_{\mathbf{a}\in\mathbb{R}^k} \|\widehat{\mathbf{y}}_c - \mathbf{V}_c\mathbf{a}\|_2^2. \tag{2.2}$$

The solution obtained from the corresponding normal equation of the above problem is given by $\mathbf{a} = (\mathbf{V}_c^T\mathbf{V}_c)^{-1}\mathbf{V}_c^T\widehat{\mathbf{y}}_c$. That is,

$$\widehat{\mathbf{y}}_g \;\approx\; \mathbf{V}_g\mathbf{a} \;=\; \mathbf{V}_g(\mathbf{V}_c^T\mathbf{V}_c)^{-1}\mathbf{V}_c^T\widehat{\mathbf{y}}_c. \tag{2.3}$$

The steps described above are summarized in Algorithm 2.

Algorithm 2 Gappy POD method for approximating missing data

INPUT:

- Complete snapshot set $\{\mathbf{y}_j\}_{j=1}^{n_s} \subset \mathbb{R}^n$ and, dimension $k \leq rank(\{\mathbf{y}_j\}_{j=1}^{n_s})$
- Incomplete data $\widehat{\mathbf{y}} \in \mathbb{R}^n$ with known entries $\widehat{y}_j$, $j \in \mathcal{C}$ and unknown entries $\widehat{y}_j$, $j \in \mathcal{G}$

OUTPUT:

- Approximation: $\widehat{\mathbf{y}}_g = [\widehat{y}_j]$, $j \in \mathcal{G} = \{g_1, g_2, \ldots, g_{n_g}\}$

1: Create snapshot matrix : $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_{n_s}] \in \mathbb{R}^{n \times n_s}$and let $r = rank(\mathbf{Y})$.
2: Compute POD basis $\mathbf{V}$ of rank $k \leq r$ for $\mathbf{Y}$ from Algorithm 1.
3: Find coefficient vector $\mathbf{a}$ from $\widehat{\mathbf{y}}_c$ using least-squares problem in (2.2): $\min_{\mathbf{a}\in\mathbb{R}^k} \|\widehat{\mathbf{y}}_c - \mathbf{V}_c\mathbf{a}\|_2^2$.
4: Compute the approximation $\widehat{\mathbf{y}}_g \;\approx\; \mathbf{V}_g\mathbf{a}$.

3 Accelerated POD-LS method (Gappy POD)

First, this section describes a greedy-based technique called discrete empirical interpolation method (DEIM), which is used in this work to reduce computational complexity of the standard GPOD (LS-POD) approach. Two small variants of missing data approximations using DEIM is then later derived.

 ISBN: 978-84-617-8694-7

3.1 Discrete Empirical Interpolation Method (DEIM)

DEIM was first introduced for the purpose of approximating the nonlinear term in the differential equations [9]. In this work, the interpolation indices from this method will be used to reduce the computational complexity of GPOD in Step 3 of Algorithm 2. This section describes DEIM in a general setting and provides the corresponding greedy algorithm for selecting *important* components that can be used in the approximation.

Consider a vector $\mathbf{f} \in \mathbb{R}^n$ by projecting on a low-dimensional subspace, span$\{\mathbf{U}\}$ where $\mathbf{U} \in \mathbb{R}^{n\times m}$ is the matrix of rank $m \leq n$ with orthogonal columns, i.e. $\mathbf{f} \approx \mathbf{U}\mathbf{d}$ for $\mathbf{d} \in \mathbb{R}^m$. The m components of the nonlinear vector $\mathbf{f}$ are selected by a greedy algorithm [2,9] to specify $\mathbf{d}$ using the 2-norm least-squares approximation. In particular, suppose $\wp_1, \wp_2, \ldots, \wp_m$ are the indices of the selected components in $\mathbf{f}$ and define $\mathbf{P} = [\mathbf{e}_{\wp_1}, \ldots, \mathbf{e}_{\wp_m}] \in \mathbb{R}^{n\times m}$, where $\mathbf{e}_{\wp_i} = [0, \ldots, 0, 1, 0, \ldots, 0]^T \in \mathbb{R}^n$ is the $\wp_i$-th column of the identity matrix $\mathbf{I}_n \in \mathbb{R}^{n\times n}$, for $i = 1, \ldots, m$. Note that, as in the previous section, pre-multiplying $\mathbf{P}^T$ is equivalent to extracting the m rows corresponding to the interpolation indices $\wp_1, \ldots, \wp_m$,. The coefficient vector $\mathbf{d}$ in the DEIM approximation solves the following minimization problem

$$\min_{\mathbf{d}\in\mathbb{R}^m} \|\mathbf{P}^T\mathbf{f} - \mathbf{P}^T\mathbf{U}\mathbf{d}\|_2^2$$

which gives $\mathbf{d} = (\mathbf{P}^T\mathbf{U})^+\mathbf{P}^T\mathbf{f}$, where $(\mathbf{P}^T\mathbf{U})^+ = [(\mathbf{P}^T\mathbf{U})^T(\mathbf{P}\mathbf{U})]^{-1}(\mathbf{P}^T\mathbf{U})^T$ is the pseudo-inverse of $\mathbf{P}^T\mathbf{U}$. Since $\mathbf{P}^T\mathbf{U}$ is a square matrix and it is shown to be invertible [9], $(\mathbf{P}^T\mathbf{U})^+ = (\mathbf{P}^T\mathbf{U})^{-1}$ and the DEIM approximation for $\mathbf{f}$ becomes

$$\mathbf{f} \approx \mathbf{U}(\mathbf{P}\mathbf{U})^{-1}\mathbf{P}^T\mathbf{f}.$$

The sets of indices $\{\wp_1, \wp_2, \ldots, \wp_m\}$ is obtained by DEIM index selection algorithm [9], shown in Algorithm 3, which is a greedy procedure that aim to capture the variation of the spatial behavior of the input basis using the infinity norm.

From Algorithm 3, DEIM selects the interpolation indices so that the approximation has smallest error $\mathbf{r} = \mathbf{u}_j - \mathbf{U}\mathbf{c}$ in each iteration j. The procedure of DEIM Algorithm 3 can be described as follows. First, the input a basis of rank m, which can be obtained by using POD of nonlinear term. Then, it selects the first index of a component in the first basis vector $\mathbf{u}_1$ with the largest absolute value. Next, each of the other indices is selected from the component with largest absolute residual error $\mathbf{r} = \mathbf{u}_\ell - \mathbf{U}\mathbf{c}$ in each step.

The corresponding error of DEIM approximation was proposed in [9] and an extension of this error bound of to the state-space error estimate can be found in [8].

3.2 Accelerated POD-LS method by using DEIM

This work particularly focuses on the situation when the incomplete data $\widehat{\mathbf{y}}$ is in a high-dimensional space, i.e. the value of n is large, which may result in a large number of known

 ISBN: 978-84-617-8694-7

Algorithm 3 Algorithm to create for Interpolation Indices DEIM

INPUT: $\{\mathbf{u}_\ell\}_{\ell=1}^m \subset \mathbb{R}^n$ linearly independent

components n_c, even though there are a lot of unknown components n_g. In this case, the main computational work in approximating missing components may occur while solving for the coefficient vector $\mathbf{a}$ in (2.2) or in Step 3 of Algorithm 2. One possible way to reduce this computational work is to use only small number known components to specify $\mathbf{a} \in \mathbb{R}^k$. These components have to be carefully selected so that they can represent all other n_c components and maintain the same accuracy in the approximation. For this purpose, the procedure for selecting DEIM indices of *important* components from Algorithm 3 will be used as described next.

Recall from Step 3 in Algorithm 2 that, it has to solve for $\mathbf{a}$ from

$$\min_{\mathbf{a}\in\mathbb{R}^k} \|\widehat{\mathbf{y}}_c - \mathbf{V}_c\mathbf{a}\|_2^2.$$

Suppose $\mathbf{V}_c \in \mathbb{R}^{n_c\times k}$ has linearly independent columns. Then, for a given DEIM dimension $m \leq \min\{n_c, k\}$, the columns of $\mathbf{V}_c$ can be used as an input of Algorithm 3 to select m DEIM indices that can cover the variations of n_c components.

In many applications when n is much larger than the number of available complete data n_s , i.e. $n > n_s \geq k$, we have $\min\{n, k\} = k$. If we want to use DEIM dimension $m > k$, using $\mathbf{V}_c = \mathbf{C}^T\mathbf{V} \in \mathbb{R}^{n_c\times k}$ will not be enough and this could limit the accuracy of the approximation. Therefore, in this work, all columns of the left singular matrix $\bar{\mathbf{V}} \in \mathbb{R}^{n\times r}$ from SVD of complete snapshot matrix $\mathbf{Y}$ will be used, where $r = rank(\mathbf{Y})$. In particular, consider the matrix

$$\bar{\mathbf{V}}_c := \mathbf{C}^T\bar{\mathbf{V}} \in \mathbb{R}^{n_c\times r}, \tag{3.1}$$

which comes from $\bar{\mathbf{V}}$ with selected rows corresponding to the n_c known components in $\mathcal{C}$.

Suppose $\bar{\mathbf{V}}_c \in \mathbb{R}^{n_c\times r}$ has linearly independent columns. Then, the columns of $\bar{\mathbf{V}}_c$ can be used in Algorithm 3 to select m DEIM indices, where the largest dimension m is $\min\{n_c, r\}$.

 ISBN: 978-84-617-8694-7

In this case, suppose $\wp_1, \wp_2, \ldots, \wp_m$ are the output indices of DEIM Algorithm 3 and let $\mathbf{P} = [\mathbf{e}_{\wp_1}, \ldots, \mathbf{e}_{\wp_m}] \in \mathbb{R}^{n_c \times m}$ as defined earlier in this section. The vector $\mathbf{a}$ in (2.2) can be computed from a smaller least-squares problem:

$$\min_{\mathbf{a}\in\mathbb{R}^k} \|\mathbf{P}^T\widehat{\mathbf{y}}_c - \mathbf{P}^T\bar{\mathbf{V}}_c\mathbf{a}\|_2^2. \tag{3.2}$$

Note that, we have assumed that $\bar{\mathbf{V}}_c \in \mathbb{R}^{n_c \times r}$ has linearly independent columns, which may not hold in general cases. To avoid this assumption, we can apply SVD on the matrix $\bar{\mathbf{V}}_c$ and use the set of first m corresponding left singular vectors as an input of DEIM algorithm 3. The accelerated POD-LS steps are summarized in Algorithm 4 for both cases of (i) using $\bar{\mathbf{V}}_c$ directly as an input (ii) using the set of left singular vectors of $\bar{\mathbf{V}}_c$ as an input to DEIM algorithm 3.

Algorithm 4 Accelerated POD-LS method for approximating missing data

INPUT:

- Complete snapshot set $\{\mathbf{y}_j\}_{j=1}^{n_s} \subset \mathbb{R}^n$ and, dimension $k \leq rank(\{\mathbf{y}_j\}_{j=1}^{n_s})$
- Incomplete data $\widehat{\mathbf{y}} \in \mathbb{R}^n$ with known entries $\widehat{y}_j$, $j \in \mathcal{C}$ and unknown entries $\widehat{y}_j$, $j \in \mathcal{G}$

OUTPUT:

- Approximation: $\widehat{\mathbf{y}}_g = [\widehat{y}_j]$, $j \in \mathcal{G} = \{g_1, g_2, \ldots, g_{n_g}\}$

1: Create snapshot matrix : $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_{n_s}] \in \mathbb{R}^{n\times n_s}$and let $r = rank(\mathbf{Y})$.

2: Compute POD basis $\mathbf{V}$ of rank $k \leq r$ for $\mathbf{Y}$ from Algorithm 1.

3: Find coefficient vector $\mathbf{a}$

3.1 Find indices $\vec{\wp} = [\wp_1, \ldots, \wp_m]^T \in \mathbb{R}^m$ and $\mathbf{P}$ from Algorithm 3 by using input from either
(i) $\bar{\mathbf{V}}_c$ defined in (3.1), or
(ii) Left singular vectors of $\bar{\mathbf{V}}_c$ from Algorithm 1.

3.2 Solve $\mathbf{a}$ from (3.2): $\min_{\mathbf{a}\in\mathbb{R}^k} \|\mathbf{P}^T\widehat{\mathbf{y}}_c - \mathbf{P}^T\bar{\mathbf{V}}_c\mathbf{a}\|_2^2$..

4: Compute the approximation $\widehat{\mathbf{y}}_g \approx \mathbf{V}_g\mathbf{a}$.

Remarks: In practice, the additional computation for DEIM indices can be done in advance and reused for many incomplete snapshots. Once the DEIM indices are found from Algorithm 3, the term $\mathbf{P}^T\widehat{\mathbf{y}}_c$ and $\mathbf{P}^T\bar{\mathbf{V}}_c$ can be computed without actually performing matrix multiplication, since this can be done through selected row indices.

The next section applies the techniques introduced in Algorithm 4 on the miscible flow data and compares with the standard Gappy POD approach in Algorithm 2.

 ISBN: 978-84-617-8694-7

4 Numerical Results

This section considers two numerical tests that compare the proposed algorithm with the standard Gappy POD method when applied to miscible flow data with spatial dimension $n = 15000$. The first test considers the effects of POD dimension k and DEIM dimension m on accuracy and computation time of the approximations. The other numerical test considers different amount of missing components in the data. An example of the incomplete snapshot for the concentration flow is shown in the first plot of Figure 1.

4.1 Numerical Test 1

This numerical test investigates different dimensions of POD and DEIM. Using the same notations defined in the previous sections, this numerical experiment uses $n_s = 200$ complete snapshots and tests the algorithms on 50 incomplete snapshots. Each of these incomplete snapshots consists of 50% unknown components (missing or gappy data). I.e. there are 7500 known and unknown components, since the total dimension is $n = 15000$. This section compares the accelerated POD-LS approaches in Algorithm 4 both cases (i) and (ii) with the standard least-squares (LS) or Gappy POD.

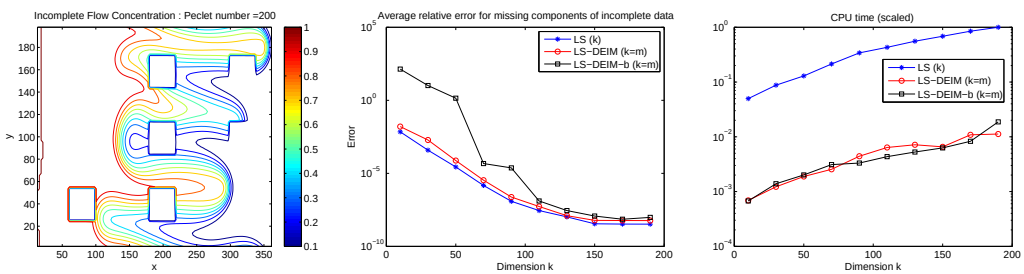

Figure 1: Comparison of average relative errors and CPU time for LS (Gappy POD)Algorithm 2, LS-DEIM: Algorithm 4(i), and LS-DEIM-b Algorithm 4(ii), when using different POD dimension (k) and DEIM dimension (m) with k =m.

The middle plot in Figure 1 shows that the approximations from the proposed accelerated POD-LS method Algorithm 4 (i) are very accurate when compared to the Gappy POD approach, for different POD dimension k and DEIM dimension m with $k = m$. However, the results from Algorithm 4(ii) are less accurate for $k, m < 100$. The CPU times are equivalent for Algorithm 4 in both cases (i) and (ii). However, these two cases use much less computational time than the standard LS, i.e. roughly 100 times less CPU time.

 ISBN: 978-84-617-8694-7

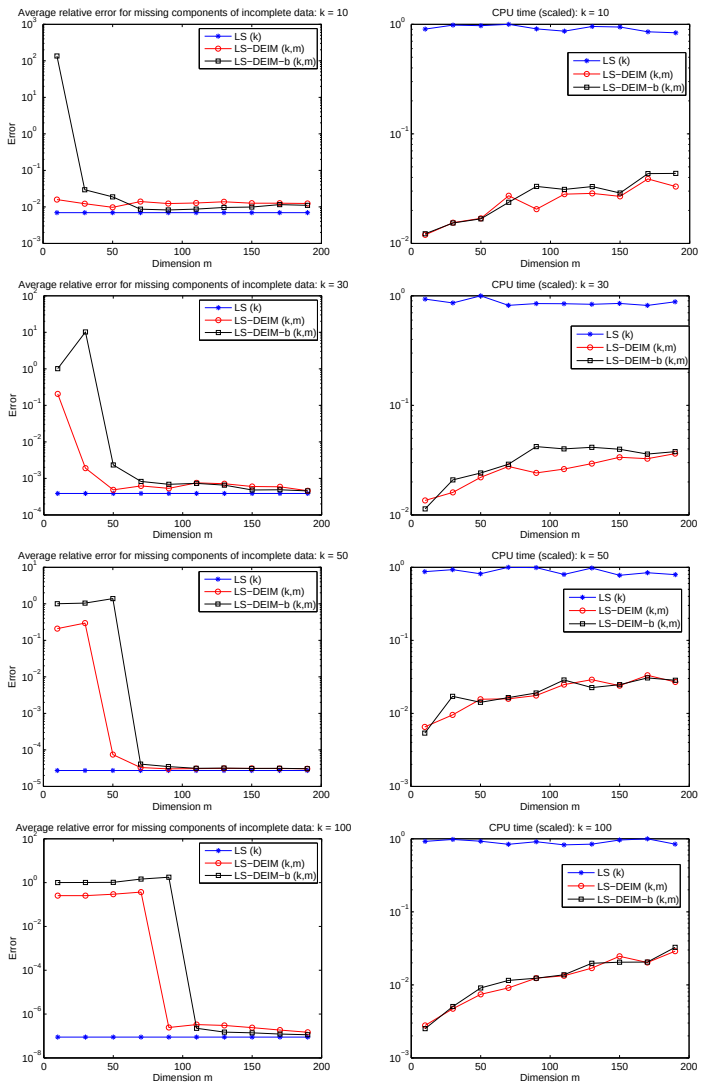

Figure 2: Comparison of average relative errors and CPU time (scaled) for LS (Gappy POD)Algorithm 2, LS-DEIM: Algorithm 4(i), and LS-DEIM-b Algorithm 4(ii), when different DEIM dimensions are used for a fixed dimension of POD (k = 10, 30, 50, 100).

Figure 2 considers different DEIM dimensions for each of the 4 fixed dimensions of POD $k = 10, 30, 50, 100$. The reduction in the CPU time is similar to the results given in Figure 1. From the 4 error plots in Figure 2, as expected, the accuracy is shown to be increased as the POD dimension k gets larger. For a fixed dimension k, increasing the DEIM dimension m for Algorithm 4 in both cases (i) and (ii) may not always improve the accuracy, which is

shown through the flat portion of the error plots. The accuracy depends on both dimensions k and m that are used together. In addition, there might not be an obvious convergence trend, e.g. for $k = 50$ and $k = 100$ there are jumps of the errors at around $m = 60$ and $m = 100$, respectively. This suggests that the appropriate dimension of m is roughly equal to k.

4.2 Numerical Test 2

This numerical test considers the effect of having different amount of missing data in the incomplete snapshots. This numerical experiment uses $n_s = 200$ complete snapshots and tests the algorithms on 50 incomplete snapshots. Each of these incomplete snapshots may contain 10% to 90% unknown components (missing or gappy data) of the total dimension is $n = 15000$. This section compares the accelerated POD-LS approaches in Algorithm 4 (i) with the standard least-squares (LS) or Gappy POD. The results are shown in Figure 3 when $m = k$ for $k = 20, 30$. Notice that, when the amount of missing data is less than 70%, there is no significant different in the accuracy. When 90% of data components are missing, the approximation becomes inaccurate.

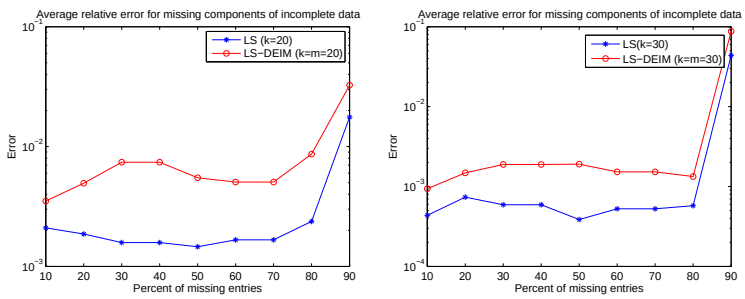

Figure 3: Comparison of average relative errors for LS (Gappy POD)Algorithm 2 and LS-DEIM: Algorithm 4(i) when different percentages of unknown (missing) components when $m = k$ for $k = 20, 30$.

5 Conclusion

This work has presented an approach, called accelerated POD-LS method, for decreasing computational time for reconstructing missing components of incomplete samples. This approach is based on the existing Gappy-POD method, which uses POD basis with least-squares approximation. The proposed method can reduce the computational complexity by using a greedy algorithm from DEIM index selection process to choose only crucial available components used in the approximation. The numerical results demonstrate the accuracy and the efficiency of the proposed method through the reconstruction of missing components

in the concentration flow data. The CPU time is shown to be around $\mathcal{O}(10^{-1})$ to $\mathcal{O}(10^{-2})$ times reduction while the accuracy is of the same order as the standard POD-LS method. Hence, the proposed approach has also shown the potential to reduce approximation time for high-dimensional data. Theoretical analysis of this approach can be considered in the future to provide a rigorous error bound for the approximation of missing data.

Abstract

A bi-parametric family of derivative-free optimal iterative methods of order four, for solving nonlinear equations, is presented. From its error equation, different iterative schemes with memory can be designed increasing the order of convergence up to six. This family applied on quadratic polynomials gives us a rational operator whose dynamics is studied. The stability of its fixed points, in terms of the values of the parameters, its critical points and their associated parameter planes, etc. give us important information about which members of the family have good properties of stability and whether in any of them appear chaos in the iterative process.

Key words: Iterative method, stability, parameter plane, dynamical plane, chaos

1 Introduction

Solving nonlinear equations $f(x) = 0$, $f : I \subseteq \mathbb{R} \to \mathbb{R}$, or nonlinear systems $F(x) = 0$, $F : D \subseteq \mathbb{R}^n \to \mathbb{R}^n$, are important problems with interesting applications in many fields of Science and Engineering. Analytical methods for solving such problems are hardly available and so, it is only possible to obtain approximate solutions by applying numerical methods based on iterative algorithms.

Due to the limitations of one-point methods (Chebyshev, Halley, etc.), the multi-point schemes appear in the literature and have and spectacular development in the last years. Multi-point iterative methods are defined as methods that require evaluation of f and its derivatives at a number of values of the independent variable. These methods are divided into two classes: without and with memory. The methods of the first class have as iterative expression

$$x_{k+1} = \Phi(x_k), \quad k = 0, 1, 2, \ldots$$

 ISBN: 978-84-617-8694-7

whilst for the second one

$$x_{k+1} = \Phi(x_k, x_{k-1}, \ldots), \quad k = 0, 1, 2, \ldots$$

being $\Phi(x)$ the fixed point function.

The main motivation in the construction of new methods is to achieve the highest computational efficiency; that is, it is desirable to attain as high as possible convergence order with a fixed number of function evaluations per iteration. In this context, Kung and Traub presented in [3] a conjecture that says: the order of an iterative method without memory, which needs d functional evaluations per iteration, is at most 2^{d-1}. When the order reaches this bound, the method is called optimal.

The basic idea for the construction of multi-point methods with memory was introduced by Traub [6], who presented a version with memory from the Steffensen's method. Recently, based on this method, some schemes with memory have been developed by several authors. We can see an interesting overview in [5].

In this work, our starting point is the King's family of fourth-order schemes

$$\begin{array}{rcl} y_k & = & x_k - \frac{f(x_k)}{f'(x_k)}, \\ x_{k+1} & = & y_k - \frac{f(x_k)+\alpha f(y_k)}{f(x_k)+(\alpha-2)f(y_k)} \frac{f(y_k)}{f'(x_k)}, \end{array}$$

where α is a disposable parameter. From this class, we design a derivative-free new family of fourth-order methods, whose error equation allows us to introduce memory in the iterative expression that increase the order of convergence up to two units. The parameters of the family give us the possibility to analyze the stability of the different members in terms of the values of these parameters. By using tools of complex dynamics we analyze the stability of the fixed points of the rational operator that appears when our family is applied on a second degree polynomial. The parameter plane associated to each critical point gives us important information about the stability of the elements of the family and which of them have unstable behavior.

2 Parametric families of iterative schemes

Following the structure of the King's family and replacing the derivative by a first order divided difference we present the following schemes:

$$\begin{array}{rcl} y_k & = & x_k - \frac{f(x_k)}{f[x_k, w_k])}, \\ x_{k+1} & = & y_k - \frac{f(x_k)+\alpha f(y_k)}{\mu f(x_k)+\beta f(y_k)} \frac{f(y_k)}{f[y_k, w_k]}, \end{array} \tag{1}$$

where $w_k = x_k + \gamma f(x_k)$, with α, β, γ and μ real parameters, $\gamma \neq 0$.

The order of convergence of the methods (1) is established in the following result. Its proof only requires the development in Taylor series of the elements of the iterative expression and some algebraic manipulations.

 ISBN: 978-84-617-8694-7

Theorem 1 *Let us suppose that $f : I \subseteq \mathbb{R} \to \mathbb{R}$ is a sufficiently differentiable function in an open interval I and $x^* \in I$ is a simple root of $f(x) = 0$. If the initial approximation x_0 is close enough of x^*, then the iterative schemes (1) have optimal fourth-order convergence when $\mu = 1$, $\beta = \alpha - 1$ and for all nonzero γ, being in this case the error equation*

$$e_{k+1} = (1 + \gamma f'(x^*))^2 c_2 (2 + \alpha + \alpha\gamma f'(x^*) c_2^2 - c_3) e_k^4 + O(e_k^5), \tag{2}$$

where $e_k = x_k - x^*$, $k = 0, 1, \ldots$ and $c_j = \frac{1}{j!}\frac{f^{(k)}(x^*)}{f'(x^*)}$, $k \geq 2$.

Let us observe that the first factor in the second step of (1) can be considered as a particular case of a weight function $H(t)$, where $t = f(y)/f(x)$. So, we consider the family

$$\begin{array}{rcl} y_k & = & x_k - \frac{f(x_k)}{f[x_k, w_k])}, \\ x_{k+1} & = & y_k - H(t_k)\frac{f(y_k)}{f[y_k, w_k]}, \end{array} \tag{3}$$

where $H(t)$ is a weight function of variable $t = f(y)/f(x)$.

Theorem 1 can be generalized in the following way:

Theorem 2 *Let us suppose that $f : I \subseteq \mathbb{R} \to \mathbb{R}$ is a sufficiently differentiable function in an open interval I and $x^* \in I$ is a simple root of $f(x) = 0$. If the initial approximation x_0 is close enough of x^* and function $H(t)$ satisfies the conditions $H(0) = H'(0) = 1$ and $H''(0) < \infty$, then the iterative schemes (3) have optimal fourth-order convergence, for all nonzero γ, being in this case the error equation*

$$e_{k+1} = (-1/2)(1 + \gamma f'(x^*))^2 c_2 \left((-6 + \gamma f'(x^*)(-2 + H''(0)) + H''(0))c_2^2 + 2c_3\right) e_k^4 + O(e_k^5), \tag{4}$$

where $e_k = x_k - x^*$, $k = 0, 1, \ldots$ and $c_j = \frac{1}{j!}\frac{f^{(k)}(x^*)}{f'(x^*)}$, $k \geq 2$.

Let us observe that family (3) supports the Kung-Traub conjecture, having optimal efficiency index $I = 4^{1/3} \approx 1.587$. On the other hand, by observing the expression of the error equation (4) we can choose different values of the free disposable parameters in order to obtain iterative methods with memory, increasing the order of convergence.

Although we can work with both expressions (1) and (3), we are going to introduce memory in the first of them.

3 Iterative methods with memory

We are going to design derivative-free schemes with memory based on the proposed methods of the family (1).

From equation (2) we can assure that the order of convergence of family (1) increase up to six if $\gamma = \frac{-1}{f'(x^*)}$, but the value of $f'(x^*)$ is not available in practice and such acceleration

 ISBN: 978-84-617-8694-7

is not possible. However, we can use an approximation $\bar{f}'(x^*) \approx f'(x^*)$, calculated by using known information. Therefore, by setting $\gamma = -1/\bar{f}'(x^*)$ we can increase the convergence order without using new functional evaluations. The main idea in constructing methods with memory consists of the calculation of the parameter $\gamma = \gamma_k$ as the iteration proceeds by $\gamma_k = -1/\bar{f}'(x^*)$, $k = 1, 2, \ldots$. We are going to consider different approximations of $f'(x^*)$.

(1) Let $N_1(t) = N_1(t, x_k, x_{k-1})$ be the Newton's interpolation polynomial of first degree through two available approximations x_k, x_{k-1}, that is $N_1(t) = f(x_k) + f[x_k, x_{k-1}](t - x_k)$, so

$$\gamma_k = \frac{-1}{N_1'(x_k)} = \frac{-1}{f[x_k, x_{k-1}]} = -\frac{x_k - x_{k-1}}{f(x_k) - f(x_{k-1})},$$

and the algorithm denoted by MM1(α) can be presented in the following way:

- x_0, γ_0 are given,
- $w_k = x_k + \gamma_k f(x_k)$, $k = 0, 1, 2, \ldots$
- $y_k = x_k - \frac{f(x_k)}{f[x_k, w_k]}$,
- $x_{k+1} = y_k - \frac{f(x_k)+\alpha f(y_k)}{f(x_k)+(\alpha-1)f(y_k)} \frac{f(x_k)}{f[y_k, w_k]}$,

where $\gamma_k = \frac{-1}{f[x_k, x_{k-1}]}$ and α is a free parameter.

By using Taylor expansions we obtain the following error expression

$$e_{k+1} = (2c_2^5 - c_2^3 c_3) e_{k-1}^2 e_k^4 + O_7(e_k e_{k-1}),$$

where $O_7(e_k e_{k-1})$ indicates that the sum of the exponents of e_{k-1} and e_k in the rejected terms is at least 7. By applying Theorem 9.2.9 of [4], we establish the following result

Theorem 3 *Let x^* be a simple zero of a sufficiently differentiable function $f : I \subseteq \mathbb{R} \to \mathbb{R}$ in an open interval I. If x_0 is close enough to x^* and γ_0 is given, then the R-order of family MM1(α) is at least $2 + \sqrt{6} \approx 4.45$ that corresponds to the positive root of polynomial $p^2 - 4p - 2$.*

(2) Let $N_2(t) = N_2(t, x_k, x_{k-1}, y_{k-1})$ (can be also used $N_2(t) = N_2(t, x_k, x_{k-1}, u_{k-1})$) be the Newton's interpolation polynomial of second degree, that is $N_2(t) = f(x_k) + f[x_k, x_{k-1}](t - x_k) + f[x_k, x_{k-1}, y_{k-1}](t - x_k)(t - x_{k-1})$, therefore

$$\gamma_k = \frac{-1}{N_2'(x_k)} = \frac{-1}{f[x_k, x_{k-1}] + f[x_k, x_{k-1}, y_{k-1}](x_k - x_{k-1})},$$

and a similar algorithm to the previous one, denoted by MM2(α), can be presented.

 ISBN: 978-84-617-8694-7

(3) Let $N_3(t) = N_3(t, x_k, x_{k-1}, y_{k-1}, u_{k-1})$ be the Newton's interpolation polynomial of third degree, $N_3(t) = f(x_k) + f[x_k, x_{k-1}](t - x_k) + f[x_k, x_{k-1}, y_{k-1}](t - x_k)(t - x_{k-1}) + f[x_k, x_{k-1}, y_{k-1}, u_{k-1}](t - x_k)(t - x_{k-1})(t - y_{k-1})$, then

$$\begin{aligned} N_3'(x_k) = & \quad f[x_k, x_{k-1}] + f[x_k, x_{k-1}, y_{k-1}](x_k - x_{k-1}) \\ + & \quad f[x_k, x_{k-1}, y_{k-1}, u_{k-1}](x_k - x_{k-1})(x_k - y_{k-1}) \end{aligned}$$

and

$$\gamma_k = \frac{-1}{N_3'(x_k)}.$$

The algorithm denoted by MM3(α) can be presented in the following way:

- x_0, γ_0 are given,
- $w_k = x_k + \gamma_k f(x_k)$, $k = 0, 1, 2, \ldots$
- $y_k = x_k - \frac{f(x_k)}{f[x_k, w_k]}$,
- $x_{k+1} = y_k - \frac{f(x_k)+\alpha f(y_k)}{f(x_k)+(\alpha-1)f(y_k)} \frac{f(x_k)}{f[y_k, w_k]}$,

where $\gamma_k = \frac{-1}{N_3'(x_k)}$ and α is a free parameter.

Theorem 4 *Let x^* be a simple zero of a sufficiently differentiable function $f : I \subseteq \mathbb{R} \to \mathbb{R}$ in an open interval I. If x_0 is close enough to x^* and γ_0 is given, then the R-order of family MM3 is at least* 6.

Many other approximations of $f'(x^*)$ are possible, but they either are of sixth order (with more computational cost) or lower than six.

Let us observe that family (1) has two free parameters γ and α. In the next section, we analyze the stability of the elements of the family taking into account the values of these parameters.

4 Dynamical analysis

In order to study the dynamical behavior of the proposed schemes, the recall of some fundamentals is mandatory. Further explanations can be found in [1, 2].

Let $M : \mathbb{R} \to \mathbb{R}$ be a rational function. The orbit of a point $x_0 \in \mathbb{R}$ is defined as the set $\{x_0, M(x_0), M^2(x_0), \ldots, M^n(x_0), \ldots\}$. A point x_0 is a fixed point, x_0^F, of M if $M(x_0^F) = x_0^F$. The multiplier $|M'(x_0^F)|$ classifies the fixed points in attracting, repelling, or neutral if its value is lower than, greater than, or equal to 1, respectively. x_0^F is called superattracting when $M'(x_0^F) = 0$.

 ISBN: 978-84-617-8694-7

The basin of attraction of an attracting fixed point x^*, $\mathcal{A}(x^*)$, is defined as the set of pre-images of any order such that

$$\mathcal{A}(x^*) = \{x_0 \in \mathbb{R} : M^n(x_0) \to x^*, n \to \infty\}. \tag{5}$$

The Fatou set, $\mathcal{F}(M)$, includes the points whose orbits tend to an attracting point x^*. The Julia set, $\mathcal{J}(M)$, is its complementary. It covers the repelling points and sets the borders between the basins of attraction.

The fixed point operator of the biparametric family (1) is

$$M_f(x) = y - \frac{f(x) + \alpha f(y)}{f(x) + (\alpha - 1)f(y)} \frac{f(y)}{f[y, w]}, \tag{6}$$

where $w = x + \gamma f(x)$ and $y = x - \frac{f(x)}{f[x,w]}$.

We are going to analyze the dynamical behavior of the rational function obtained when family (1) is applied on $f(x) = x^2 - 1$. In this case, expression (6) is $M_f(x) = \frac{N_{11}(x)}{D_{10}(x)}$, where $N_{11}(x)$ and $D_{10}(x)$ are polynomials of degrees 11 and 10, respectively, depending on x, α and γ.

There are 10 fixed points of $M_f(x)$. $x^F_{1,2} = x^*_{1,2} = \pm 1$ are superattracting points, while $x^F_{3-10}(\alpha, \gamma)$ are the roots of an 8th-degree polynomial: $x^F_{3,4} \in \mathbb{R}$, $x^F_{5-10} \in \mathbb{C}$. Since our purpose is the study of the real dynamics, x^F_{5-10} are rejected. The evaluation of $|M'_f(x^F_{3,4})|$ establishes the behavior of these points. For different values of α and γ, $x^F_{3,4}$ have different dynamical features, as the stability plane of Figure 1 represents. A mesh of 100×100 points covers the values of $\alpha \in [-2, 2], \gamma \in [-2, 2]$. The white area represents where the multiplier is lower than 1, while the corresponding black represents where the multiplier is greater than 1. Its dynamical meaning is immediate, since white and black regions represent attracting and repelling behavior, respectively.

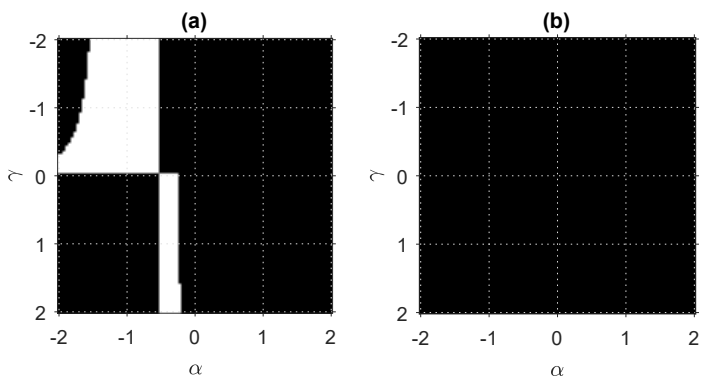

Figure 1: Stability plane of (a) x^F_3 and (b) x^F_4.

 ISBN: 978-84-617-8694-7

Therefore, x_3^F has both behaviors, depending on the value of α and γ. For assuring the convergence of the method to $x_{1,2}^*$, white areas must be avoided. In addition, it is not difficult to prove that the infinity is also an attracting fixed point.

Computing $|M_f'(x)| = 0$, 16 critical points can be found. As expected, $x_{1,2}^C = x_{1,2}^*$. $x_{3,4}^C = \frac{-1\pm\gamma}{\gamma}$ are pre-images of $x_{1,2}^*$. $x_{5-10}^C \in \mathbb{R}$ depend on the values of α and γ. Finally, $x_{11-16}^C \in \mathbb{C}$ are left out of the study since we are only interested in real dynamics.

A classical result (due to Fatou and Julia) establishes that there is at least one critical point associated with each invariant Fatou component, so it is interesting to analyze the behavior of each free critical point (critical point different to the roots of the polynomial) used as initial estimation for all the elements of the family.

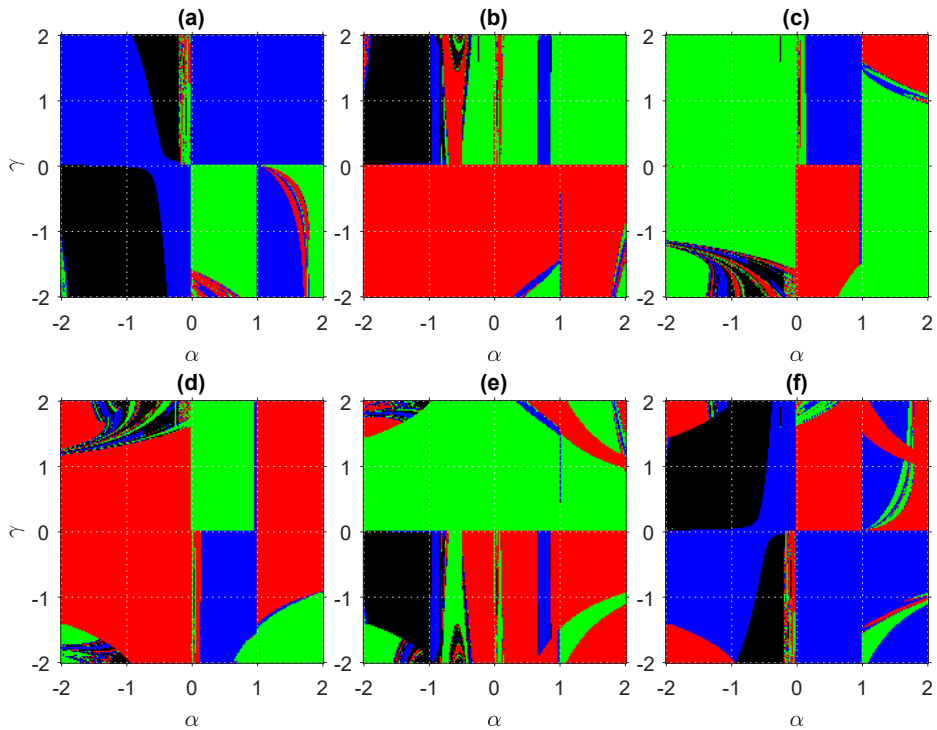

Figure 2: Parameter planes of (a) x_5^C, (b) x_6^C, (c) x_7^C, (d) x_8^C, (e) x_9^C, and (f) x_{10}^C (red: x_1^*, green: x_2^*, blue: x_∞^*, black: other).

The parameter plane represents the family of methods $M_f(x)$, where each point (α, γ) stands for an individual method. If the orbit of the free critical point tends to $-1, 1$, or ∞, the point is colored in red, green, or blue, respectively. If x^C does not converge to any of those points, the point is colored in black. Figure 2 shows the parameter planes of x_{5-10}^C.

The unified parameter plane represented in Figure 3 gathers in one image the main

information of Figure 2. It is composed by the superposition of the black regions. In this way, the election of a point in the white region guarantees that the corresponding scheme tends to ± 1 or ∞, while the set of methods in the black region do not.

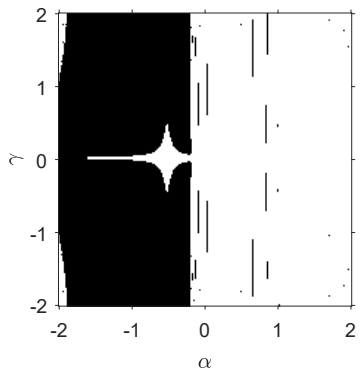

Figure 3: Unified parameter plane of x_{5-10}^{C}.

In order to visualize the behavior of each method, the dynamical line is introduced. Analogously to the dynamical plane for complex variable, the dynamical line represents the basins of attraction, plotting in different colors where the orbit of each initial estimation tends. In coherence to Figure 2, the red color is assigned to those initial approximations that tends to $x_1^* = -1$. Analogously, the green color to $x_2^* = 1$, the blue color to $x^* = \infty$ and the black one to those initial guess that tends to a point different than the previous three. The final orbit of 1001 initial values of $x \in [-2, 2]$ has been calculated, and the convergence to a point is set when its distance is lower than 10^{-3}.

Figure 4 represents the dynamical line of a set of methods whose orbits tend to $-1, 1$, or ∞, i.e., methods that belong to the white area of the unified parameter plane. On the contrary, Figure 5 shows methods whose points also tend to another fixed point.

Note that every point in Figure 4 tends to one of the attracting points. However, when a value of (α, γ) of the black region of Figure 3 is chosen, some points tend to a different point. For instance, these points can be found in Figures 5(a-d) for $x_0 = -0.2$, $x_0 = 0.2$, $x_0 = -0.28$ and $x_0 = 0.28$, respectively.

As expected from the attracting area of x_3^F and the unified parameter plane, the election of methods with $\alpha > 0$ is capital, as proved in Figures 4 and 5.

Abstract

Solutions of the problems of disintegration of an arbitrary discontinuity of the generalized Hopf equation are under analysis. These solutions are constructed from the sequence of non-tipping Riemann waves and shock waves having the stable stationary or non-stationary structure.

Key words: special discontinuity, Hopf equation, problems of disintegration of an arbitrary discontinuity

1 Introduction

In [1, 2], devoted to investigation of the solutions of the Hopf equations with complex nonlinearity, for selection of discontinuities, which have been used for construction of the solution, the request of existence of the stationary structure of the discontinuity has been posed. The structure of discontinuities has been described by the generalized (in the sense of nonlinearity) Korteweg-de Vries-Burgers equation. Appearance of the resent works [3, 4], in which spectral stability of the solutions describing the structure is investigated, makes it possible to include effectively in the notion of the permissible discontinuity the claim of stability of its structure and from this point of view revise before obtained results. We call admissible (i. e. realizable in practice for disintegration of an arbitrary discontinuity) discontinuities with structure, having stability property.

Introduction of the request of stability of the structure in the notion of admissibility of discontinuities results in cutting down the set of admissible discontinuities, described in [1, 2], and eliminate non-uniqueness of the solution of the problem about disintegration of the arbitrary shock, discovered in previous investigations [1]. Furthermore, for construction

 ISBN: 978-84-617-8694-7

of the solution of the problem we have used the discontinuities with structure, containing the internal periodic oscillations (non-stationary structures). Variation of the quantities in such discontinuities may not coincide with variation of the quantities in any discontinuities with stationary structure. It has been shown [5] that the solution of the problem of disintegration of the arbitrary discontinuity in this setting always uniquely exists.

2 Discontinuities with a stationary structure

RWe consider the generalized KdVB equation

$$\frac{\partial v}{\partial t} + \frac{\partial \varphi(v)}{\partial x} = \mu \frac{\partial^2 v}{\partial x^2} - m \frac{\partial^3 v}{\partial x^3}, \tag{1}$$

$$m, \mu = \text{const}, \qquad v = v(x, t).$$

On the right hand side of the equation (1) the term, containing the coefficient m, describes dispersion effects (the coefficient m is the parameter of dispersion). We assume everywhere throughout the paper that $m > 0$. The term, containing the coefficient μ, takes into account viscous effects and it determines dissipation in the system (the coefficient μ is the parameter of dissipation).

In this paper we use the following potential

$$\varphi(v) = v^4 - v^2. \tag{2}$$

The characteristic property of this potential appears to be the presence of two points where the second derivative changes its sign. We study stability of traveling waves representing discontinuity structures obeying the equation

$$\frac{\partial v}{\partial t} + \frac{\partial \varphi(v)}{\partial x} = 0, \tag{3}$$

which is the formal limit of (1), when we consider processes characterized by a large spatial scale L (then both terms on the right hand side of (1) become small in comparison with the terms on the left hand side).

Equation (3) can be called the generalized Hopf equation; it can be transformed into the known Hopf equation when $\varphi(v)$ is a quadratic function of v.

Equation (3) (as well as (1)) expresses the conservation law, consequently the corresponding relation on the discontinuity can be written in the following form:

$$W = \frac{[\varphi(v)]}{[v]}. \tag{4}$$

 ISBN: 978-84-617-8694-7

Here W is the speed of the discontinuity, and quadratic brackets denote the difference of functions in front of the discontinuity and behind it.

Make the change of variables in (1) for $\mu \neq 0$

$$t \to t\sqrt{m}, \quad x \to x\sqrt{m}, \quad \gamma = \sqrt{m}/\mu, \quad \varphi(v) = f(u-1), \quad v = u - 1. \tag{5}$$

Equation (1) takes the form

$$\frac{\partial u}{\partial t} + \frac{\partial f(u)}{\partial x} + \frac{\partial^3 u}{\partial x^3} = \frac{1}{\gamma}\frac{\partial^2 u}{\partial x^2}. \tag{6}$$

The stationary structure of the discontinuity is described by the following equations:

$$u = u(\xi), \qquad \xi = x - Wt,$$

$$\frac{d^2u}{d\xi^2} - \frac{1}{\gamma}\frac{du}{d\xi} = Wu - f(u), \tag{7}$$

$$\lim_{\xi \to -\infty} u(\xi) = u_l, \quad \lim_{\xi \to +\infty} u(\xi) = u_r.$$

If a solution of (7) exists, then from the point of view of the large scale of the length it has to represent a discontinuity with a stationary structure, where $u = u_r$ and $u = u_l$ are the states in front of the discontinuity ($\xi > 0$) and behind the discontinuity ($\xi < 0$). The states u_l and u_r satisfy the relations (4) and they represent, therefore, the states, in front of a discontinuity and behind it corresponding to the conservation law. We assume that the state in front of a discontinuity is taken in the form $u_r = 0$.

Construction of numerous discontinuities, having the stationary structure is specified, which are caused, besides dispersion and dissipation, also by the complex nonlinearity which is given by the potential (2). When the function $f(u)$ is given in such a way, among the solutions of the equation (1) special discontinuities are possible. A discontinuity is called special when its structure represents a heteroclinic phase curve, connecting in the $(u, du/d\xi)$ -plane two singular points of the saddle type (one of these points corresponds to the state in front of the discontinuity, and the other corresponds to the state behind the discontinuity). The number of special discontinuities increases when γ grows [6]. In this setting, the entire set of discontinuities with stationary structure varies and becomes more complex. This set consists of special and non-special discontinuities. The structure of the non-special discontinuity represents the phase curve, connecting two stationary points: the saddle (corresponds to the state in front of a discontinuity) and the focus or the node (corresponds to the state behind a discontinuity).

 ISBN: 978-84-617-8694-7

3 Linear stability of heteroclinic solutions

For investigation of linear stability of heteroclinic stationary solutions of (6), we look for a solution of the form [7, 8, 9]

$$u(x,t) = U(\xi) + w(\xi,t). \tag{8}$$

The function $w(\xi,t)$ satisfies the linearization of equation (7), i. e.,

$$\frac{\partial w}{\partial t} = \frac{\partial}{\partial \xi}\Big(- \frac{\partial^2 w}{\partial \xi^2} + \frac{1}{\gamma}\frac{\partial w}{\partial \xi} + (W - f'(U(\xi)))w\Big), \quad f'(U) = \frac{df(U)}{dU}. \tag{9}$$

The function $U(\xi)$ satisfies the equation (7) and obeys the conditions

$$\lim_{\xi\to-\infty} U(\xi) = u_l, \quad \lim_{\xi\to+\infty} U(\xi) = 0.$$

D e f i n i t i o n 2. The solution $U(\xi)$ of equation (7) is called spectrally (linearly) unstable if there exists a solution of (9) of the form

$$w(\xi,t) = \mathrm{e}^{\lambda t} Y(\xi) \tag{10}$$

with $\mathrm{Re}\,\lambda > 0$, $Y(\xi) \to 0$ for $\xi \to \pm\infty$.

4 Conclusion and Discussion

Solution of problems which are described by systems of nonlinear hyperbolic equations necessarily involve discontinuities, and their proper treatment can cause considerable difficulties. A problem of this type is considered in the present work. The mentioned difficulties are associated with theoretical selection of the admissible discontinuities, i. e. discontinuities that can exist in real media. The naturally occurring requirement for discontinuous solutions obeying nonlinear hyperbolic equations (here we consider the Hopf equation (3)) is the convention that the discontinuities represent the singular limit of solutions to complicated equations, when terms describing small scale processes are taken into consideration (in concrete physical problems, these terms have to correspond to the real processes). In this paper the complicated problem is represented by the equation (1). Previously, the existence of a stationary discontinuity structure has been used as an admissability requirement in many works (see, for example, [1, 6, 10, 11]). However, solutions of standard self-similar problems constructed with the help of so defined admissible discontinuities turned out to be non-unique [1].

In this work we modified the notion of an admissible discontinuity and considered the solutions of the equations (3), (1) from a new point of view. Specifically, admissible discontinuities were treated as discontinuities with a stable structure, which can be stationary

 ISBN: 978-84-617-8694-7

or periodic in time. Accordingly, discontinuities with stationary unstable structures were excluded from the set of discontinuities regarded previously as admissible, while discontinuities with stable and time-periodic structures were added to this set (their stability and periodicity were verified by direct numerical computation). As a result we showed that the solution of the problem of arbitrary discontinuity disintegration constructed in this work uniquely exists for all parameter values. This was done using an example of the KdVB equation with the potential providing the existence of a rich set of front solutions to the equation. Non-uniqueness in the problem of arbitrary discontinuity disintegration more or less frequently occurs in continuum mechanics and physics. Gas dynamics with non-standard equations of state gives such an example [12]. The other famous example is an elastic media. Wave processes there are described, as a rule, by a hyperbolic system of equations and hence, inevitably discontinuities appear, which, unlike usual gas dynamics, occur to be non unique, giving thereby a fundamental example of non-uniqueness of shock wave in mechanics of continuous media [2]. Therefore, in this field the question about selection of admissible discontinuous solutions (shock waves) is extremely important. In this sense, the criterion of uniqueness we obtained can be used for the unique selection of front solutions and simple waves) which solve the problem of arbitrary discontinuity disintegration in a wide class of media which are described by hyperbolic systems of equations.

The results of our study were achieved in in several steps.

- The form of the discontinuous solutions with a structure dependending on a physical parameter of the problem (namely, the relation between dispersion and dissipation) was described. The types of these solutions and their properties were examined.

- The dynamical (spectral) stability of these solutions was analysed.

- The problem of arbitrary discontinuity disintegration was solved using admissible discontinuities with either a stationary or non-stationary structure in time asymptotics of the initial discontinuity.

An efficient numerical method for 2D systems of singularly perturbed parabolic reaction-diffusion equations

C. Clavero[1] and J.L. Gracia[1]

[1] *Department of Applied Mathematics and IUMA, University of Zaragoza, Spain*

emails: clavero@unizar.es, jlgracia@unizar.es

Abstract

In this paper we propose an efficient numerical method to solve parabolic initial-boundary two dimensional coupled singularly perturbed systems of reaction-diffusion type. The diffusion parameter, which can be sufficiently small, is the same in all the equations of the system. In general, the exact solution of the problem has parabolic boundary layers at the boundary of the spatial domain. The fully discrete scheme combines a splitting or additive scheme, to discretize in time, and the classical central finite difference scheme, to discretize in space. Then, if the time derivatives are discretized on a uniform mesh and the spatial derivatives on a special piecewise uniform mesh of Shishkin type, the method is uniformly convergent, having first order in time and almost second order in space. Some numerical results are showed, which corroborate in practice the good theoretical properties of the method.

Key words: 2D parabolic systems, reaction-diffusion, additive methods, piecewise uniform meshes, uniform convergence
MSC 2000: 65N05, 65M06, 65N06, 65N12

1 Introduction

In this work we are interested in approximating the solution of two dimensional parabolic singularly perturbed coupled reaction-diffusion systems of ℓ equations, given by

$$\left\{ \begin{array}{l} L_\varepsilon \mathbf{u} \equiv \dfrac{\partial \mathbf{u}}{\partial t}(\mathbf{x},t) + \mathcal{L}_{\mathbf{x},\varepsilon}\mathbf{u}(\mathbf{x},t) = \mathbf{f}(\mathbf{x},t),\ (\mathbf{x},t) \in Q = \Omega \times (0,T], \\ \mathbf{u}(\mathbf{x},t) = \mathbf{0},\ \mathbf{x} \in \partial\Omega,\ t \in (0,T],\ \mathbf{u}(\mathbf{x},0) = \mathbf{0},\ \mathbf{x} \in \overline{\Omega}, \end{array} \right. \tag{1}$$

 ISBN: 978-84-617-8694-7

where $\Omega = (0,1)^2$ and the spatial differential operator $\mathcal{L}_{\mathbf{x},\varepsilon}$ is defined as

$$\mathcal{L}_{\mathbf{x},\varepsilon}\mathbf{u} \equiv -\mathcal{D}\Delta\mathbf{u} + \mathcal{A}\mathbf{u}, \tag{2}$$

with $\mathcal{D} = \mathrm{diag}(\varepsilon,\ldots,\varepsilon)$, $\mathcal{A}(\mathbf{x},t) = (a_{ij}(\mathbf{x},t))$, $i,j = 1,2,\ldots,\ell$. We assume that the diffusion parameter ε, $0 < \varepsilon \leq 1$, can be sufficiently small, that the reaction matrix $\mathcal{A}$ is an M-matrix, i.e., for $(\mathbf{x},t) \in \overline{Q}$ it satisfies

$$\sum_{j=1}^{\ell} a_{ij} \geq \alpha > 0,\ a_{ii} > 0,\ i = 1,2,\ldots,\ell,\ a_{ij} \leq 0, \quad \text{if} \quad i \neq j, \tag{3}$$

and also that the components of the right-hand side of the differential equation, $\mathbf{f}(\mathbf{x},t) = (f_1(\mathbf{x},t), f_2(\mathbf{x},t),\ldots,f_\ell(\mathbf{x},t))^T$, and the reaction matrix $\mathcal{A}$ are sufficiently smooth functions, which satisfy sufficient compatibility conditions, in order to guarantee that the exact solution $\mathbf{u} \in C^{4,2}(\overline{Q})$.

There exists many works in the literature (see for instance [2, 3, 7, 8] and references therein), where 1D singularly perturbed systems of reaction-diffusion type, in both elliptic or parabolic case, are analyzed. In those papers, the time variable is discretized by using the backward Euler method, on a uniform mesh, and the spatial variable is discretized by the classical central finite difference scheme, defined on a piecewise uniform mesh of Shishkin type. Then, the resulting schemes are uniformly convergent in both variables. At each time level of the time discretization, the numerical approximation is obtained by solving a linear system which requires a high computational cost, due to the components of the discrete solution are coupled. In order to reduce this computational cost, it is very convenient to use techniques that decouple the components. This idea is used in [1], where a splitting (or additive) scheme, defined on a uniform mesh, is used to discretize in time. Here, we are interested in extending this idea to the class of problems (1), where the dimension of the spatial variable makes considerably more difficult the resolution of the continuous problem.

In [5, 6, 9] the case of 2D elliptic singularly perturbed systems is analyzed; from those papers, it follows that parabolic boundary layers, of width $\mathcal{O}(\sqrt{\varepsilon})$, appear at the boundary $\partial\Omega$ of the spatial domain. Similarly to the case of parabolic problems with a single equation ($\ell = 1$), parabolic boundary layers are expected in the exact solution of problem (1). Therefore, uniformly convergent methods are necessary to find accurate approximations to the solution for any value of the diffusion parameter, with a number of grid points which is also independent of ε.

The paper is organized as follows. In Section 2 we construct the fully discrete scheme, which combines an additive method to discretize in time and the central finite difference scheme to discretize in space; we also give the result proving the uniform convergence, with respect to the diffusion parameter, of the numerical method. In Section 3, some results obtained for different test problems are showed, which corroborate, from a numerical point of view, the order of uniform convergence of the method.

2 The fully discrete scheme: uniform convergence

The analysis of the asymptotic behavior of the exact solution, following similar ideas and techniques as in [5, 6] for systems of elliptic reaction-diffusion equations, shows that the solution of (1) has parabolic boundary layers at the boundary of the spatial domain. Then, to approximate that solution we need an efficient numerical scheme.

The first step to construct this method is the time discretization. For that, we consider a uniform mesh, $\overline{\omega}^M = \{t_m = m\tau,\ 0 \leq m \leq M,\ \tau = T/M\}$, and the discretization is given by

$$\begin{array}{l} \mathbf{z}^0 = \mathbf{u}(\mathbf{x},0) = \mathbf{0}, \\ \left\{ \begin{array}{l} \text{For } m = 0, 1, \cdots, M-1, \\ \tau^{-1}(\mathbf{z}^{m+1} - \mathbf{z}^m) - \mathcal{D}\Delta \mathbf{z}^{m+1} + \mathcal{M}^{m+1}\mathbf{z}^{m+1} - \mathcal{N}^{m+1}\mathbf{z}^m = \mathbf{f}^{m+1}, \text{ in } \Omega, \\ \mathbf{z}^{m+1} = \mathbf{0}, \quad \text{on } \partial\Omega, \end{array} \right. \end{array} \tag{4}$$

where $\mathbf{f}^{m+1} = \mathbf{f}(\mathbf{x}, t_{m+1})$, $m = 0, 1, \cdots, M-1$, the operator $\mathcal{M}^{m+1}$ is given by

$$\mathcal{M}^{m+1}(\mathbf{x}) = \begin{pmatrix} a_{11}(\mathbf{x}, t_{m+1}) & 0 & \cdots & \cdots & 0 \\ a_{21}(\mathbf{x}, t_{m+1}) & a_{22}(\mathbf{x}, t_{m+1}) & 0 & \cdots & 0 \\ \vdots & \vdots & & \ddots & \vdots \\ a_{m1}(\mathbf{x}, t_{m+1}) & a_{m2}(\mathbf{x}, t_{m+1}) & \cdots & \cdots & a_{mm}(\mathbf{x}, t_{m+1}) \end{pmatrix} \tag{5}$$

and $\mathcal{N}^{m+1}(\mathbf{x}) = \mathcal{M}^{m+1}(\mathbf{x}) - \mathcal{A}^{m+1}(\mathbf{x})$. In this way, at the time level t_{m+1} the components of the vector unknown $\mathbf{z}^{m+1}$ are decoupled.

To obtain the fully discrete method, we discretize (4) with the classical central difference scheme, which is defined on a piecewise uniform mesh, $\overline{\Omega}^N \equiv I_{x,\varepsilon,N} \times I_{y,\varepsilon,N}$, given as a tensor product of one dimensional piecewise uniform Shishkin meshes, $I_{x,\varepsilon,N} = \{0 = x_0 < \ldots < x_N = 1\}$, $I_{y,\varepsilon,N} = \{0 = y_0 < \ldots < y_N = 1\}$, where N, the discretization parameter, is a positive integer. We only give the details of the construction of $I_{x,\varepsilon,N}$ and similarly can be done for $I_{y,\varepsilon,N}$. For simplicity in the presentation, we take the same value N for both spatial variables, but a similar result follows in the case that the number of grid points at each spatial direction is different.

We know that parabolic boundary layers of width $\mathcal{O}(\sqrt{\varepsilon})$ appear in $\partial\Omega$; so, the grid points must condense in the boundary layer regions. In this paper, we choose a piecewise uniform mesh of Shishkin type. Then, in the x-spatial variable, the grid points of the mesh are given by (see [4])

$$x_j = \begin{cases} jh, & j = 0, \ldots, N/4, \\ x_{N/4} + (j - N/4)H, & j = N/4+1, \ldots, 3N/4, \\ x_{3N/4} + (j - 3N/4)h, & j = 3N/4+1, \ldots, N, \end{cases} \tag{6a}$$

where $h = 4\sigma/N,\ H = 2(1-2\sigma)/N$, and the transition parameter σ is defined by

$$\sigma = \min\left\{1/4, \sqrt{\varepsilon}\ln N\right\}. \tag{6b}$$

 ISBN: 978-84-617-8694-7

We denote by $\overline{Q}^{N,M} = \overline{\Omega}^N \times \overline{\omega}^M$ the corresponding grid for the $(\mathbf{x}, t)$-variables, by $Q^{N,M} = \overline{Q}^{N,M} \cap Q$, $\partial\Omega^{N,M} = \overline{Q}^{N,M} \backslash Q^{N,M}$, and by $\mathbf{U} = \{\mathbf{U}^0, \ldots, \mathbf{U}^M\}$ the vector numerical approximation on the grid $\overline{Q}^{N,M}$. Thus, $\mathbf{u}(\mathbf{x}, t_m) \approx \mathbf{U}^m(\mathbf{x})$ with $\mathbf{x} \in \overline{Q}^{N,M}$.

The fully discrete scheme is defined as

$$\begin{array}{l} \mathbf{U}^0 = \mathbf{0}, \\ \left\{ \begin{array}{l} \text{For } m = 0, 1, \cdots, M-1, \\ \tau^{-1}(\mathbf{U}^{m+1} - \mathbf{U}^m) - \mathcal{D}\left(\delta_x^2 + \delta_y^2\right)\mathbf{U}^{m+1} + \mathcal{M}^{m+1}\mathbf{U}^{m+1} - \mathcal{N}^{m+1}\mathbf{U}^m = \mathbf{f}^{m+1}, \text{in } Q^{N,M}, \\ \mathbf{U}^{m+1} = \mathbf{U}^{m+1} = \mathbf{0}, \text{ on } \partial\Omega^{N,M}, \end{array} \right. \end{array} \tag{7}$$

where

$$\delta_x^2 Z_{i,j} = \frac{2}{h_i + h_{i+1}} \left(\frac{Z_{i+1,j} - Z_{i,j}}{h_{i+1}} - \frac{Z_{i,j} - Z_{i-1,j}}{h_i} \right),$$
$$\delta_y^2 Z_{i,j} = \frac{2}{h_j + h_{j+1}} \left(\frac{Z_{i,j+1} - Z_{i,j}}{h_{j+1}} - \frac{Z_{i,j} - Z_{i,j-1}}{h_j} \right),$$

are the standard approximations of the second order derivative, at each spatial variable on a nonuniform mesh, with $h_i = x_i - x_{i-1},\ h_j = y_j - y_{j-1},\ i, j = 1, \ldots, N$.

The proposed numerical scheme decouples the ℓ components of the vector problem and then ℓ discrete problems are solved at each time level. Each discrete problem approximates one of the unknowns using a five-point approximation whose associated $N \times N$ matrix is a tridiagonal block matrix.

The following result proves the uniform convergence of the fully discrete scheme, having first order in time and almost second order in space.

Theorem 1 *Let* $\mathbf{U}$ *be the numerical solution of (7) on* $\overline{Q}^{N,M}$ *using a uniform mesh in time and the piecewise uniform Shishkin mesh* (6) *in space, and let* $\mathbf{u}$ *be the solution of the continuous problem (1). Then, the following error bound is satisfied*

$$\max_{0 \le m \le M} \max_{\mathbf{x} \in \overline{Q}^{N,M}} |\mathbf{U}^m(\mathbf{x}) - \mathbf{u}(\mathbf{x}, t_m)| \le C(M^{-1} + (N^{-1} \ln N)^2), \tag{8}$$

where C *is a positive constant independent of the diffusion parameter* ε *and the discretization parameters* N *and* M.

3 Numerical results

In this section we show the numerical results obtained for some test problem of type (1). The first example is defined when the reaction matrix and the right-hand side are

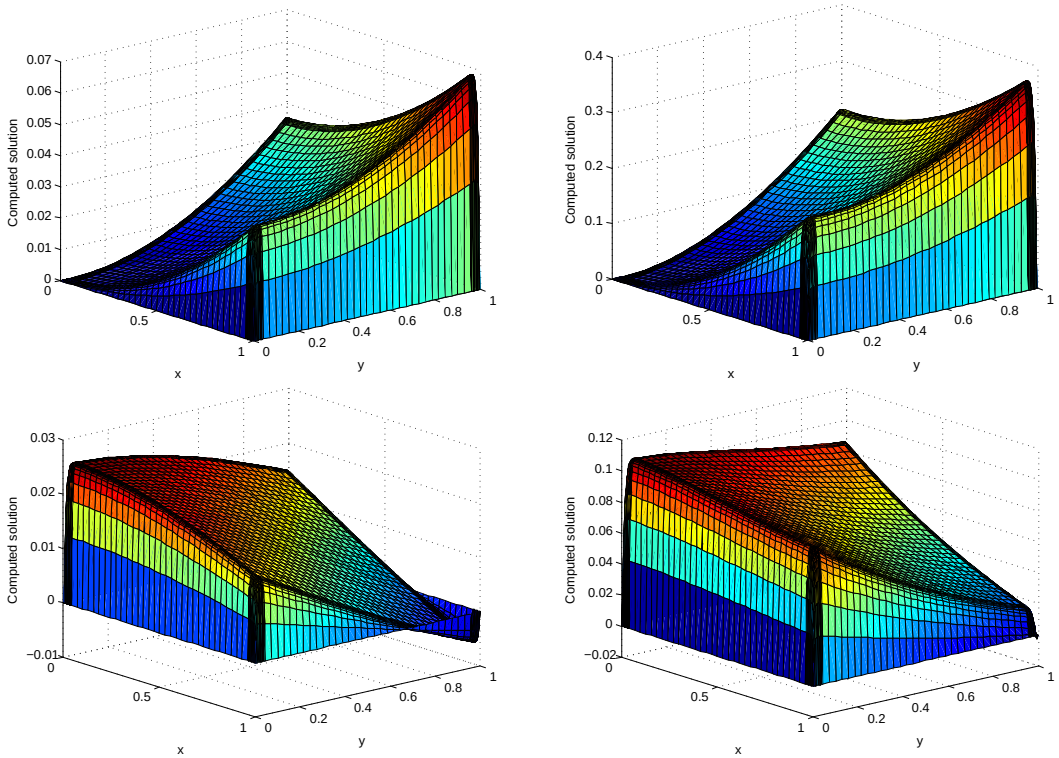
$$\mathcal{A} = \begin{pmatrix} 1 + t(x+y) & -t\sin(x+y) \\ t(\cos(xy) - 1) & (t+1)(1+xy) \end{pmatrix}, \quad \mathbf{f} = \begin{pmatrix} t^2(x^2+y^2) \\ (1 - e^{-t})\cos(x+y) \end{pmatrix}, \tag{9}$$

 ISBN: 978-84-617-8694-7

and the final time is $T = 1$. The exact solution of problem (1) and (9) is unknown.

Figure 1 displays the numerical solution, at $t = 0.5$ and $t = 1$, using the scheme (7) when the discretization parameters are $N = 64$, $M = 32$ and the diffusion parameter is $\varepsilon = 10^{-4}$. From it, we clearly see the boundary layers at the four sides of the spatial domain.

Figure 1: Components u_1 (first row) and u_2 (second row) at $t = 0.5$ (left figures) and $t = 1$ (right figures) of problem (1) and (9) for $\varepsilon = 10^{-4}$ with $N = 64$ and $M = 32$



As the exact solution is unknown, we cannot calculate exactly the errors; to approximate them, we use a variant of the double-mesh principle (see [4]). Then, the maximum errors for each value of ε are approximated by

$$\mathbf{d}_{\varepsilon}^{N,M} = \max_{0\leq m\leq M} \max_{0\leq i,j\leq N} |\mathbf{U}_{i,j}^{m} - \widehat{\mathbf{U}}_{2i,2j}^{2m}|,$$

where $\{\widehat{\mathbf{U}}_{i,j}^{m}\}$ is the numerical solution on a finer mesh $\{(\hat{x}_i, \hat{y}_j, \hat{t}_m)\}$, which has the mesh

 ISBN: 978-84-617-8694-7

points of the coarse mesh and their midpoints, i.e.,

$$\begin{array}{l} \hat{x}_{2i} = x_i, \quad i = 0, \ldots, N, \quad \hat{x}_{2i+1} = (x_i + x_{i+1})/2, \quad i = 0, \ldots, N-1, \\ \hat{y}_{2j} = y_j, \quad j = 0, \ldots, N, \quad \hat{y}_{2j+1} = (y_j + y_{j+1})/2, \quad j = 0, \ldots, N-1, \\ \hat{t}_{2m} = t_m, \quad m = 0, \ldots, M, \quad \hat{t}_{2m+1} = (t_m + t_{m+1})/2, \quad m = 0, \ldots, M-1. \end{array} \tag{10}$$

From the maximum two-mesh differences $\mathbf{d}_\varepsilon^{N,M}$, we obtain the ε-uniform two-mesh differences by

$$\mathbf{d}^{N,M} = \max_\varepsilon \mathbf{d}_\varepsilon^{N,M}.$$

From the approximated maximum errors $\mathbf{d}_\varepsilon^{N,M}$, in a standard way, the numerical orders of convergence, for each value of ε, are calculated by

$$p_\varepsilon^{N,M} = \log\left(\mathbf{d}_\varepsilon^{N,M}/\mathbf{d}_\varepsilon^{2N,2M}\right)/\log 2,$$

and from the approximated uniform maximum errors $\mathbf{d}^{N,M}$, the numerical uniform orders of convergence are calculated by

$$p^{N,M} = \log\left(\mathbf{d}^{N,M}/\mathbf{d}^{2N,2M}\right)/\log 2.$$

Tables 1 and 2 show the maximum two-mesh differences and the orders of convergence for components u_1 and u_2 respectively; from them, we clearly deduce that the method is first-order uniformly convergent. Moreover, we can conclude that the errors associated with the time discretization dominate into the global error of the numerical method.

In Tables 3 and 4 the discretization parameters are multiplied by different factors so that the errors associated with the space discretization dominate into the global errors. The space and time discretization parameters are multiplied by a factor of 2 and 4, respectively. The computed orders of convergence now show almost second order of convergence, in agreement with Theorem 1.

In the second example the reaction matrix and the right-hand side are

$$\mathcal{A} = \begin{pmatrix} e^{x+y} & -(x+y) & -tx \\ -(x+y) & (t+1)(3+x+y) & -t\sin(y) \\ -tx & -t\sin(y) & e^t(2+\cos(x+y)) \end{pmatrix}, \quad \mathbf{f} = \begin{pmatrix} txy \\ (1-e^{-t})\sin(xy) \\ (t+1)\cos(x+y) \end{pmatrix}, \tag{11}$$

and the final time is again $T = 1$. The computed solutions with the finite difference scheme (7) at $t = 0.5$ and $t = 1$ are displayed in Figure 2. These surfaces show the presence of boundary layers in the three components of the solution.

Similarly to the previous example, we show the numerical results for each component in separate tables. The maximum two-mesh differences and the orders of convergence for u_i, $i = 1, 2, 3$ are given in Tables 5-7 respectively, where the discretization parameters N and M are multiplied by a factor of 2. The ε-uniform computed orders of convergence shows first order, and it again agrees with Theorem 1.

Abstract

In this work we derive important properties regarding matrix invariants which occur in the theory of differential equations with reflection.

Key words: differential equations with reflection, matrix invariants.

1 Introduction

In recent works regarding the solution and Green's functions of Differential Equations with Reflection (see for instance [1–3, 8]) the strong relation between linear analysis and linear algebra is highlighted. In particular, in the most recent of the aforementioned works, the authors obtain an explicit fundamental matrix for the system of differential equations with reflection

$$Hu(t) := Fu'(t) + Gu'(-t) + Au(t) + Bu(-t) = 0, t \in \mathbb{R}, \tag{1.1}$$

where $n \in \mathbb{N}$, $A, B, F, G \in \mathcal{M}_n(\mathbb{R})$ and $u : \mathbb{R} \to \mathbb{R}^n$. To be precise, they prove the following result.

Theorem 1.1 ([3])**.** *Assume $F - G$ and $F + G$ are invertible. Then*

$$X(t) := \sum_{k=0}^{\infty} \frac{E^k t^{2k}}{(2k)!} - (F+G)^{-1}(A+B) \sum_{k=0}^{\infty} \frac{E^k t^{2k+1}}{(2k+1)!},$$

where $E = (F-G)^{-1}(A-B)(F+G)^{-1}(A+B)$, is a fundamental matrix of problem (1.1)*. If we further assume $A-B$ and $A+B$ are invertible, then E is invertible and we can consider a square root Ω of E. Then,*

$$X(t) = \cosh \Omega t - (F+G)^{-1}(A+B)\Omega^{-1} \sinh \Omega t.$$

 ISBN: 978-84-617-8694-7

What is more, in another recent work the authors proved an analog of the Liouville's formula for the case with reflections in systems of order two.

Theorem 1.2 (Abel-Jacobi-Liouville Identity [5])**.** *Let $n = 2$ in equation (1.1). Then $(|X|, |X'|)$ is the unique solution of the system of differential equations*

$$\begin{aligned} x'' &= \operatorname{tr}(E)x - 2y, \\ y'' &= -2|E|x + \operatorname{tr}(E)y, \end{aligned}$$

subject to the one point conditions

$$x(0) = 1, \quad y(0) = |M_+|, \quad x'(0) = -\operatorname{tr}(M_+), \quad y'(0) = \operatorname{tr}(\operatorname{Adj}(M_+)E).$$

The authors also presented in that work the following conjecture:

Conjecture 1.3. *For any $n \geq 1$, if $X(t)$ is a fundamental matrix of problem (1.1), then $|X(t)|$ can be obtained as a component of the solution of a linear system of differential equations with constant coefficients, those coefficients depending only on the different matrix invariants of E, which is defined as in Theorem 1.1.*

In order to attempt proving this conjecture, and taking into account the proof of Theorem 1.2, we need to study the different matrix invariants of the matrices appearing in the theory.

2 The Y matrix

For $X(t)$ the fundamental matrix of the problem, define

$$Y(t) := X(t)^{-1}X'(t). \tag{2.1}$$

We have that $X = S_1 - M_+S_2$ where S_1 and S_2 s are power series in E which we can formally give, by using $\Omega = \sqrt{E}$, as $S_1 = \cosh(\Omega t)$, $S_2 = \Omega^{-1}\sinh(\Omega t)$.

Notice both are indeed power series in $\Omega^2 = E$. Since $X'' = XE$ and $(Y^{-1})' = -Y^{-1}Y'Y^{-1}$ we have that

$$Y' = E - Y^2. \tag{2.2}$$

Using the construction of [6] we build an associated ODE system

$$z' = \begin{pmatrix} 0 & E \\ I & 0 \end{pmatrix} z.$$

The system has as fundamental matrix

$$\begin{pmatrix} \cosh(\Omega t) & \Omega^{-1}\sinh(\Omega t) \\ \Omega\sinh(\Omega t) & \cosh(\Omega t) \end{pmatrix}.$$

 ISBN: 978-84-617-8694-7

The solution of equation (2.2) is then given by

$$Y(t) = [\cosh(\Omega t)Y(0) + \Omega \sinh(\Omega t)] \left[\Omega^{-1} \sinh(\Omega t)Y(0) + \cosh(\Omega t)\right]^{-1},$$

which in terms of the S functions is $Y(t) = [-S_1 M_+ + E S_2] [-S_2 M_+ + S_1]^{-1}$, where we fix the initial condition with $Y(0) = X'(0) = -M_+$. This seems like a commuted version of expression (2.1), but it is nothing more than the hypergeometric identity.

Consider the Liouville equation for Y itself, that is,

$$(\log |Y|)' = \mathrm{Tr}\left(Y^{-1}Y'\right) = \mathrm{Tr}\left(Y - Y^{-1}E\right).$$

Then we have $\mathrm{Tr}(Y^{-1}E) = \mathrm{Tr}(Y) - (\log |Y|)'$, which can be calculated in terms of invariants of $|X|$.

3 Complex systems

The main involution occurring in the theory of complex variable is the complex conjugation $\mathcal{C} : \mathbb{C} \to \mathbb{C}$, $\mathcal{C}(z) = \overline{z}$. It is, in fact, a reflection with respect to the second variable if we write $z = (x, y) \in \mathbb{R}^2$: $\mathcal{C}(x, y) = (x, -y)$.

We consider now an operator L acting on $z(t)$ as

$$A_0 z(t) + A_1 \overline{z(t)} + B_0 z(t) + B_1 \overline{z'(t)}, \tag{3.1}$$

where $z : \mathbb{R} \to \mathbb{C}^n$, and $A_i, B_i \in \mathcal{M}_{n\times n}(\mathbb{C}) := \mathcal{M}$.

We can consider a extended algebra $\mathcal{M}^*$ by with the linear operation of complex conjugation which acts as $\mathcal{C}z = \overline{z}, z \in \mathbb{C}^n$.

It is easy to see that the following properties hold[1],

$$\mathcal{C}^2 = I, \mathcal{C}A = \overline{A}\mathcal{C}, \tag{3.2}$$

where $\overline{A}$ is the complex conjugate of A.

The we consider the free product quotiented by these relations,

$$\mathcal{M}^* = \mathcal{M} \star \{\mathcal{C}\} \,/ \left(\mathcal{C}^2 = I, \mathcal{C}A = \overline{A}\mathcal{C}\right).$$

Now, we can see that this is in fact a $\mathbb{Z}_2$-graded algebra. Due to the conditions (3.2), we can move any $\mathcal{C}$'s to the right, and any power of it is reduced modulo 2. Therefore, any element of $A \in \mathcal{M}^*$ can be written as $\mathbf{A} = A_0 + A_1\mathcal{C}$ with $A_0, A_1 \in \mathcal{M}$. As a vector space, $\mathcal{M}^* = \mathcal{M} \oplus \mathcal{M}$.

[1] In fact, one could use here any involution for which matrix conjugation verifies $\mathcal{C}A\mathcal{C} \in \mathcal{M}$ by defining $\overline{A}$ suitably.

 ISBN: 978-84-617-8694-7

The grading is clear by looking at the product of two generic elements,

$$\mathbf{AB} = (A_0 + A_1\mathcal{C})(B_0 + B_1\mathcal{C}) = \left(A_0B_0 + A_1\overline{B_1}\right) + \left(A_0B_1 + A_1\overline{B_0}\right)\mathcal{C}. \tag{3.3}$$

We can also calculate a explicit inverse, using $(I - A\mathcal{C})(I + A\mathcal{C}) = I - A\overline{A}$, from where $(I + A\mathcal{C})^{-1} = \left(I - A\overline{A}\right)(I - A\mathcal{C})$.

Since $(AB)^{-1} = B^{-1}A^{-1}$, we can generalize it to

$$(A_0 + A_1\mathcal{C})^{-1} = \left(A_1^{-1}A_0 - \overline{A_0^{-1}A_1}\right)^{-1}\left(A_1^{-1} - \overline{A_0^{-1}}\mathcal{C}\right).$$

As it is, the expression is unclear when either $A_i = 0$. We rewrite

$$\mathbf{A}^{-1} = \Delta(A_0, A_1) + \Delta\left(\overline{A_1}, \overline{A_0}\right)\mathcal{C}, \tag{3.4}$$

with

$$\Delta(A_0, A_1) = \begin{cases} 0, & A_0 = 0, A_1 \neq 0, \\ \left(A_0 - A_1\overline{A_0^{-1}A_1}\right)^{-1}, & A_0 \neq 0, A_1 \neq 0. \end{cases}$$

As a last note, this can of course be realized as a matrix algebra over $\mathbb{R}^{2n}$, although it does not lead to anything new (other than clutter). For the record, one can take a representation

$$\rho(z) = \left(\begin{array}{c} \Re z \\ \hline \Im z \end{array}\right), \quad \rho(A) = \left(\begin{array}{c|c} \Re A & -\Im A \\ \hline \Im A & \Re A \end{array}\right), \quad \rho(\mathcal{C}) = \left(\begin{array}{c|c} I & 0 \\ \hline 0 & -I \end{array}\right),$$

for which it is easy to see that properties such as (3.2) or (3.3) hold.

3.1 Equation reduction

With these tools, one can rewrite equation (3.1) as $\mathbf{B}z'(t) + \mathbf{A}z(t) = 0$, which can be reduced to $z'(t) + \left(\mathbf{B}^{-1}\mathbf{A}\right)z(t) = 0$. This means we can just focus on the study of

$$z'(t) + A_0z(t) + A_1\overline{z(t)} = 0.$$

Of course, one could now look for a fundamental operator inside the $\mathcal{M}^*$ algebra, such that solutions fulfill

$$z(t) = \mathbf{X}(t)z(0),$$

which is

$$\mathbf{X} = \cosh(\mathbf{A}t) - \sinh(\mathbf{A}t).$$

Unfortunately, it does not seem easy to calculate terms like $\mathbf{A}^n$ at the moment. We could in principle directly get an explicit fundamental matrix if we could write a manageable

 ISBN: 978-84-617-8694-7

expression. However, we do learn something important. Since $\mathbf{A}^n \in \mathcal{M}^*$, then $\cosh(\mathbf{A}t) \in \mathcal{M}^*$ too. Hence, if we want to find fundamental matrices for the problem, the ansatz must be of the form

$$z(t) = \left(X_0(t) + X_1(t)\mathcal{C}\right) z(0) = X_0(t)z(0) + X_1(t)\overline{z(0)},$$

where $X(0) = I$ and $Y(0) = 0$ as to agree with $\mathbf{X}(0) = I$.

3.2 $\mathbf{A^n}$ generating function

The components of $\mathbf{A}^n$ can still be algorithmically computed by using the expression

$$(I - t\mathbf{A})^{-1} = \sum_{n=0}^{\infty} (t\mathbf{A}).$$

By writing the explicit inverse of $I - t\mathbf{A} = (I - tA_0) - tA_1\mathcal{C}$, we get

$$\mathbf{A}^n = \frac{1}{n!}\frac{\mathrm{d}}{\mathrm{d}t}\left[\left(A_1^{-1}(I - tA_0) - \overline{(I - tA_0)^{-1}A_1}\right)^{-1}\left(A_1^{-1} - \overline{(t^{-1}I - A_0)^{-1}}\mathcal{C}\right)\right]_{t=0}.$$

3.3 Ansatz

We take the system

$$z' + Az + \overline{Bz} = 0, z : \mathbb{R} \to \mathbb{C}^n, A, B \in \mathcal{M}$$

and introduce the ansatz

$$z = Xz_0 + \overline{Yz_0}, z_0 = z(0), X, Y : \mathbb{R} \to \mathcal{M},$$

$$\left(X' + AX + \overline{B}Y\right) z_0 + \left(Y' + \overline{A}Y + BX\right)\overline{z_0} = 0,$$

$$\begin{cases} X' + AX + \overline{B}Y = 0, \\ Y' + \overline{A}Y + BX = 0. \end{cases} \tag{3.5}$$

This a ordinary system. Take X'' and substitute Y' and Y through equation (3.5),

$$X'' + AX' + \overline{B}\left(-BX - \overline{A\overline{B^{-1}}}\left(-X' - AX\right)\right) = 0,$$
$$X'' + \left(A + \overline{BAB^{-1}}\right)X' + \left(\overline{BAB^{-1}}A - \overline{B}B\right)X = 0.$$

Unsurprisingly, we get a very similar structure to the inverses in expression (3.4).For the sake of notation, we will rename the coefficients as

$$X'' + FX' + GX = 0.$$

Repeating the process, we get

$$Y'' + \overline{F}Y' + \overline{G}Y = 0.$$

The initial conditions for this second order problem are given by $\mathbf{X}(0) = I$ and equation (3.5). That is,

$$X(0) = I, \quad Y(0) = 0, \quad X'(0) = -A, \quad Y'(0) = -\overline{A}.$$

In principle, we could now take as an ansatz

$$X = \alpha e^{(\Gamma+\Omega)t} + \beta e^{(\Gamma-\Omega)t},$$

subject to the conditions

$$X(0) = \alpha + \beta, X'(0) = \alpha(\Gamma + \Omega) + \beta(\Gamma - \Omega),$$

which can be inverted into

$$\begin{aligned}\alpha =& \frac{1}{2}\left[X'(0) - X(0)\left(\Gamma - \Omega\right)\right]\Omega^{-1},\\ \beta =& -\frac{1}{2}\left[X'(0) - X(0)\left(\Gamma + \Omega\right)\right]\Omega^{-1}.\end{aligned}$$

4 Generalized matrix invariants

In the following section we use the concept of crossed or generalized matrix invariants which can be found in [7] and [4] among others.

4.1 Definition and basic properties

Let $X_1, \ldots, X_N \in GL\left(n\right)$. Define

$$Z\left(X_1, \ldots, X_N\right) := \det\left(I + \sum_{i=1}^{N} \alpha_i X_i\right) := \sum_{m_i} \alpha_1^{m_1} \ldots \alpha_N^{m_N} Z_{m_1,\ldots,m_N}\left(X_1, \ldots, X_N\right). \quad (4.1)$$

Since det is an algebraic combination of matrix entries, the expansion is a polynomial in the α_i variables. We can however take the sum to be over all integer values of m_i by suitably defining its α-coefficients, $Z_{m_1,\ldots,m_N}$, as zero when not corresponding to any power that appears in the det expansion. In particular,

$$Z_{m_1,\ldots,m_N}\left(X_1, \ldots, X_n\right) = 0 \text{ if } \min\left\{m_i\right\} < 0. \quad (4.2)$$

 ISBN: 978-84-617-8694-7

These Z coefficients then give us the *generalized matrix invariants*, which reduce to the usual ones when we only consider one matrix (or set the other indices to 0). We can get explicit expressions in terms of traces via

$$\det(I+\alpha X) = e^{\mathrm{Tr}\log(I+\alpha X)} \tag{4.3}$$

by expanding the Taylor series around $\alpha = 0$ and using the linearity of the trace. This already gives, looking at the leading order of the exponential expansion,

$$Z_{0,\dots,0}(X_1,\dots,X_n) = 1. \tag{4.4}$$

In the same way, we can reduce any expression with a 0 index,

$$Z_{n_1,\dots,n_{N-1},0}\left(X_1,\dots,X_N\right) = Z_{n_1,\dots,n_{N-1}}\left(X_1,\dots,X_{N-1}\right).$$

Looking at higher coefficients upon expanding the exponential returns higher invariants. For instance,

$$\begin{aligned}
\mathrm{Tr}\log\left(I+\alpha X\right) =& \alpha \mathrm{Tr}\left(X\right) - \frac{\alpha^2}{2}\mathrm{Tr}\left(X^2\right) + \frac{\alpha^3}{3}\mathrm{Tr}\left(X^3\right) + O\left(\alpha^4\right),\\
Z_1(X) =& \mathrm{Tr}(X),\\
Z_2(X) =& \frac{1}{2}\left(\mathrm{Tr}(X)^2 - \mathrm{Tr}(X^2)\right),\\
Z_3(X) =& \frac{1}{6}\left(\mathrm{Tr}(X)^3 - 3\mathrm{Tr}(X^2)\mathrm{Tr}(X) + \mathrm{Tr}(X^3)\right),
\end{aligned}$$

etc, but also

$$Z_{1,1}(X,Y) = \mathrm{Tr}(X)\mathrm{Tr}(Y) - \mathrm{Tr}(XY).$$

Of course, equation (4.3) is usually proven using Liouville's formula. We will make contact with it again later, when looking at the derivatives of the Z invariants themselves.

4.2 Factorization

Consider

$$\det\left(1+\alpha A + \sum_i \beta_i B\right),$$

and the fact that

$$\det\left(\alpha A\right) = \alpha^n \det A.$$

Extract this determinant from the original expansion,

$$\begin{aligned}
\det\left(I+\alpha A + \sum_i \beta_i B\right) &= \sum_{l,m_i} \alpha^l \left(\prod \beta^{m_i}\right) Z_{l,m_1,\dots,m_N}\left(A,B_1,\dots,B_N\right)\\
&= \det\left(A\right) \sum_{l,m_i} \alpha^l \left(\prod \beta_i^{m_i}\right) Z_{n-l-\sum m_i,m_1,\dots,m_N}\left(A^{-1},A^{-1}B_1,\dots,A^{-1}B_N\right).
\end{aligned}$$

 ISBN: 978-84-617-8694-7

To equate the two polynomials, we equate every coefficient and get a **duality** relationship

$$Z_{l,m_1,\ldots,m_N}\left(A,B_1,\ldots,B_N\right)=\det\left(A\right)Z_{n-l-\sum m_i,m_1,\ldots,m_N}\left(A^{-1},A^{-1}B_1,\ldots,A^{-1}B_N\right). \tag{4.5}$$

Already an interesting property comes from the fact that any Z with negative indices must be 0, by equation (4.2). The dual of this statement is then

$$Z_{m_1,\ldots,m_N}\left(X_1,\ldots,X_N\right)=0 \text{ if } \sum_i m_i > n.$$

We will call the sum of all indices $\sum m_i$ the **order** of the trace $Z_{m_1,\ldots,m_N}$. That an invariant of order higher than the size of the matrix is zero reduces, as expected, to the usual property of matrix invariants when we have a single matrix, and together with expression (4.2) ensures that only a finite number of Z invariants for any given set of X_i is non-zero.

We can also take a dual of equation (4.4), which is the well known

$$Z_n\left(X\right)=\det\left(X\right)$$

or

$$1=\det\left(X\right)Z_n\left(X^{-1}\right).$$

Now, this statement gets interesting when we introduce more matrices. Consider the two matrix case,

$$Z_{l,m}\left(A,B\right)=\det\left(A\right)Z_{n-l-m,m}\left(A^{-1},A^{-1}B\right)$$

and set $A=X$, $B=XY$, and $l+m=n$,

$$Z_{n-m,m}\left(X,XY\right)=\det\left(X\right)Z_{0,m}\left(X^{-1},Y\right)=\det\left(X\right)Z_m\left(Y\right).$$

This, which is the generalization of

$$\det\left(XY\right)=\det\left(X\right)\det\left(Y\right),$$

allows us to decompose order n invariants of a product into products of invariants. In particular, we get the $n=2$ expression with which we built the ODE system.

More generally,

$$Z_{n-\sum m_i,m_1,\ldots,m_N}\left(X,XY_1,\ldots,XY_N\right)=\det\left(X\right)Z_{m_1,\ldots,m_N}\left(Y_1,\ldots,Y_N\right). \tag{4.6}$$

 ISBN: 978-84-617-8694-7

4.3 Small-ε expansion

By using expression (4.1) we can easily derive distributivity properties, which can be applied to calculate

$$\begin{aligned}
&Z_{l,m_1,\dots,m_N}\left(A_1+\varepsilon A_2+O\left(\varepsilon^2\right),B_1,\dots,B_N\right)\\
=&\sum_{i=0}^{l}\varepsilon^i Z_{l-i,i,m_1,\dots,m_N}\left(A_1,A_2+O\left(\varepsilon\right),B_1,\dots,B_N\right)\\
=&\sum_{i=0}^{l}\varepsilon^i \left[Z_{l-i,i,m_1,\dots,m_N}\left(A_1,A_2,B_1,\dots,B_N\right)+O\left(\varepsilon\right)\right]\\
=&\sum_{i=0}^{1}\varepsilon^i Z_{l-i,i,m_1,\dots,m_N}\left(A_1,A_2,B_1,\dots,B_N\right)+O\left(\varepsilon^2\right)\\
=&Z_{l,m_1,\dots,m_N}\left(A_1,B_1,\dots,B_N\right)+\varepsilon Z_{l-1,1,m_1,\dots,m_N}\left(A_1,A_2,B_1,\dots,B_N\right)+O\left(\varepsilon^2\right).
\end{aligned}$$

4.4 Derivatives

As we have seen before, the derivatives of the invariants play an essential role in the theory. We would now like to have a formula for derivatives of the form

$$\frac{\mathrm{d}}{\mathrm{d}t}Z_m\left(X\left(t\right)\right).$$

Consider

$$Z^{(m_0,m_1,m_2,\dots)}\left(X\right):=Z_{m_0,m_1,m_2,\dots}\left(X,X',X'',\dots\right),$$

such that for some N we have $m_i=0$ for every $i>N$.

We can retrieve its first derivative from its Taylor series, which we can in turn get from its small ε expansion.

$$\begin{aligned}
&Z^{(m_0,m_1,\dots)}\left(X+\varepsilon X'+O\left(\varepsilon^2\right)\right)\\
=&Z^{(m_0,m_1,m_2,\dots)}\left(X\right)+\varepsilon\left(m_1+1\right)Z_{m_0-1,m_1+1,m_2,\dots}\left(X,X',X'',\dots\right)\\
&+\varepsilon\left(m_2+1\right)Z_{m_0,m_1-1,m_2+1,\dots}\left(X,X',X'',\dots\right)+\cdots
\end{aligned}$$

Taking the ε term we get the first coefficient of the Taylor series, i. e., the first derivative,

$$\left(Z^{(m_0,m_1,m_2,\dots)}\left(X\right)\right)'=\sum_{i=1}^{\infty}\left(m_i+1\right)Z^{(m_0,\dots,m_{i-1}-1,m_i+1,\dots)}\left(X\right).$$

Notice that the infinite sum is merely formal, since by equation (4.2) it is guaranteed to terminate as soon as all the remaining m_i are 0, due to the $m_{i-1}-1$ index at every term.

 ISBN: 978-84-617-8694-7

For the first few derivatives, we find via recursion the general expressions

$$\begin{aligned} Z_m(X)' &= \left(Z^{(m)}\right)' = Z^{(m-1,1)}, \\ Z_m(X)'' &= \left(Z^{(m)}\right)'' = 2Z^{(m-2,2)} + Z^{(m-1,0,1)}, \\ Z_m(X)''' &= \left(Z^{(m)}\right)''' = 6Z^{(m-3,3)} + 3Z^{(m-2,1,1)} + Z^{(m-1,0,0,1)}. \end{aligned}$$

Something very important (albeit somehow obvious, following Leibniz's rule for matrices), is that the order of the invariants involved in the expressions is preserved.

This allows us to use the factorization formula (4.6) over the derivatives of the determinant, which corresponds to Z_n.

As a small note, if we take in the first derivative $m = n$ together with expression (4.5), we get

$$\det(X)' = Z_{n-1,1}\left(X, X'\right) = \det(X)\, Z_1\left(X^{-1}X'\right) = \det(X)\,\mathrm{Tr}\left(X^{-1}X'\right),$$

the usual Liouville's Formula.

4.5 Application to the differential system of invariants for n > 2

In the matrix dimension $m = 2$ case, taking derivatives of the determinant eventually closes, since $X'' = XE$. This follows from

$$\det(X)'' = Z_m(X)'' = 2Z^{(m-2,2)}(X) + Z^{(m-1,0,1)}(X).$$

The $Z^{(m-1,0,1)}(X)$ can be immediately rewritten as a determinant by using the duality formula,

$$Z_{m-1,0,1}(X, X', X'') = \det(X) Z_1(X^{-1}X'') = \det(X)\,\mathrm{tr}(E),$$

and, when $m = 2$,

$$Z^{(m-2,2)}(X) = Z^{(0,2)}(X) = \det(X').$$

Of course, now we can do the same for X',

$$\det(X')'' = 2Z^{(m-2,2)}(X) + Z^{(m-1,0,1)}(X)$$

and, for $m = 2$,

$$\det(X')'' = 2\det(X'') + \det(X')\,\mathrm{tr}(E) = 2\det(E)\det(X) + \det(X')\,\mathrm{tr}(E),$$

closing the system as we had found in Theorem 1.2. The problem is now obvious, since for $m > 2$, $Z^{(m-2,2)}(X)$ will involve a non trivial product between X and X'. One could consider this as a new variable for the system, but its derivatives will now concern objects

 ISBN: 978-84-617-8694-7

of the form $Z^{(m-2,1,1)}(X)$ which, if understood as yet another variable of the system, would yield upon derivation

$$Z^{(m-2,1,0,1)}(X),\ Z^{(m-2,1,0,0,1)}(X),\ Z^{(m-2,1,0,\ldots,0,1)},\ldots$$

Notice that this will always involve a term in X', and a term in X, so that we cannot perform the same trick as we did for $Z^{(m-1,0,1)}(X)$ –namely, using $X'' = XE$ to factor the determinant out. Hence, the system of second derivatives of invariants for $m > 2$ does not close.

Abstract

The Basel Committee of Banking Supervision has recently set out the revised standards for minimum capital requirements for market risk. The Committee has focused, among others, on the two key areas of moving from Value-at-Risk (VaR) to Expected Shortfall (ES) and considering a comprehensive incorporation of the risk of market illiquidity by extending the risk measurement horizon. The estimation of the ES for several trading desks and taking into account different liquidity horizons is computationally very involved. We present a novel numerical method to compute the VaR and ES of a given portfolio within the stochastic holding period framework. Two approaches are considered, the delta-gamma approximation, for modelling the change in value of the portfolio as a quadratic approximation of the change in value of the risk factors, and some of the state-of-the-art stochastic processes for driving the dynamics of the log-value change of the portfolio like the Merton jump-diffusion model and the Kou model. Central to this procedure is the application of the SWIFT method developed for option pricing, that appears to be a very efficient and robust Fourier inversion method for risk management purposes.

Key words: market risk, liquidity risk, stochastic liquidity horizon, value-at-risk, expected shortfall, Fourier transform inversion, Shannon wavelets.

MSC 2000: 91G60, 62P05, 60E10, 65T60

1 Introduction

The Basel Committee of Banking Supervision states in the consultative documents [1, 2] that *"the financial crisis exposed material weaknesses in the overall design of the framework for capitalising trading activities. The level of capital required against trading book*

exposures proved insufficient to absorb losses". Within the mentioned documents, the Basel Committee initiated a fundamental review of the trading book regime, beginning with an assessment of those things that went wrong. The revised standards for minimum capital requirements for market risk were recently established in [3].

The Committee has focused, among others, on the two key areas of moving from VaR to ES and considering a comprehensive incorporation of the risk of market illiquidity. In regards to the first issue, a number of weaknesses have been identified with using VaR for determining regulatory capital requirements, including its inability to capture the risk in the tail. For this reason, the Committee has considered alternative risk metrics like, in particular, the ES, which measures the riskiness of a position by considering both the size and the likelihood of losses above a certain confidence level. The second issue relies on the importance of incorporating the risk of market illiquidity as a key consideration in banks' regulatory capital requirements for trading portfolios. The assumption that trading book risk positions where liquid, i.e., that banks could exit or hedge these positions over a ten-day horizon proved to be false during the recent crisis.

The estimation of the ES for several trading desks and taking into account different liquidity horizons is computationally very involved. In this work we present some of the results obtained in [5]. We compute the VaR and ES risk measures of a market portfolio and we assume that the holding period follows a certain positive stochastic process to account for liquidity risk. We will therefore measure the risk in the situation where the holding period is the liquidity horizon. To our best knowledge, this idea was first introduced in [4] as a proposal to open a research effort in stochastic holding period models for risk measures. In that paper the authors assume that the log-return on the portfolio value is normally distributed, which facilitates the calculation of the risk measures. Within this work, we give a step further by considering more realistic models for the log-value of the portfolio. On the one hand we propose the use of the delta-gamma approach, where it is assumed that the change in portfolio value is a quadratic function of the changes in the risk factors. On the other hand, we consider the Merton jump diffusion model and the Kou model to drive the log-return on the portfolio value. Under any of these scenarios, the closed formulae to compute the risk measures within the Gaussian setting in [4] are not available anymore.

2 Risk measures and stochastic liquidity horizon

Let us assume that the liquidity horizon follows a certain stochastic process $\{H(t)\}_{t\geq 0}$ where $H(t)$ is a positive random variable associated to the liquidity horizon at time $t \geq 0$. Let $V(t)$ be the value of the portfolio under consideration at time t. We are interested in measuring the change in value of the portfolio within the stochastic liquidity horizon framework. To do this, we consider two different approaches. The first one is the well-known delta-gamma approximation, which assumes that the change in value of the portfolio is a quadratic

 ISBN: 978-84-617-8694-7

function of the change in value of the risk factors. Within the present context of stochastic liquidity horizon, the change in value of the portfolio under the delta-gamma approach is defined as $\Delta V := V(t + H(t)) - V(t)$. To our best knowledge, this is the first time that the delta-gamma approach is considered with an stochastic holding period. The second approach consists of assuming that the value of the portfolio follows a certain stochastic process and we are therefore interested in measuring the change in the log-value of the portfolio rather than in the value itself. Then, we define $X := \ln(V(t + H(t))) - \ln(V(t))$. Let $f_{\Delta V}$ (respectively f_X) be the probability density function (PDF) of ΔV (respectively X) and $F_{\Delta V}$ (respectively F_X) its cumulative distribution function (CDF). If we assume that we short the portfolio, then the right tail of f_X represents losses. Given some confidence level $\alpha \in (0, 1)$, the VaR to measure the risk of holding the portfolio during the stochastic period $H(t)$ is given by the smallest number l such that the probability that the loss X exceeds l is no larger than $1 - \alpha$, where typically $\alpha \geq 0.95$. Formally,

$$\mathrm{VaR}(\alpha) := \inf\{l \in \mathbb{R} : \mathbb{P}(X > l) \leq 1 - \alpha\} = \inf\{l \in \mathbb{R} : F_X(l) \geq \alpha\}. \tag{1}$$

By definition, ES is related to VaR by,

$$\mathrm{ES}(\alpha) := \frac{1}{1-\alpha} \int_\alpha^1 \mathrm{VaR}(u)\, du.$$

Instead of fixing a particular level α, we average VaR over all levels $u \geq \alpha$. Obviously, $\mathrm{ES}(\alpha)$ depends only on the distribution of X, and $\mathrm{ES}(\alpha) \geq \mathrm{VaR}(\alpha)$. For continuous loss distributions an even more intuitive expression can be derived that shows that ES can be interpreted as the expected loss that is incurred in the event that VaR is exceeded. For an integrable loss X with continuous distribution function F_X and for any $\alpha \in (0, 1)$ we have,

$$\mathrm{ES}(\alpha) = \mathbb{E}(X | X \geq \mathrm{VaR}(\alpha)),$$

or, in integral form,

$$\mathrm{ES}(\alpha) = \frac{1}{1-\alpha} \int_{\mathrm{VaR}(\alpha)}^{+\infty} x f_X(x)\, dx. \tag{2}$$

Note that when we work under the delta-gamma approach, then we replace X, F_X, f_X by $\Delta V, F_{\Delta V}, f_{\Delta V}$ in (1) and (2). It is worth remarking that ES is a coherent measure of risk, satisfying in particular, the axiom of sub-additivity in line with the concept of diversification.

In practice, analytical expressions are not available, and Monte Carlo (MC) simulation is often used to compute the risk measures, being the main drawback the computational effort. From this point of view, the situation worsens when we consider a stochastic liquidity horizon $H(t)$, since an extra source of randomness is introduced and must be simulated as well. For this reason, there is an increasing interest in looking for alternative and more efficient methods. Here we propose the SWIFT method, which was originally developed for

 ISBN: 978-84-617-8694-7

European options pricing in [6]. The SWIFT method gives us an accurate and extremely fast recovery of the density function and we give a prescription on how to select the parameters appearing in the numerical method. All these features make our proposal efficient, robust and reliable for practical implementations.

The Neumann Problem for Bending of Elastic Plates

Christian Constanda[1] **and Dale Doty**[1]

[1] *Department of Mathematics, The University of Tulsa*

emails: christian-constanda@utulsa.edu, dale-doty@utulsa.edu

Abstract

A generalized Fourier series method is constructed to approximate the solution of the Neumann problem in a finite domain for the system of equations governing the bending of elastic plates with transverse shear deformation. The method is illustrated by an example with computation performed by four different techniques that are contrasted and compared for efficiency, accuracy, and stability.

Key words: elastic plates, Neumann problem, generalized Fourier series

Solutions of boundary value problems for an elliptic mathematical model can be approximated by expanding them in a complete set of functions in a conveniently chosen space—for example, L^2. The technique becomes more user-friendly when these functions are closely connected with the structure of the layer potentials constructed for the problem. Computation based on such expansions, however, is hampered by the fact that the Gram–Schmidt process used to orthonormalize the selected set is numerically unstable and, to our knowledge, has not been properly brought under control, particularly in the case of Neumann-type boundary conditions. In what follows, we aim to indicate a procedure that circumvents this obstacle and leads to excellent numerical results to within a prescribed accuracy. The technique is illustrated in application to an interior Neumann problem for the system governing the bending of elastic plates with transverse shear deformation.

Let S be a finite domain in $\mathbb{R}^2$ bounded by a simple, closed, C^2-curve ∂S, let x and y be generic points in S or on ∂S, and let $h_0 = \text{const} > 0,\ h_0 \ll \text{diam}\, S$. We assume that the three-dimensional region $(S \cup \partial S) \times [-h_0/2, h_0/2]$ is occupied by a homogeneous and isotropic elastic material with Lamé constants λ and μ, and write $h^2 = h_0^2/12$.

The Neumann problem for the process of bending is

$$A(\partial_1, \partial_2)u(x) = 0,\ \ x \in S, \quad T(\partial_1, \partial_2)u(x) = \mathcal{Q}(x),\ \ x \in \partial S, \tag{1}$$

ISBN: 978-84-617-8694-7

where the partial differential operators A and T are

$$A(\partial_1,\partial_2)=\begin{pmatrix} h^2\mu\Delta+h^2(\lambda+\mu)\partial_1^2-\mu & h^2(\lambda+\mu)\partial_1\partial_2 & -\mu\partial_1\\ h^2(\lambda+\mu)\partial_1\partial_2 & h^2\mu\Delta+h^2(\lambda+\mu)\partial_2^2-\mu & -\mu\partial_2\\ \mu\partial_1 & \mu\partial_2 & \mu\Delta \end{pmatrix},$$

$$T(\partial_1,\partial_2)=\begin{pmatrix} h^2(\lambda+2\mu)\nu_1\partial_1+h^2\mu\nu_2\partial_2 & h^2\mu\nu_2\partial_1+h^2\lambda\nu_1\partial_2 & 0\\ h^2\lambda\nu_2\partial_1+h^2\mu\nu_1\partial_2 & h^2\mu\nu_1\partial_1+h^2(\lambda+2\mu)\nu_2\partial_2 & 0\\ \mu\nu_1 & \mu\nu_2 & \mu(\nu_1\partial_1+\nu_2\partial_2) \end{pmatrix},$$

$u=(u_1,u_2,u_3)^{\mathrm{T}}$ is a vector characterizing the displacements and $\nu=(\nu_1,\nu_2)^{\mathrm{T}}$ is the unit vector of the outward normal to ∂S. We also consider the matrix of fundamental solutions $D(x,y)$ computed in [1] and the associated matrix $P(x,y)=(T(\partial_y)D(y,x))^{\mathrm{T}}$.

Problem (1) is solvable for any $\mathcal{Q}\in C^{(0,\alpha)}(\partial S)$, $\alpha\in(0,1)$, iff

$$\int\limits_{\partial S}(\mathcal{Q}_\alpha-x_\alpha\mathcal{Q}_3)\,ds=0,\ \ \alpha=1,2,\quad \int\limits_{\partial S}\mathcal{Q}_3\,ds=0. \tag{2}$$

The solution $u\in C^2(S)\cap C^1(S\cup\partial S)$ is unique up to a rigid displacement [1].

According to Somigliana's representation formula,

$$\phi(x)u(x)=-\int\limits_{\partial S}P(x,y)\rho(y)\,ds(y)+\mathcal{L}(x),\quad x\in\mathbb{R}^2, \tag{3}$$

where

$$\phi(x)=\begin{cases}1, & x\in S,\\ 1/2, & x\in\partial S,\\ 0, & x\in\mathbb{R}^2\setminus(S\cup\partial S),\end{cases}$$

ρ is the trace of u on ∂S, and

$$\mathcal{L}(x)=\int\limits_{\partial S}D(x,y)\mathcal{Q}(y)\,ds(y),\quad x\in\mathbb{R}^2. \tag{4}$$

Let S be a disk of radius r centered at origin, let ∂S_* be a circle of radius $r_*>r$, also centered at the origin, and let $\{x^{(k)}\}_{k=1}^{\infty}$ be a set of points densely distributed on ∂S_*. We construct the vector functions

$$\tau^{(jk)}(x)=T(\partial_x)D^{(j)}(x,x^{(k)}),\quad k=1,2,\dots,$$

where $D^{(j)}$ are the columns of D. The set of these functions, which are the rows of $P(x^{(k)},x)$, augmented with a basis for the space of rigid displacements, is linearly independent on ∂S

 ISBN: 978-84-617-8694-7

and complete in $L^2(\partial S)$. We re-order the sequence $\{\tau^{(11)}, \tau^{(21)}, \tau^{(31)}, \tau^{(12)}, \tau^{(22)}, \tau^{(32)}, \ldots\}$ as $\{\tau^{(1)}, \tau^{(2)}, \tau^{(3)}, \tau^{(4)}, \tau^{(5)}, \tau^{(6)}, \ldots\}$ and orthonormalize it to obtain a sequence $\{\eta^{(k)}\}_{k=1}^{\infty}$.

Seeking an approximation of the unknown vector function ρ in the form

$$\rho^{(n)} = \sum_{k=1}^{n} \langle \eta^{(k)}, \rho \rangle \eta^{(k)} = \sum_{k=1}^{n} \sum_{i=1}^{k} \tilde{r}_{ik} \langle \tau^{(i)}, \rho \rangle \left(\sum_{j=1}^{k} \tilde{r}_{jk} \tau^{(j)} \right), \quad n = 1, 2, \ldots, \tag{5}$$

where the $\tilde{r}_{ik}$ are the orthonormalization coefficients and $\langle \cdot, \cdot \rangle$ is the inner product on $L^2(\partial S)$, we use (3) to construct (up to an arbitrary rigid displacement) the approximate solution

$$u^{(n)}(x) = -\int_{\partial S} P(x, y) \rho^{(n)}(y)\, ds(y) + \mathcal{L}(x), \quad x \in S. \tag{6}$$

From (3) with $x \in \mathbb{R}^2 \setminus (S \cup \partial S)$ replaced by $x^{(k)}$ it follows that

$$\int_{\partial S} P(x^{(k)}, x) \rho(x)\, ds(x) = \mathcal{L}(x^{(k)}),$$

so, given the definitions of P and $\tau^{(jk)}$, we have $\langle \tau^{(jk)}, \rho \rangle = \mathcal{L}_j(x^{(k)})$ for $j = 1, 2, 3$ and $k = 1, 2, \ldots$, or, after re-indexing,

$$\langle \tau^{(3(k-1)+j)}, \rho \rangle = \mathcal{L}_j(x^{(k)}), \quad j = 1, 2, 3, \quad k = 1, 2, \ldots. \tag{7}$$

In conclusion, $u^{(n)}$ is given by (6), with $\rho^{(n)}$ computed from (5), $\langle \tau^{(i)}, \rho \rangle$ from (7), and $\mathcal{L}_j(x^{(k)})$ from (4). The sequence $u^{(n)}$ converges uniformly in the L^2-norm on any closed subdomain of S to a solution u of the problem. This solution may contain a specific rigid displacement, which can be easily identified.

As an illustration of the method, we choose $\lambda = \mu = 1$, $h = 0.5$, $r = 1$, $r_* = 2$,

$$\{x^{(1)}, x^{(2)}, x^{(3)}, \ldots\}_{\text{Cartesian}} = \{(2, 0), (2, \pi), (2, \pi/2), (2, 3\pi/2), (2, \pi/4), \ldots\}_{\text{Polar}},$$
$$\mathcal{Q}(x)|_{x_1 = \cos\theta,\, x_2 = \sin\theta} = \big(6\cos\theta + 3\cos(3\theta) - 20\cos(4\theta),$$
$$- 6\sin\theta + 3\sin(3\theta) + 20\sin(4\theta),\, 18\cos(2\theta)\big)^{\mathrm{T}}.$$

It is easy to verify that $\mathcal{Q}$ satisfies the solvability conditions (2).

The set $\{\tau^{(k)}\}_{k=1}^{\infty}$ is orthonormalized by three different procedures: the classical Gram–Schmidt (CGS), the modified Gram–Schmidt (MGS), and the Householder reflections (HR) (see [2] and [3]). We also use a fourth technique, which, based on row reduction, obviates the need for orthonormalization. Below are the results obtained by the MGS method.

Fig. 1 displays the three components of $u^{(150)}$ in S, and the approximate computed traces of these components on ∂S. Fig. 2 shows the corresponding computational errors. The curves on the left in Fig. 3 are the graphs (in terms of the polar angle) of the computed

 ISBN: 978-84-617-8694-7

traces of the components of $u^{(150)}$ on ∂S. The graph on the right in Fig. 3 (drawn in a logarithmic scale) indicates the exponential convergence in the L^2-norm of the sequence of approximations to the exact solution as the number of the sample points $x^{(k)}$ increases.

The solution u constructed in this example contains no rigid displacements.

Abstract

The dynamical analysis of iterative methods without memory for solving nonlinear models, by using complex dynamics tools, is a very useful technique to study their stability and reliability. A parametric family of order four, applied on quadratic polynomials, gives us a rational operator whose dynamics is studied. The stability of its fixed points, in terms of the value of the parameter, its critical points and their associated parameter planes, etc. give us important information about which members of the family have good properties of stability and whether in any of them appear chaos in the iterative process.

Key words: Iterative methods, nonlinear equations, stability, parameter plane, basin of attraction, rational operator

1 Introduction

The design of fixed point iterative schemes for solving equations and systems of nonlinear equations is an important and challenging task in the field of Numerical Analysis. To find the solution x^* of a nonlinear equation $f(x) = 0$, $f : I \subseteq \mathbb{R} \to \mathbb{R}$, or a nonlinear system $F(x) = 0$, $F : D \subseteq \mathbb{R}^n \to \mathbb{R}^n$, is a classical and difficult problem with many applications in Science and Engineering.

In the last years, many iterative methods have been constructed for solving these type of problems, see for example [1] and [2] and the references therein. Many times, the researchers design a parametric family of iterative methods, all of them with the same order of convergence but, all members have the same stability? Does the width of the basins of attraction depend on the value of the parameter?, Which elements of the family have

 ISBN: 978-84-617-8694-7

chaotic behavior?, ... We can found the answer of these and other questions by analyzing the dynamical behavior of the rational operator associated to the iterative method on low degree polynomials.

Our goal in this paper is to carry out a dynamical study of the parametric family of iterative methods designed for solving nonlinear equations $f(x) = 0$. The idea for constructing this class appears in [3]. By using tools of complex dynamics we analyze the stability of the fixed points of the rational operator that appears when our family is applied on an arbitrary second degree polynomial. The parameter plane associated to each critical point gives us important information about the stability of the elements of the family and which of them have unstable behavior.

Now, we are going to recall some dynamical concepts of complex dynamics that we use in this work. Given a rational function $R : \hat{\mathbb{C}} \to \hat{\mathbb{C}}$, where $\hat{\mathbb{C}}$ is the Riemann sphere, the *orbit of a point* $z_0 \in \hat{\mathbb{C}}$ is defined as:

$$\{z_0,\, R(z_0),\, R^2(z_0), \ldots, R^n(z_0), \ldots\}.$$

We analyze the phase plane of the map R by classifying the starting points from the asymptotic behavior of their orbits. A $z_0 \in \hat{\mathbb{C}}$ is called a *fixed point* if $R(z_0) = z_0$. A *periodic point* z_0 of period $p > 1$ is a point such that $R^p(z_0) = z_0$ and $R^k(z_0) \neq z_0$, for $k < p$. A *pre-periodic point* is a point z_0 that is not periodic but there exists a $k > 0$ such that $R^k(z_0)$ is periodic. A *critical point* z_0 is a point where the derivative of the rational function vanishes, $R'(z_0) = 0$. Moreover, a fixed point z_0 is called *attractor* if $|R'(z_0)| < 1$, *superattractor* if $|R'(z_0)| = 0$, *repulsor* if $|R'(z_0)| > 1$ and *parabolic* if $|R'(z_0)| = 1$.

The basin of attraction of an attractor α is defined as:

$$\mathcal{A}(\alpha) = \{z_0 \in \hat{\mathbb{C}} \,:\, R^n(z_0) \to \alpha,\ n \to \infty\}.$$

The *immediate basin of attraction* of an attractor is the connected component of its basin of attraction that holds the attractor.

The *Fatou set* of the rational function R, $\mathcal{F}(R)$, is the set of points $z \in \hat{\mathbb{C}}$ whose orbits tend to an attractor (fixed point, periodic orbit or infinity). Its complement in $\hat{\mathbb{C}}$ is the *Julia set*, $\mathcal{J}(R)$. That means that the basin of attraction of any fixed point belongs to the Fatou set and the boundaries of these basins of attraction belong to the Julia set.

The following theorem establishes a classical result of Fatou and Julia that we use in the study of parameter space associated to the family.

Theorem 1 *Let R be a rational function. The immediate basin of attraction of an attracting fixed or periodic point holds, at least, a critical point.*

By using this result, one can be sure to find all the stable behavior associated to a rational function R, by analyzing the performance of R on the set of critical points.

 ISBN: 978-84-617-8694-7

1.1 The parametric family

By adding a new step to Newton's method, we construct the following two-step scheme

$$\begin{aligned} y_k &= x_k - \frac{f(x_k)}{f'(x_k)}, \\ x_{k+1} &= y_k - \left(\alpha_1 + \alpha_2 \frac{f'(x_k)}{f'(y_k)} + \alpha_3 \left(\frac{f'(x_k)}{f'(y_k)}\right)^2\right) \frac{f(y_k)}{f'(y_k)}, \quad k = 0, 1, \ldots, \end{aligned} \tag{1}$$

where α_1, α_2 and α_3 are free parameters.

The following result establishes the convergence of family (1).

Theorem 2 *Let $f : I \subseteq \mathbb{R} \to \mathbb{R}$ be a sufficiently differentiable function in an open interval I and $x^* \in I$ a root of equation $f(x) = 0$. Choosing an initial approximation x_0 close enough to x^*, the iterative scheme defined by (1) has fourth-order convergence when $\alpha_2 = 3 - 2\alpha_1$ and $\alpha_3 = -2 + \alpha_1$, being α_1 a free parameter. In particular, if $\alpha_1 = \frac{5}{4}$ then method (1) has order five.*

Which is the relation between the values of the free parameter α_1 and the stability of the corresponding iterative method? Under the point of view of complex dynamics, we are going to study the general convergence of the families on quadratic polynomials. It is known that, if the iterative method satisfies the scaling theorem (and family (1) doesw), the roots of a polynomial can be transformed by an affine map with no qualitative changes on the dynamics of the family. So, we can use a generic quadratic polynomial $p(z) = (z-a)(z-b)$. The rational operator obtained when family (1) is applied on $p(z)$ has the expression:

$$\begin{aligned} T_{p,\alpha_1,a,b}(z) &= \frac{(a-z)(b-z)}{a+b-2z} + z \\ &+(a-z)^2(b-z)^2 \left[\frac{(a^4+b^4-4a^3z-4b^3z+4(1+\alpha_1)b^2z^2-8\alpha_1 bz^3}{(a+b-2z)(a^2+b^2-2az-2bz+2z^2)^3}\right. \\ &+\frac{4\alpha_1 z^4 - 4az((-1+2\alpha_1)b^2+(2-4\alpha_1)bz+2\alpha_1 z^2)}{(a+b-2z)(a^2+b^2-2az-2bz+2z^2)^3} \\ &\left.+\frac{a^2((-2+4\alpha_1)b^2+(4-8\alpha_1)bz+4(1+\alpha_1)z^2))}{(a+b-2z)(a^2+b^2-2az-2bz+2z^2)^3}\right], \end{aligned}$$

depending on parameter α_1 and also on the roots of the polynomial a and b.

Blanchard in [4] considered the conjugacy map $h(z) = \dfrac{z-a}{z-b}$, (a Möbius transformation) with the following properties:

$$\text{i)}\ \ h(\infty) = 1, \qquad \text{ii)}\ \ h(a) = 0, \qquad \text{iii)}\ \ h(b) = \infty,$$

and proved that, for quadratic polynomials, Newton's operator is conjugate to the rational map z^2. In an analogous way, operator $T_{p,\alpha_1,a,b}(z)$ on quadratic polynomials is conjugated to operator $O_{\alpha_1}(z)$,

 ISBN: 978-84-617-8694-7

$$O_{\alpha_1}(z) = \left(h \circ T_{p,\alpha_1,a,b} \circ h^{-1}\right)(z) = -z^4 \frac{5 - 4\alpha_1 + 2z^2 + z^4}{-1 - 2z^2 + -5z^4 + 4\alpha_1 z^4}, \tag{2}$$

We observe that parameters a and b have been obviated in $O_{\alpha_1}(z)$.

In the following sections we study the fixed and critical points of operator $O_{\alpha_1}(z)$, the stability of the fixed points, the parameter plane associated to the family and some dynamical planes describing different behavior: stability, periodic orbits, ...

2 Analysis of the fixed and critical points

Firstly, we study the fixed points of the rational function $O_{\alpha_1}(z)$ that are not related with the original roots of the polynomial $p(z)$ (called *strange fixed points*), and the *free critical points*, that is, the critical points of $O_{\alpha_1}(z)$ different from 0 and ∞, which are associated to the roots of $p(z)$.

Fixed points of $O_{\alpha_1}(z)$ are the roots of equation $O_{\alpha_1}(z) = z$, that is, $z = 0$, $z = \infty$ and the strange fixed points $ex_1(\alpha_1) = 1$ and the roots of the polynomial

$$r(\alpha_1, z) = 1 + z + 3z^2 + (-2 + 4\alpha_1)z^3 + 3z^4 + z^5 + z^6,$$

that are denoted by $ex_i(\alpha_1)$, $i = 2, 3, 4, 5, 6, 7$.

Therefore, there are seven strange fixed points, except in the following cases:

i) If $\alpha_1 = 1$, then the operator is $O_1(z) = z^4$, so there are no strange fixed points.

ii) If $\alpha_1 = 2$, then the operator is $O_2(z) = -z^4 \frac{3+z^2}{1+3z^2}$. There are only six strange fixed points as $ex_2(\alpha_1) = ex_3(\alpha_1) = -1$.

iii) If $\alpha_1 = -2$, there are only five strange fixed point as $ex_2(\alpha_1) = ex_3(\alpha_1) = 1$.

On the other hand, in order to determine the critical points, we calculate the first derivative of $O_{\alpha_1}(z)$:

$$O'_{\alpha_1}(z) = -4z^3 \frac{(1+z^2)^2(-5 + 4\alpha_1 + 2(1 - 2\alpha_1)z^2 + (-5 + 4\alpha_1)z^4)}{(1 + 2z^2 + (5 - 4\alpha_1)z^4)^2}.$$

As we have said, a classical result establishes that there is, at least, one critical point associated with each invariant Fatou component. Due to the order of convergence of the methods under study, it is clear that $z = 0$ and $z = \infty$ (related to the roots of the polynomial by means of Möbius map) are critical points and give rise to their respective Fatou components, but there exist in the family some free critical points, some of them depending on the value of the parameter.

Proposition 1 *By analyzing the equation $O'_{\alpha_1}(z) = 0$ of the family, we obtain:*

 ISBN: 978-84-617-8694-7

a) If $\alpha_1 = 1$ there is no free critical points of operator $O_{\alpha_1}(z)$.

b) If $\alpha_1 = 2$ or $\alpha_1 = \frac{5}{4}$, then $z = -i$ and $z = i$ are the only free critical points.

c) In any other case,

$$cr_1(\alpha_1) = -i,$$

$$cr_2(\alpha_1) = i,$$

$$cr_3(\alpha_1) = -\sqrt{\frac{1 - 2\alpha_1 + 2\sqrt{3}\sqrt{-2 + 3\alpha_1 - \alpha_1^2}}{5 - 4\alpha_1}},$$

$$cr_4(\alpha_1) = \sqrt{\frac{1 - 2\alpha_1 + 2\sqrt{3}\sqrt{-2 + 3\alpha_1 - \alpha_1^2}}{5 - 4\alpha_1}},$$

$$cr_5(\alpha_1) = -\sqrt{\frac{-1 + 2\alpha_1 + 2\sqrt{3}\sqrt{-2 + 3\alpha_1 - \alpha_1^2}}{-5 + 4\alpha_1}},$$

and

$$cr_6(\alpha_1) = \sqrt{\frac{-1 + 2\alpha_1 + 2\sqrt{3}\sqrt{-2 + 3\alpha_1 - \alpha_1^2}}{-5 + 4\alpha_1}},$$

are free critical points.

Let us remark that $cr_1(\alpha_1)$ and $cr_2(\alpha_1)$ are pre-images of $z = 1$ and $cr_3(\alpha_1)$ and $cr_5(\alpha_1)$ are conjugated, as well as $cr_4(\alpha_1)$ and $cr_6(\alpha_1)$. Therefore, we only have two independent free critical points.

3 Stability of the fixed points

Of course, $z = 0$ and $z = \infty$ are superattracting fixed points but, which is the character of the rest of fixed points? The following results answer this question.

The character of the strange fixed point $ex_1(\alpha_1) = 1$ of the family, $\alpha_1 \neq 2$, is as follows:

i) If $|\alpha_1 - 2| > 4$, then $ex_1(\alpha_1) = 1$ is an attractor.

ii) When $|\alpha_1 - 2| = 4$, $ex_1(\alpha_1) = 1$ is a parabolic point.

 ISBN: 978-84-617-8694-7

iii) If $|\alpha_1 - 2| < 4$, then $ex_1(\alpha_1) = 1$ is a repulsor.

The analysis of the stability of strange fixed points $ex_i(\alpha_1), i = 2, 3, 4$ shows that they are repulsors for any value of the parameter. Finally, the character of the strange fixed points $ex_i(\alpha_1), i = 5, 6$ is as follows:

i) If $|\alpha_1 + 1| < 1$, then both points are attractors.

ii) When $|\alpha_1 + 1| = 1$, $ex_5(\alpha_1)$ and $ex_6(\alpha_1)$ are parabolic points.

iii) If $|\alpha_1 + 1| > 1$, then both points are repulsors.

In Figure 1, we represent the stability regions of all strange fixed points $ex_i(\alpha_1)$, $i = 1, 2, 3, 4, 5, 6$.

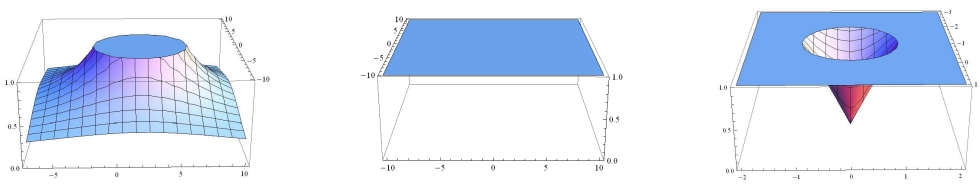

Figure 1: Stability regions of $ex_1(\alpha_1)$ (left),$ex_i(\alpha_1)$, $i = 2, 3, 4$ (middle) and $ex_i(\alpha_1)$, $i = 5, 6$ (right).

4 The parameter space

The parameter space associated with an independent free critical point of operator is obtained by associating each point of the complex plane with a value of α_1, i.e., with an element of family. Every value of the parameter belonging to the same connected component of the parameter space gives rise to subsets of schemes of the family with similar dynamical behavior. So, it is interesting to find regions of the parameter plane as much stable as possible, because these values of the parameter will give us the best members of the family in terms of numerical stability.

When we consider the independent free critical points of operator $O_{\alpha_1}(z)$ as a starting point of the iterative scheme of the family associated to each complex value of α_1, we paint this point of the complex plane in red if the method converges to any of the roots (zero and infinity) and they are black in other cases. The color used is brighter when the number of iterations is lower. Then, the parameter plane P_1 is obtained. A mesh of 500×500 points has been used, 250 has been the maximum number of iterations involved and 10^{-3} the tolerance used as a stopping criterium.

 ISBN: 978-84-617-8694-7

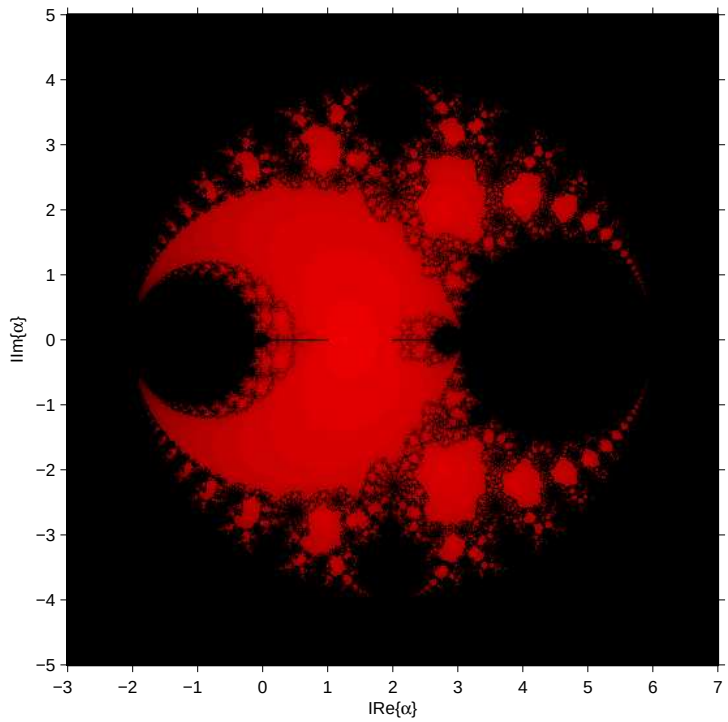

Figure 2: Parameter plane P_1 associated to $cr_i(\alpha_1)$, $i = 3, 4, 5, 6$

We obtain an only parameter plane due to the fact that $cr_4(\alpha_1)$ is equal in module to $cr_6(\alpha_1)$ and the operator's powers are even numbers. We can observe that the best real values of the parameter α_1 are between 1 and 2.

4.1 Dynamical Planes

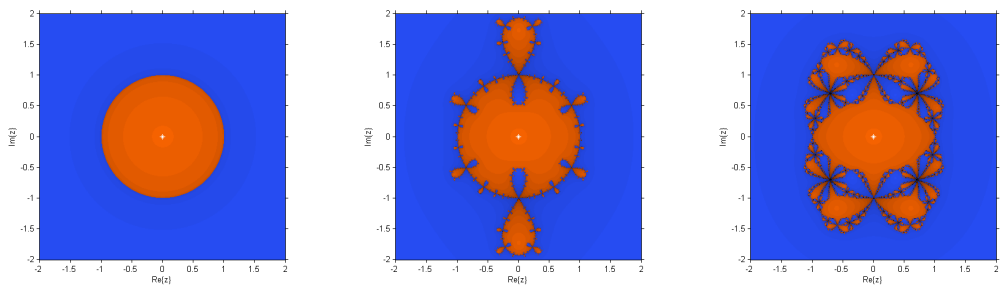
In this section we show, by means of dynamical planes, the qualitative behavior of the different elements of family. We select these elements by using the conclusions obtained by analyzing the parameter plane of the family and the stability analysis made on fixed points.

The dynamical plane associated to a value of the parameter, that is, obtained by iterating an element of family, is generated by using each point of the complex plane as initial estimation (we have used a mesh of 400×400 points). We paint in blue the points whose orbit converges to infinity, in orange the points converging to zero (with a tolerance of 10^{-3}), in other colors (green, red, etc.) those points whose orbit converges to one of the strange fixed points (all fixed points appear marked as a white star in the figures) and in black if it

 ISBN: 978-84-617-8694-7

reaches the maximum number of 40 iterations without converging to any of the fixed points.

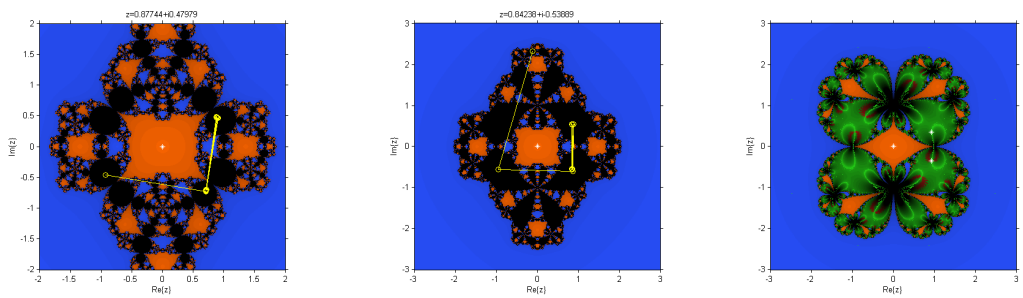
There are some regions in parameter spaces whose corresponding iterative methods have good numerical behavior, in terms of stability and efficiency. They correspond to values of the parameter painted in red. In Figure 3 we show the dynamical planes corresponding to stable values of the parameter, specifically $\alpha_1 = 1$, $\alpha_1 = 2$ and $\alpha_1 = 0.5$.



(a) $\alpha_1 = 1$ (b) $\alpha_1 = 2$ (c) $\alpha_1 = 0.5$

Figure 3: Some dynamical planes with stable behavior

On the other hand, unstable behavior is found when we choose values of α_1 in the black region of parameter plane. In Figure 4, dynamical planes corresponding to values of parameter $\alpha_1 = 3$, $\alpha_1 = 3.5$ and $\alpha_1 = -1.5$ are presented.



(a) $\alpha_1 = 3$ (b) $\alpha_1 = 3.5$ (c) $\alpha_1 = -1.5$

Figure 4: Dynamical planes with unstable behavior

In Figure 4a and 4b we can observe periodic orbits of period two, while in Figure 4c four basins of attraction appear, two of them corresponding to the roots of $p(z)$ and the other ones are the basins of attraction of the strange fixed points $ex_i(\alpha_1)$, $i = 5, 6$.

Abstract

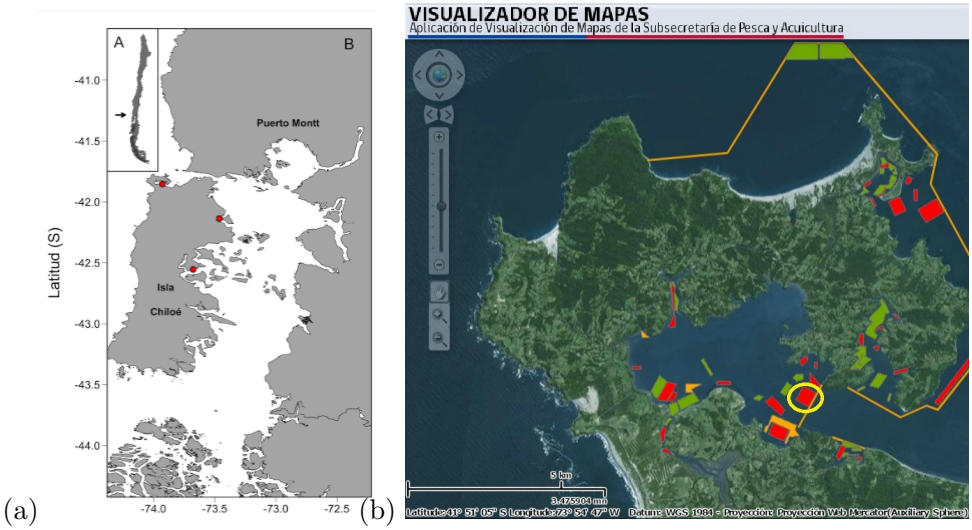
A growth mathematical model (individual-population) of biomass for *Mytilus chilensis* is introduced. This incorporates the energy variable when assuming a predation component by means of the filtering. We will assume that the prey is the phytoplankton one and the predators are the filtering organisms. A new generalized Monod type biomass gain function is considered. Some simulations based in biogeographic data are included.

Key words: biomass curve, Mytilus chilensis, mathematical model
MSC 2000: 92B05

1 Introduction

The aquaculture is a important productive sector in Chilean economy [4]. Chile is the third world producer of mollusc with with 78,500 tons of annual production [4]. The Mytiliculture is a part of this productive areas, which is concentrated in the South of Chile in Los Lagos region [4]. The *Mylitus chilensis* (Hupe 1854) is a filtering bivalve of the family Mylidae. This molluscs is widely distributed along the Chilean coast from Arica (18 degrees South) to Cape Horn (56 degrees South) [6] to depths of 25 [m] [1]. Along the latitudinal range of

 ISBN: 978-84-617-8694-7



(a) (b)

Figure 1: (a) Chiloé island. (b) Satellite image of cultures in Chiloé island, Quetalmahue sector.

Chile, the shell-shape differences in the population of *Mytilus chilensis* are highly significant [5, 12] and these are related with the latitude and origin [12].

The main objective of this work is to propose a mathematical model to predict the individual biomass growth (in average) of the *Mytilus chilensis* in suspensions cultures, in a such manner that the consulting Fishing Partners company can estimate the production in each of the growing areas (see figure 1-(b)). In mathematical terms, the main result of this work, it is the formulation of an ordinary differential equations system, which model the relation between individual growth and food, considering a set of environmental and biological parameters.

The relation between *Mytilus chilensis* and fitoplankton is assumed as an interaction prey-predator, supposing that the fouling effect is nule. The spatial-temporal scale was choice including biotics and abiotics factors. In this first approach, we have supposed that the culture area is shared among some producers. In addition, we have assumed that there exists a temporal horizon, which is the average time between sowing and spawning.

The biological and environmental main assumptions are: (i) The volume of water in the culture area is constant. (ii) The phytoplankton growth is external to the culture area. (iii) On the culture area only exists consumption of phytoplankton. (iv) The fouling is neglected. (v) The consumption of phytoplankton is proportional to its concentration. (vi)

[1]Founded by CONICYT PAI/Academia 79150021 2016-2018.

[3]Founded by Portafolio de Innovación Corfo 16GPI723

 ISBN: 978-84-617-8694-7

Assimilated energy is proportional to consumption. And, (v) the gain of biomass from the potential energy (assimilated less metabolic) is determined by a generalized Monod type function.

The resulting biomass curves (in time) are visualized with the sigmoid shape, which is similar to the individual growth curves obtained by means of statistical methods applied to predict the growth in bivalve, see [3].

2 Model deduction

2.1 Population growth

Let us consider that the culture process presents the following stage: seeding, individual growth and spawning. The model is limited at individual growth stage. We also assume that the number of individuals is only affected by detachment of the rope, since the death implies detachment. Then, denoting by δ_k *the detachment rate* at time k, it follows that

$$\delta_k = \frac{1}{n_k}\frac{n_k - n_{k+1}}{t_{k+1} - t_k}\,, \quad k = 1, \cdots, m-1\,,$$

where n_k is the number of individuals at time k. By now, the relation, in the extremes of $[t, t+\Delta t]$, is given by

$$n(t+\Delta t) = n(t)[1 - \delta\,\Delta t]\,.$$

In conclusion, the daily detachment is proportional to the numbers of individuals. Taking the limit as $\Delta t \to 0$ we obtain the differential equation

$$n'(t) = -\delta\, n(t)\,.$$

Therefore, after a intial time $t_0 > 0$ where the number of individuals is n_0, we have exponential decay given by

$$n(t) = n_0\, \exp\{\delta(t - t_0)\}, \quad \text{for} \quad t \geq t_0,$$

where t_0 is the first time of count.

Denoting by $N(t)$ the total number of individual in the culture area at t day, we can conclude that

$$N(t) = L \cdot n(t) = L\, n_0\, \exp\{\delta(t - t_0)\}, \quad \text{for} \quad t \geq t_0, \tag{1}$$

where L is the length of culture rope.

 ISBN: 978-84-617-8694-7

2.2 Phytoplankton Abundance

Let us denote the total concentration of phytoplankton in the culture area by $C(t)$ [cel/m^3]. We assume that the phytoplankton abundance is affected by the consumption of individuals and by that enters through the flow. We denote by Ω the culture zone defined as a body of water with constant volume $V\,[m^3]$ with an external flux of fresh water $Q[m^3/day]$ assuming that the same amount of water leaves Ω. Let us represent by $C^e[cel/m^3]$ the external flux of phytoplankton entering to Ω. Notice that $A(t)[cel] = C(t)[cel/m^3]\,V[m^3]$, describe the total phytoplankton on Ω at t-day and the variation during the time interval $[t, t+\Delta t]$ is given by,

$$A(t+\Delta t) - A(t) = \left[\left\{ \begin{array}{c} \text{Entering} \\ \text{for day} \end{array} \right\} - \left\{ \begin{array}{c} \text{Consumption} \\ \text{for day} \end{array} \right\} - \left\{ \begin{array}{c} \text{Outgoing} \\ \text{for day} \end{array} \right\} \right] \Delta t\,.$$

We have that,

$$\text{Entering for day} =: C^e[cel/m^3] \cdot Q[m^3/day]$$

and

$$\text{Outgoing for day} =: C(t)[cel/m^3] \cdot Q[m^3/day]\,.$$

Then, taking the limit as $\Delta t \to 0$ we obtain

$$A'(t) = C'(t)\,V = (C^e - C(t))Q - \{\text{consumption for day}\}\ .$$

Therefore,

$$C'(t) = (C^e - C(t))\,D - \frac{1}{V}\{\text{consumption for day}\}. \tag{2}$$

Noticing that $D = (Q/V)[day^{-1}]$ is the *dilution*.

2.3 Phytoplankton consumption

Let us consider that the phytoplankton consumption on Ω is dependent on: (1) The phytoplankton concentration $C(t)$ $[cel/m^3]$. (2) The total numbers of individuals $N(t)[ind]$. And, (3) The biomass $b(t)$ $[gr]$. We also assume that one unity of biomass consumes $F(C)$ $[cel/day]$ of phytoplankton and the fouling consumption is negligible. Thus, we can define $F(\cdot)$ as follows,

$$F(C)[cel/day] = \nu(t)[m^3/day] \cdot C[cel/m^3]\,.$$

where $\nu(t)$ is the number of cubic meters a unit of biomass is capable of filtering in one day and it changes with the age. We define $\nu(t)$ by

$$v(t) = \nu\frac{t}{T}\,, \tag{3}$$

where ν is the maximal consumption $[gr/m^3]$ for 1 [gr] of biomass at spawning time and T is the spawinng time.

ISBN: 978-84-617-8694-7

2.4 Energy assimilation

Let us suppose that one biomass unit of *Mytilus chilensis* transforms its consumption $F(C)[cel/day]$ into Energy represented by $E(C)\,[cal/day]$ and it is assumed proportional to $F(C)[cel/day]$

$$E(C)[cal/day] = q[cal/cel] \cdot F(C)[cel/day]\,,$$

where q denotes the amount of calories containing in one cell of phytoplankton.

2.5 Biomass gain

In [11] the author proposes that the assimilated energy is divided into biomass gain and metabolism maintenance. We denote by $\mathcal{E} = E - M$, which is the difference between the assimilated energy (E) and the one that is spent to maintain its metabolism (M).

Here, we introduce the generalized Monod function,

$$G_r(\mathcal{E}) = G_\infty \left\{ \frac{\mathcal{E}}{\mathcal{E}+a} \right\}^\alpha , \tag{4}$$

where G_∞ is a parameter of maximal efficiency. The metabolims is modeled as follows,

$$M(t) = (M_{max} - M_{min}) \left(1 - \frac{t}{T}\right) + M_{\min},$$

where M_{max} and M_{min} are the maximal and minimal metabolic spent, respectively, given in the literature [10], assuming that the metabolism is increasing respect to the age.

3 The model

The prey-predator interaction between one specie of phytoplankton (prey) and the *Mytilus chilensis* (predator) is modeled by the no linear system, non-autonomous of ordinary differential equations, that follows

$$\left\{ \begin{array}{rcl} C'(t) & = & \{C^e - C(t)\} \cdot D - \frac{L}{V} n_0 e^{-\delta t} \nu(t) C(t) b(t)\,, \\ \\ b'(t) & = & G_\infty \left\{ \frac{qM(t)\nu(t)C(t)}{qM(t)\nu(t)C(t)+a} \right\}^\alpha b(t)\,, \end{array} \right. \tag{5}$$

where $C(t)$ is the phytoplankton concentration $[gr/m^3]$ at time t [day] and $b(t)$ is the individual biomass of one *Mytilus chilensis* $[gr]$ at time t [day].

emails: fcordova@ucm.cl, rvalle@ucm.cl, kvilches@ucm.cl

Abstract

The multiplicative arithmetic is the base of the Bigeometric Calculus. In this work, we present the fundamental elements to construct a multiplicative linear algebra. Some important concepts and examples are given to visualized the effects of the multiplicative arithmetic properties over about what has traditionally been understood as linearity.
Key words: Non-newtonian arithmetic, Linearity, Matrix-matrix exponentiation

1 Introduction

The complete ordered field that gives arithmetic support to the bi-geometrical calculus is that of the positive real numbers endowed with two operations. The usual multiplication, as the first operation, and the *e-exponentiation* as the second one, which is defined by: $a \star b = a^{\ln(b)}$, $a, b \in \mathbb{R}^+$, see [3, 4, 5]. In other words, the operation $\star$ makes the calculation of powers a commutative operation.

If the intention is to advance towards generalizations or expansions of the bi-geometric or multiplicative calculus, for example towards larger dimensions, it is necessary to rescue the expressions that would have a linear algebra of multiplicative base. Notice that, just as the family of functions $y = ax$, $a \in \mathbb{R}$, corresponds to the functions that have constant multiplicative derivative, the lineal ones, it is of waiting, that one of the type $z = x^a y^b$, $a, b \in \mathbb{R}$, responds to the re-signification of the concept of linearity.

The multiplicative calculation in several variables has proved to be useful, for example, in the treatment of images with multiplicative noise, see [6], however, we know that a fundamental theoretical support to work in larger dimensions is the need for a linear algebra, in this work, that necessity guides our purpose.

As a novelty, in this paper we explore the traditional concepts of linear algebra, such as: vector space, linear transformations and matrix representations. In particular new

 ISBN: 978-84-617-8694-7

operations are introduced between matrices, and as a main result, we gives meaning to the idea of matrix raised to a matrix. Unlike other existing ones, see [1, 2, 7], this has an easier definition.

The present work (summary) is organized as follows: In Section 2, we give some preliminary of mathematical base. Section 3 is oriented toward a reconstruction of the the linear algebra. Finally, in Section 4, we introduce power between matrices and its properties are presented.

2 Mathematical preliminary

Let be $(\mathbb{R}^+, \cdot, \star)$ the field of the positive real numbers with the operations given by: (i) The usual product $a \cdot b$ and (ii) the *exponentiation* defined by $a \star b = a^{ln(b)}$. As we know, this field is an isomorphic copy of $(\mathbb{R}, +, \cdot)$. Notice that, if $\mathcal{P} =]1, \infty[$, then $\mathcal{P}$ divides the positives into three mutually exclusive categories, in effect, for each $a \in \Re$, we have $a \in \mathcal{P}$, $a = 1$ or $a^{-1} \in \mathcal{P}$. The elements of $\mathcal{P}$ are named *e-positive* numbers and if a, b are *e-positive* numbers, then the same with $a \cdot b$ and $a \star b$. Moreover, $\mathbb{R}^+$, with the *relative value* given by

$$[x] = \begin{cases} x\,, & x \geq 1\,, \\ x^{-1}\,, & x < 1\,, \end{cases} \tag{1}$$

is a *relative metric space*. In general, $\mathbb{R}^+$ is a complete ordered field. For $x, y \in \mathbb{R}^+$, some immediate properties are: (i) $[x] \geq 1$, (ii) $[x] = 1$ iff $x = 1$, (iii) $[x \star y] = [x] \star [y]$, and (iv) $[x \cdot y] \leq [x] \cdot [y]$, the last one is the triangular inequality.

3 Fundamental elements for a Linear Algebra

Let us define the pair $(V, \mathbb{R}^+)$ as an *e-vector space*, if we have an internal operations $v \cdot u$, for all v, $u \in V$ and an external one $\alpha \star v$, for all $\alpha \in \mathbb{R}^+$ and for all $v \in V$, that satisfy the following list of properties:

- Commutative: If u, $v \in V$, then $v \cdot u = u \cdot v$.
- Associative: If u, v and $w \in V$, then $v \cdot (u \cdot w) = (v \cdot u) \cdot w$.
- Neutral element: There exists $1 \in V$, such that $v \cdot 1 = v = 1 \cdot v$, for all $v \in V$.
- Inverse element: For each $v \in V$ there is a unique vector $v^{-1} \in V$, such that $v \cdot v^{-1} = 1 = v^{-1} \cdot v$.
- Compatibility of scalar multiplication with vector multiplication: Given $\alpha, \beta \in \mathbb{R}^+$, $(\alpha \star \beta) \star v = \alpha \star (\beta \star v)$, for all $v \in V$.

ISBN: 978-84-617-8694-7

- Distributive with respect to scalars: Given $\alpha, \beta \in \mathbb{R}^+$, then $(\alpha \cdot \beta) \star v = (\alpha \star v) \cdot (\beta \star v)$, for all $v \in V$.
- Distributive with respect to vectors: Given $\alpha \in \mathbb{R}^+$, $\alpha \star (u \cdot v) = (\alpha \star u) \cdot (\alpha \star v)$, for all u, $v \in V$.
- Identity element of scalar multiplication: The element $e \in V$ (e is the euler number) satisfies $e \star v = v$, for all $v \in V$.

It is possible to think of many examples of vector spaces from the multiplicative perspective, all in analogy with those of the additive approximation of linear algebra. Here are a few examples of *e-vector space*:

Euclidean Space: Let us consider, for any natural number n, the space $\mathbb{R}^n_+ = \mathbb{R}^+ \times \cdots \times \mathbb{R}^+$, n-times, of the $(x_1, \cdots, x_n)$, such that $x_i \in \mathbb{R}^+$ for each $i \in \{1, \cdots, n\}$. We consider the following operations:

- *Vector multiplication*: Given $u = (x_1, \cdots, x_n)$ and $v = (y_1, \cdots, y_n)$ in $\mathbb{R}^n_+$, we define the multiplication between vectors by

$$u \cdot v = (x_1 y_1, \cdots, x_n y_n)\,.$$

- *Scalar multiplication*: Given $u = (x_1, \cdots, x_n)$ in $\mathbb{R}^n_+$ and $\alpha \in \mathbb{R}^+$, the scalar multiplication is defined by

$$\alpha \star u = (\alpha \star x_1, \cdots, \alpha \star x_n) = (x_1^{\ln(\alpha)}, \cdots, x_n^{\ln(\alpha)})\,.$$

It is a simple and tedious calculation to test all the properties, listed above, that make of $(V, \mathbb{R}^+)$ with $V = \mathbb{R}^n_+$ as a e-vector space. We only emphasize that the neutral element of V for the vector multiplication is $e_V = (1, \cdots, 1)$ and the inverse element for each vector $u = (x_1, \cdots, x_n)$ is given by $u_{-1} = (x_1^{-1}, \cdots, x_n^{-1})$.

In addition, we note that a *linear combination* of two elements u and v of V, with parameter $\alpha, \beta \in \mathbb{R}^+$, looks like,

$$(\alpha \star u) \cdot (\beta \star v) = \left(x_1^{\ln(\alpha)} y_1^{\ln(\beta)}, \cdots, x_n^{\ln(\alpha)} y_n^{\ln(\beta)}\right).$$

In this way, the analogue to the *canonical base* in this context is defined by $\mathcal{C} = \{e_1, \cdots, e_n\}$, where each vector in this base have the Euler number e in the i-th position. Precisely,

$$e_i = (1, \cdots, 1, e, 1, \cdots, 1)\,,$$

 ISBN: 978-84-617-8694-7

for all $i \in \{1, \cdots, n\}$. Then, the decomposition of any vector $u = (x_1, \cdots, x_n)$ in the canonical base $\mathcal{C}$ is given by,

$$u = \prod_{i=1}^{n} x_i \star e_i = (x_1 \star e_1) \cdots (x_n \star e_n) .$$

In effect, we observe that

$$\prod_{i=1}^{n} x_i \star e_i = (x_1^{\ln(e)}, x_1^{\ln(1)}, \cdots, x_1^{\ln(1)}) \cdots (x_n^{\ln(1)}, \cdots, x_n^{\ln(1)}, x_n^{\ln(e)}) = (x_1, 1, \cdots, 1) \cdots (1, \cdots, 1, x_n) .$$

Matrix Space: Let us consider, for any natural number n, the space $M_n(\mathbb{R}^+)$ of matrices with positive real numbers inputs. We proceed to define the following operations,

- *Matrix multiplication*: Given $A = (a_{ij})$ and $B = (b_{ij})$ in $M_n(\mathbb{R}^+)$, the matrix product is defined by $A \cdot B = C$, where $c_{ij} = a_{ij} \cdot b_{ij}$, for $i, j \in \{1, \cdots, n\}$.
- *Scalar multiplication*: Given $A = (a_{ij})$ in $M_n(\mathbb{R}^+)$ and $\alpha \in \mathbb{R}^+$, the scalar product is defined by $\alpha \star A = (c_{ij})$, with $c_{ij} = \alpha \star a_{ij} = a_{ij}^{\ln(\alpha)}$ for any $i, j \in \{1, \cdots, n\}$.

With the pair of multiplicative operations defined above, the set $M_n(\mathbb{R}^+)$ is a e-vector space on the field $\mathbb{R}^+$.

4 Matrix-matrix exponentiation

There exists some definitions in the literature for matrix-matrix exponentiation. In [2], for example, it is defined as $A^B = e^{\ln(A)B}$, where $\exp(X) = \sum_{n=0}^{\infty}(1/n!)X^n$ and $\ln(Y)$ denotes the unique solution of the matrix equation $e^X = Y$ with eigenvalues $\lambda \in \mathbb{C}$ such that $-\pi < Im(\lambda) < \pi$.

In this section, a novel and simple operation between matrices is defined. It is named as *matrix exponentiation* and the objective is generalize the usual a^b for $a \in \mathbb{R}^+$ and $b \in \mathbb{R}$. First we will introduce, by simple analogies sum-product and product-exponentiation, the star operation $A \star B$ between matrices $A = (a_{ij}) \in M_{m\times n}(\mathbb{R}^+)$ and $B = (b_{ij}) \in M_{n\times p}(\mathcal{K})$ as:

$$A \star B = (c_{ij}) \in M_{m\times p}(\mathbb{R}^+), \quad \text{where} \quad c_{ij} = (a_{i1} \star b_{1j}) \cdots (a_{n1} \star b_{nj}).$$

This product is not commutative, but associative and distributed with respect to the traditional product of matrices (*i.e.* $A \star (B \cdot C) = (A \star B) \cdot (A \star C)$, the matrices with the dimensions that allow the operation). The neutral element will be denoted by $E = (a_{ij})$ and is defined as $a_{ij} = e$ if $i = j$ and $a_{ij} = 1$ if $i \neq j$.

 ISBN: 978-84-617-8694-7

On the other hand, given a matrix $B = (b_{ij}) \in M(\mathbb{R})$, we will denote by e_B to the matrix $(e^{b_{ij}}) \in M(\mathbb{R}^+)$. An obvious property is $e_{B+C} = e_B \cdot e_C$, for any B, $C \in M(\mathbb{R})$.

With this previous operations, we have the conditions to introduce the following definition of powers between matrices:

Definition: *Given matrices $A \in M(\mathbb{R}^+)$ and $B \in M(\mathbb{R})$, the operation power of base A and exponent B is defined by:*

$$A^B = A \star e_B.$$

It is important to remark that intuitively $A^B = A \star e_B = A^{\ln(e_B)}$.

Example: Let us consider matrices

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in M(\mathbb{R}^+) \quad \text{and} \quad B = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \in M(\mathbb{R}),$$

then

$$A^B = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \star \begin{pmatrix} e^{\alpha} & e^{\beta} \\ e^{\gamma} & e^{\delta} \end{pmatrix} = \begin{pmatrix} (a \star e^{\alpha})(b \star e^{\gamma}) & (a \star e^{\beta})(b \star e^{\delta}) \\ (c \star e^{\alpha})(d \star e^{\gamma}) & (c \star e^{\beta})(d \star e^{\delta}) \end{pmatrix},$$

this is

$$A^B = \begin{pmatrix} a^{\alpha} b^{\gamma} & a^{\beta} b^{\delta} \\ c^{\alpha} d^{\gamma} & c^{\beta} d^{\delta} \end{pmatrix}.$$

Some properties:

1. Given $A \in M(\mathbb{R}^+)$ and B, $C \in M(\mathbb{R})$, then $A^{(B+C)} = A^B \cdot A^C$.
2. Given $A \in M(\mathbb{R}^+)$ and B, $C \in M(\mathbb{R})$, then $(A^B)^C = A^{B \cdot C}$.
3. Given $A \in M(\mathbb{R}^+)$ and O the null matrix of $M(\mathbb{R})$, then $A^O = 1$, where 1 is the matrix for which all its entries are equal to 1.
4. Given $A \in M(\mathbb{R}^+)$ and Id the identity matrix of $M(\mathbb{R})$, then $A^{Id} = A$.
5. Given $B \in M(\mathbb{R})$, then $E^B = e_B$.
6. Given $1 \in M(\mathbb{R}^+)$, then $1^B = 1$.

5 Conclusions and perspectives

The multiplicative arithmetic, base of the bi-geometric calculus, allows us to introduce novel concepts in the traditional Linear Algebra and the idea of linearity is resignified.

Abstract

This paper provides a characterization for the solvability of multi-adjoint relation equations by using multi-adjoint object-oriented concept lattices theory. Moreover, when multi-adjoint relation equations are solvable, we give an interpretation of their solutions as the intensions of the concepts in a multi-adjoint object-oriented concept lattice. Finally, we introduce a procedure in order to obtain two approximate solutions for unsolvable multi-adjoint relation equations.

Key words: Multi-adjoint object-oriented concept lattice; Fuzzy relation equations; Approximate solutions.

1 Introduction

The study of fuzzy relation equations has become an important research topic, both from theoretical and applicational perspective, since these equations were introduced by Sanchez in [23]. To the best of our knowledge, the most relevant papers focused on the resolution of fuzzy relation equations are [1, 4, 8, 9, 21, 22]. Other interesting approaches are [14, 15, 17, 18]. A generalization of fuzzy relation equations was given by Díaz-Moreno and Medina [10], who apply the multi-adjoint paradigm in order to obtain a more flexible framework than the existence environments [2, 3, 4, 20]. These general equations are known as multi-adjoint relation equations and an interesting study containing their most important properties can be found in [5, 10, 11, 12, 13, 19].

In this paper, we will present sufficient and necessary conditions in terms of concepts of multi-adjoint object-oriented concept lattices [16] to guarantee when a multi-adjoint fuzzy relation equation is solvable. Furthermore, we will provide an optimistic approximate solution and a pessimistic approximate solution based on concept lattice theory for unsolvable

multi-adjoint relation equations. These approximations are interesting when a solution of the problem is needed and the multi-adjoint relation equation is not solvable. To finish with, some illustrative examples together with conclusions and prospects for future work are given.

2 Multi-adjoint object-oriented concept lattice framework

Following the philosophy of the multi-adjoint paradigm, a generalization of the classical property and object-oriented concept lattices to a fuzzy environment was introduced in [16]. Later, the concepts of a multi-adjoint property-oriented concept lattice were related to the solutions of multi-adjoint fuzzy relation equations in [10]. Now, we are interested in interpreting the solutions of multi-adjoint fuzzy relation equations as the intensions of concepts in a multi-adjoint object-oriented concept lattice. For that reason, we need to recall some preliminary definitions and results associated with multi-adjoint object-oriented concept lattices theory.

To begin with, we will present the notion of adjoint triple which is composed by a non-commutative conjunctor and two residuated implications verifying the well-known adjoint property. Adjoint triples have been widely studied in [6] and their comparison with other general operators have been introduced in [7].

Definition 1 ([6]) *Let $(P_1, \leq_1)$, $(P_2, \leq_2)$, $(P_3, \leq_3)$ be three posets and $\&\colon P_1 \times P_2 \to P_3$, $\swarrow\colon P_3 \times P_2 \to P_1$, $\nwarrow\colon P_3 \times P_1 \to P_2$ be mappings, then $(\&, \swarrow, \nwarrow)$ is called an* adjoint triple *with respect to P_1, P_2, P_3, if the double equivalence:*

$$x \leq_1 z \swarrow y \quad \textit{iff} \quad x \,\&\, y \leq_3 z \quad \textit{iff} \quad y \leq_2 z \nwarrow x$$

is satisfied, for all $x \in P_1$, $y \in P_2$ and $z \in P_3$.

Adjoint triples play an important role as basic operators to make the computations in multi-adjoint object-oriented concept lattices environment, as it is shown in the following.

Definition 2 ([16])

- *A* multi-adjoint object-oriented frame *is a tuple $(L_1, L_2, P, \preceq_1, \preceq_2, \leq, \&_1, \swarrow^1, \nwarrow_1, \ldots, \&_n, \swarrow^n, \nwarrow_n)$ where $(L_1, \preceq_1)$ and $(L_2, \preceq_2)$ are two complete lattices, $(P, \leq)$ is a poset and $(\&_i, \swarrow^i, \nwarrow_i)$ is an adjoint triple, for all $i \in \{1, \ldots, n\}$. Multi-adjoint object-oriented frames will be denoted as $(L_1, L_2, P, \&_1, \ldots, \&_n)$.*
- *A* multi-adjoint object-oriented context *is a tuple (A, B, R, σ) such that A and B are non-empty sets, R is a P-fuzzy relation $R\colon A \times B \to P$ and $\sigma\colon A \times B \to \{1, \ldots, n\}$ is a mapping which associates any element in $A \times B$ with some particular adjoint triple in the frame.*

 ISBN: 978-84-617-8694-7

Considering a fixed multi-adjoint object-oriented frame and context, we can introduce the concept-forming operators ${}^{\uparrow_N}\colon L_2^B \to L_1^A$ and ${}^{\downarrow^\Pi}\colon L_1^A \to L_2^B$ which are defined as:

$$g^{\uparrow_N}(a) = \inf\{g(b) \swarrow^{a,b} R(a,b) \mid b \in B\} \quad (1)$$

$$f^{\downarrow^\Pi}(b) = \sup\{f(a) \,\&_{a,b}\, R(a,b) \mid a \in A\} \quad (2)$$

As usual, we define a *multi-adjoint object-oriented formal concept* $\langle g, f\rangle$ as a pair of mappings $g \in L_2^B$ and $f \in L_1^A$ satisfying that $g^{\uparrow_N} = f$ and $f^{\downarrow^\Pi} = g$. It is convenient to mention that the pair $({}^{\uparrow_N}, {}^{\downarrow^\Pi})$ forms an isotone Galois connection, the composition mapping ${}^{\uparrow_N\downarrow^\Pi}\colon L_2^B \to L_2^B$ is an interior operator and ${}^{\downarrow^\Pi\uparrow_N}\colon L_1^A \to L_1^A$ is an closure operator. These considerations are very important in order to obtain the elements of a *multi-adjoint object-oriented concept lattice*.

Theorem 1 ([16]) *Let $(L_1, L_2, P, \&_1, \ldots, \&_n)$ be a multi-adjoint object-oriented frame and (A, B, R, σ) be a multi-adjoint object-oriented context. The set of all multi-adjoint object-oriented formal concepts, which are denoted as $M_{N\Pi}(A, B, R, \sigma)$, together with the ordering $\langle g_1, f_1\rangle \preceq \langle g_2, f_2\rangle$ if and only if $g_1 \preceq_2 g_2$, or equivalently, if and only if $f_1 \preceq_1 f_2$, forms a complete lattice. This complete lattice will be called* multi-adjoint object-oriented formal concept lattice *and will be denoted as $(M_{N\Pi}(A, B, R, \sigma), \preceq)$.*

As we mentioned above, the main notions and results on the solvability of multi-adjoint fuzzy relations equations included in this paper will be based on the previous concepts corresponding to the multi-adjoint object-oriented concept lattices theory. As a consequence, a multi-adjoint object-oriented frame, denoted as $(L_1, L_2, P, \&_1, \ldots, \&_s)$, will be fixed in order to present our advances in the resolution of multi-adjoint fuzzy relations equations.

3 Solving multi-adjoint fuzzy relation equations

Multi-adjoint relation equations were introduced by Díaz-Moreno and Medina in order to generalize the usual fuzzy relation equations given in the literature [8, 9, 22]. In particular, a detailed study on multi-adjoint relation equations related to their definition, properties and solutions using multi-adjoint property-oriented concept lattices was presented in [10]. Now, we will introduce new definitions and will develop a mechanism based on multi-adjoint object-oriented (instead of property-oriented) concept lattices theory to solve multi-adjoint relation equations. This mechanism will not be studied in depth because it is very similar to the one given in [10]. We will start including the notions of multi-adjoint relation equation with sup-&-composition.

Definition 3 *Given the universes U, V, W, the fuzzy relations $S\colon V \times W \to P$, $T\colon U \times W \to L_2$, an unknown fuzzy relation $R\colon U \times V \to L_1$, and a mapping $\sigma\colon V \to \{1, \ldots, s\}$ that relates*

 ISBN: 978-84-617-8694-7

each element in V to an adjoint triple of the frame. A multi-adjoint relation equation with sup-&-composition *is the equation*

$$R \odot_\sigma S = T \tag{3}$$

that is to say,

$$\bigvee_{v \in V} (R(u,v) \,\&_v\, S(v,w)) = T(u,w), \quad u \in U, w \in W \tag{4}$$

where $\&_v$ represents the adjoint conjunctor associated with v by σ.

A mechanism to know when the multi-adjoint relation Equation (3) is solvable is given in the following theorem. It is important to emphasize that the solvability of these equations is characterized by the concepts of a multi-adjoint object-oriented concept lattice.

Theorem 2 *Let $u \in U$ and the fuzzy subset $g_u \in L_2^W$, defined as $g_u(w) = T(u,w)$, for all $w \in W$. Equation (3) can be solved if and only if $\langle g_u, g_u^{\uparrow_N} \rangle$ is a concept of $\mathcal{M}_{N\Pi}(V,W,S,\sigma)$, for all $u \in U$. In this case, the matrix R, defined by $R(u,v) = g_u^{\uparrow_N}(v)$ for all $u \in U$, $v \in V$, is the greatest solution.*

Note that, this procedure is very similar to the one given by Díaz-Moreno and Medina in the multi-adjoint property-oriented concept lattice framework [10]. For that reason, the proof will be omitted.

An illustrative example will be included in order to clarify the notions and properties on multi-adjoint relation equations previously presented.

Example 1 *Let us consider the multi-adjoint lattice $\langle [0,1], \leq, \&_1, \swarrow^1, \&_2, \swarrow^2 \rangle$ such that $(\&_1, \swarrow^1) = (\&_G, \swarrow^{\mathrm{G}})$ and $(\&_2, \swarrow^2) = (\&_P, \swarrow^{\mathrm{P}})$ are the Gödel and product adjoint pairs, respectively (see [6, 7] for more details). Given the sets $U = \{u_1, u_2\}, V = \{v_1, v_2\}, W = \{w_1, w_2, w_3\}$, the mapping $\sigma: V \to \{1,2\}$ such that $\sigma(v_1) = 1, \sigma(v_2) = 2$ and the fuzzy relations $S: V \times W \to [0,1]$ and $T: U \times W \to [0,1]$ defined by the following tables:*

Figure 1: Relation S.

	w_1	w_2	w_3
v_1	0.4	0.6	0.6
v_2	0.4	0.8	0.3

Figure 2: Relation T.

	w_1	w_2	w_3
u_1	0.4	0.7	0.4
u_2	0.4	0.5	0.3

We want to solve the multi-adjoint relation equation $(x,y) \odot_\sigma S(v,w) = T(u_1,w)$ being $v \in V, w \in W$ and x, y unknown variables. This equation is equivalent to the following system:

$$\begin{aligned} 0.4 &= (x \,\&_G\, 0.4) \vee (y \,\&_P\, 0.4) \\ 0.7 &= (x \,\&_G\, 0.6) \vee (y \,\&_P\, 0.8) \\ 0.4 &= (x \,\&_G\, 0.6) \vee (y \,\&_P\, 0.3) \end{aligned}$$

 ISBN: 978-84-617-8694-7

In order to analyze the solvability of this system, we will consider the fuzzy subset $g_{u_1} \in [0,1]^W$ *defined as* $g_{u_1}(w) = T(u_1, w)$*, for all* $w \in W$*, which is equivalent to say that* $g_{u_1}(w_1) = 0.4$*,* $g_{u_1}(w_2) = 0.7$*,* $g_{u_1}(w_3) = 0.4$*. To apply Theorem 2, we need to prove that* $\langle g_{u_1}, g_{u_1}^{\uparrow_N} \rangle$ *is a concept of* $\mathcal{M}_{N\Pi}(V, W, S, \sigma)$*, that is, we need to check if the equality* $g_{u_1}^{\uparrow_N\downarrow^\Pi} = g_{u_1}$ *holds. First of all, we will compute* $(g_{u_1})^{\uparrow_N}$*:*

$$\begin{aligned}(g_{u_1})^{\uparrow_N}(v_1) &= \inf\{0.4 \swarrow^{\mathrm{G}} 0.4, 0.7 \swarrow^{\mathrm{G}} 0.6, 0.4 \swarrow^{\mathrm{G}} 0.6\} = \inf\{1, 1, 0.4\} = 0.4\\ (g_{u_1})^{\uparrow_N}(v_2) &= \inf\{0.4 \swarrow^{\mathrm{P}} 0.4, 0.7 \swarrow^{\mathrm{P}} 0.8, 0.4 \swarrow^{\mathrm{P}} 0.3\} = \inf\{1, 0.875, 1\} = 0.875\end{aligned}$$

The fuzzy subset $(g_{\mathtt{flu}})^{\uparrow_N\downarrow^\Pi}$ *is obtained as follows:*

$$\begin{aligned}(g_{u_1})^{\uparrow_N\downarrow^\Pi}(w_1) &= \sup\{0.4 \,\&_{\mathrm{G}}\, 0.4, 0.875 \,\&_{\mathrm{P}}\, 0.4\} = \sup\{0.4, 0.35\} = 0.4\\ (g_{u_1})^{\uparrow_N\downarrow^\Pi}(w_2) &= \sup\{0.4 \,\&_{\mathrm{G}}\, 0.6, 0.875 \,\&_{\mathrm{P}}\, 0.8\} = \sup\{0.4, 0.7\} = 0.7\\ (g_{u_1})^{\uparrow_N\downarrow^\Pi}(w_3) &= \sup\{0.4 \,\&_{\mathrm{G}}\, 0.6, 0.875 \,\&_{\mathrm{P}}\, 0.3\} = \sup\{0.4, 0.2625\} = 0.4\end{aligned}$$

It is clear that the equality $g_{u_1}^{\uparrow_N\downarrow^\Pi} = g_{u_1}$ *is satisfied and therefore, we can ensure that* $\langle g_{u_1}, g_{u_1}^{\uparrow_N} \rangle$ *is a concept of* $\mathcal{M}_{N\Pi}(V, W, S, \sigma)$*. Hence, the considered system is solvable and its greatest solution is* $(g_{u_1})^{\uparrow_N} = (0.4, 0.875)$*.*

There exist different applications in which a solution is needed and the multi-adjoint fuzzy relation equations system is not solvable. In order to overcome this drawback, we can compute two approximations of the unknown variables as it is shown in the following section.

4 Optimistic and pessimistic approximations

We have provided a characterization for the solvability of multi-adjoint relations equations by means of the concepts of a multi-adjoint object-oriented concept lattice. Now, our task is focused on knowing what can we do when we need the solution of an unsolvable multi-adjoint relation equation. The answer to this question is given by the procedure developed in this section, which offer approximate solutions (an optimistic and a pessimistic approach) for unsolvable equations.

We suppose that for certain fuzzy subset $g_u \in L_2^W$, defined as $g_u(w) = T(u, w)$, for all $w \in W$, Equation (3) has not solution. Then, we present two possible alternatives in order to obtain approximate solutions for Equation (3):

- An approximation can be computed interchanging the row $T(u, w)$ by the fuzzy set $g_u^{\uparrow_N\downarrow^\Pi}$ in Equation (3). This approximation can be understand as a *pessimistic approximation*. Observe that, there exist other possibilities to obtain an approximate solution but the complexity for the computations is major.

 ISBN: 978-84-617-8694-7

- Another different approximation can be obtained by using a procedure based on the concepts whose extension is greater than g_u. In this case, we need to consider a finite object-oriented concept lattice which implies that the set

$$G = \{g \in L_2^B \mid g_u \preceq_2 g \text{ and } \langle g, g^{\uparrow_N} \rangle \in \mathcal{M}_{N\Pi}(V, W, S, \sigma)\}$$

either is empty or has minimal elements. It is easy to see that if g_m is a minimal element of G, then Equation (3) with $T(u, w) = g_m(w)$, for all $w \in W$, is solvable and $g_u \preceq_2 g_m$. As a consequence, $g_m^{\uparrow_N}$ can be considered as an *optimistic approximation.*

The following example will be useful to clarify the developed procedure previously.

Example 2 *Coming back Example 1 and considering the fuzzy subset $g_{u_2} \in [0,1]^W$ defined as $g_{u_2}(w) = (0.4, 0.5, 0.3)$, we can easily see that $\langle g_{u_2}, g_{u_2}^{\uparrow_N} \rangle$ is not a multi-adjoint object-oriented concept. Therefore, the system $(x, y) \odot_\sigma S(v, w) = g_{u_2}(w)$ is not solvable. Now, we will compute the pessimistic and optimistic approximations following the ideas introduced above:*

- *We will consider the fuzzy set $(g_{u_2})^{\uparrow_N \downarrow^\Pi}(w) = (0.3, 0.5, 0.3)$ instead of $g_{u_2}(w)$ in order to obtain the equation $(x, y) \odot_\sigma S(v, w) = (g_{u_2})^{\uparrow_N \downarrow^\Pi}(w)$. This equation is solvable and its greatest solution is $(g_{u_2})^{\uparrow_N} = (0.3, 0.625)$, which will be considered as a pessimistic approximation.*

- *In order to obtain an optimistic approximation, we will consider a finite multi-adjoint object-oriented concept lattice whose frame is composed by the regular partition $[0,1]_{10}$ and the discretizations of the Gödel and product conjunctors with respect to $[0,1]_{10}$ (see [6] for more details). We will fix the context (V, W, S, σ) given in Example 1, but in this occasion the mapping σ is associated with the discretization conjunctors. The Hasse diagram of the concept lattice $(M_{N\Pi}(A, B, R, \sigma), \preceq)$ together with the concepts is shown in Figure 3. According to Figure 3, we can ensure that the set of concepts whose extensions are greater than $g_{u_2} = (0.4, 0.5, 0.3)$ is:*

$$\{C_{13}, C_{14}, C_{15}, C_{16}, C_{17}, C_{18}, C_{19}, C_{20}, C_{21}, C_{22}, C_{23}, C_{24}, C_{25}\}$$

The previous set has two minimal elements C_{13} and C_{14} and therefore, we have two optimistic approximations. Considering the extension of C_{13}, we obtain that equation $(x, y) \odot_\sigma S(v, w) = (0.4, 0.5, 0.4)$ is solvable and its greatest solution is the intension of the concept C_{13}. Hence, $(0.4, 0.6)$ is an optimistic approximate solution of the original system. Following an analogous reasoning with the concept C_{14}, we have that $(0.3, 0.8)$ is another optimistic approximate solution of the original system.

C_9 &= \langle (0.3,0.4,0.3),(0.3,0.5)\rangle \\
C_{10} &= \langle (0.3,0.5,0.3),(0.3,0.6)\rangle \\
C_{11} &= \langle (0.4,0.4,0.4),(0.4,0.5)\rangle \\
C_{12} &= \langle (0.3,0.6,0.3),(0.3,0.7)\rangle \\
C_{13} &= \langle (0.4,0.5,0.4),(0.4,0.6)\rangle \\
C_{14} &= \langle (0.4,0.7,0.3),(0.3,0.8)\rangle \\
C_{15} &= \langle (0.4,0.6,0.4),(0.4,0.7)\rangle \\
C_{16} &= \langle (0.4,0.5,0.5),(0.5,0.6)\rangle \\
C_{17} &= \langle (0.4,0.8,0.3),(0.3,1.0)\rangle \\
C_{18} &= \langle (0.4,0.7,0.4),(0.4,0.8)\rangle \\
C_{19} &= \langle (0.4,0.6,0.5),(0.5,0.7)\rangle \\
C_{20} &= \langle (0.4,0.8,0.4),(0.4,1.0)\rangle \\
C_{21} &= \langle (0.4,0.7,0.5),(0.5,0.8)\rangle \\
C_{22} &= \langle (0.4,0.6,0.6),(1.0,0.7)\rangle \\
C_{23} &= \langle (0.4,0.8,0.5),(0.5,1.0)\rangle \\
C_{24} &= \langle (0.4,0.7,0.6),(1.0,0.8)\rangle \\
C_{25} &= \langle (0.4,0.8,0.6),(1.0,1.0)\rangle
\end{aligned}
$$

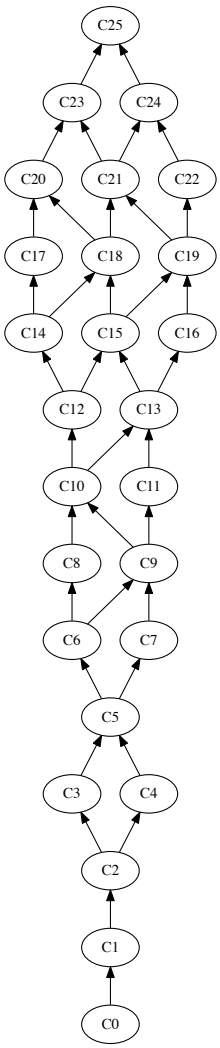

Figure 3: Hasse diagram of $(M_{N\Pi}(A,B,R,\sigma),\preceq)$ and its concepts (Example 2).

If we are interested in comparing the optimistic and the pessimistic approximations, it is necessary to compute the pessimistic approximation in the considered finite case. Solving the equation $(x,y)\odot_\sigma S(v,w)=(0.3,0.5,0.3)$ *where* $(0.3,0.5,0.3)$ *is the extension of concept* C_{11}*, we have that the pessimistic approximate solution is* $(0.3,0.6)$*. Clearly,* $(0.3,0.6)$ *is less than the optimistic approximations.*

After computing the pessimistic and optimistic approximate solutions, one can choose what approximate solution is the best in the $\wedge$*-semilattice given by the least element* $(0.3,0.6)$

 ISBN: 978-84-617-8694-7

and the maximal elements $(0.4, 0.6)$ *and* $(0.3, 0.8)$ *of the lattice* $[0,1]_{10} \times [0,1]_{10}$. *In this case, the* $\wedge$*-semilattice only has four elements:* $\{(0.3, 0.6), (0.4, 0.6), (0.3, 0.8), (0.3, 0.7)\}$.

5 Conclusions and future work

We have interpreted the solutions of multi-adjoint relation equations by using the concepst in a multi-adjoint object-oriented concept lattice. Furthermore, we have presented a mechanism in order to compute approximate solutions for unsolvable multi-adjoint relation equations. This method provides optimistic and pessimistic approximations of the considered equations based on concept lattice theory.

As a future work, we will study the interpretation of the minimal solutions of multi-adjoint relation equations and we will present real-life applications of these equations.

Abstract

At the 127^{th} European Study Group with Industry an energy sector company proposed an industrial challenge that consisted on the asset acquisition planning for its liquefied petroleum gas (LPG) cylinder business, one of the most recent business areas in the company. This business area is still in a growing phase and to satisfy the market needs and assure a sustainable growth a very tight control of the main assets, the LPG cylinders, is of paramount importance. Therefore, a detailed planning of all the assets acquisition is required, taking into consideration several variables: sales growth rate, seasonality, cylinder rotation and corresponding return rate to the filling plant. The challenge was to develop a model for the assets acquisition planning. In order to tackle this challenge, it was necessary to forecast the demand. For that purpose, time

 ISBN: 978-84-617-8694-7

series techniques were used, in particular, moving averages and exponential smoothing. The results show that the seasonality does not explain all the variation of the demand, therefore it is necessary to use a model that would consider other possible explanatory variables. According to several authors, gas consumption may be influenced by several aspects, such as, atmospheric temperatures, heliophany (a measure of the day luminosity), wind, relative humidity, rains, minimum and maximum temperatures, demand in previous periods, and prices. Therefore, in an extended version of this article a multivariate linear regression model will be used.

Key words: Industrial Mathematics, LPG bottles demand, time series, exponential smoothing forecast, moving averages.

1 Introduction

A Portuguese company in the energy sector, that will be named ALPHA for confidentiality reasons, started its activity in 2006, focusing in the production and distribution of biofuel. Since then, the company has been continuously growing, extending its business areas to other fuels, and is now operating at a national level. The company started the liquefied petroleum gas (LPG) cylinder business activities in 2012, and since then it has experienced a continuous growth. In this business, the LPG cylinder is the main asset and a correct planning of its needs is critical. The company currently commercializes propane gas and has two types of cylinders with different capacity, henceforth named type A and type B cylinders.

ALPHA wants to find a model to forecast the demand of each type of LPG cylinders. These forecasts are crucial for the company to define an assets acquisition plan, i.e., to determine the amount of LPG cylinders to acquire, and when to acquire them.

In [9], Virtullo et. al. look at the financial implication of forecasting natural gas, the nature of natural gas forecasting, the factors that impact natural gas consumption, and present a survey of the mathematical techniques and practices used to model natural gas demand. These authors argue that the most common mathematical modeling techniques used to forecast daily demand are multiple linear regression (MLR) and artificial neural networks (ANN) (for details see [8]). Paggi and Robledo presented, in [7], an application of ANN in the prediction of time series of the weekly wholesales of bottled propane gas.

In the present work, in order to tackle the challenge, an approach similar to these authors is followed and several statistical techniques are used.

This paper is organized as follows: In Section 2 an exploratory analysis of the data is made. Section 3 is devoted to determining the sales forecast of bottled propane gas for the Portuguese market and for ALPHA company. In the last section some conclusions are presented and future work is sketched.

 ISBN: 978-84-617-8694-7

2 Dataset and exploratory analysis

The dataset provided by the company included information about sales, return number of cylinders, operational stock of assets, total number of assets in the market, of the two types of propane cylinders (A – small bottles and B – large bottles), between January Year 0 (Jan/Y0) and December Year 1 (Dec/Y1). The forecast for sales during Year 2 are also provided by the company. Note that, for confidentiality reasons, the data used in this work was masked. Additional data about consumption of propane and temperature in Portugal were also collected from the Portuguese Association of Petroleum Companies – APETRO[1] and from the Portuguese Institute for Sea and Atmosphere – IPMA[2], respectively. Figure 1 and Figure 2 show this data.

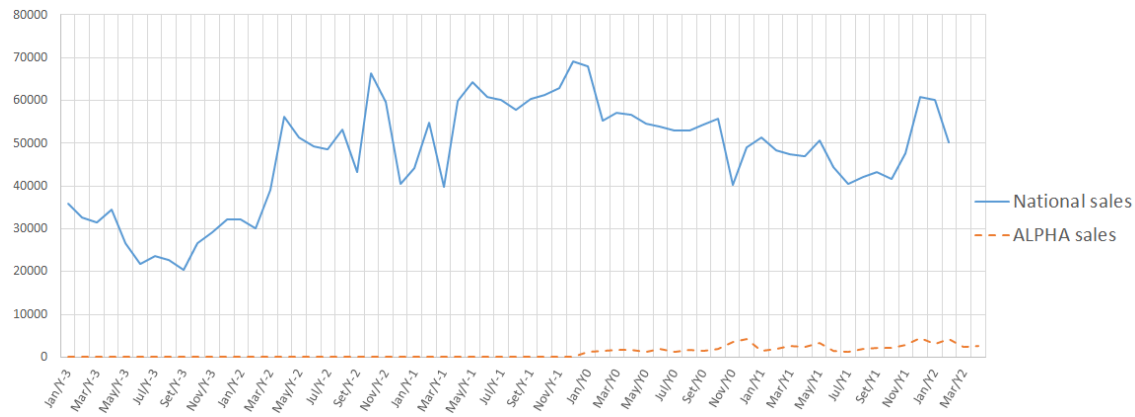

Figure 1: Comparison between national sales and ALPHA sales.

Figure 1 shows a general increase in the sales of ALPHA, however, it still represents a small percentage of the national market. Furthermore, the national and ALPHA sales of propane have different behaviors, thus in principle this is not a good indicator to forecast the company's sales when based on the national ones.

Figure 2 depicts the values of propane national sales and, simultaneously, the average temperature[3] in Portugal in the same period is shown. Since propane gas is used mostly for cooking and water heating, it is expected that whenever temperature decreases there is an increase in gas consumption. However, from Figure 2, this is not always true. In fact, for January Year -1 there is a decrease of the temperature and also a decrease of the consumption of gas.

[1] `http://www.apetro.pt`
[2] `https://www.ipma.pt`
[3] The air temperature in ($^{\circ}C$) was multiplied by a constant factor for a better comparison with the sales.

 ISBN: 978-84-617-8694-7

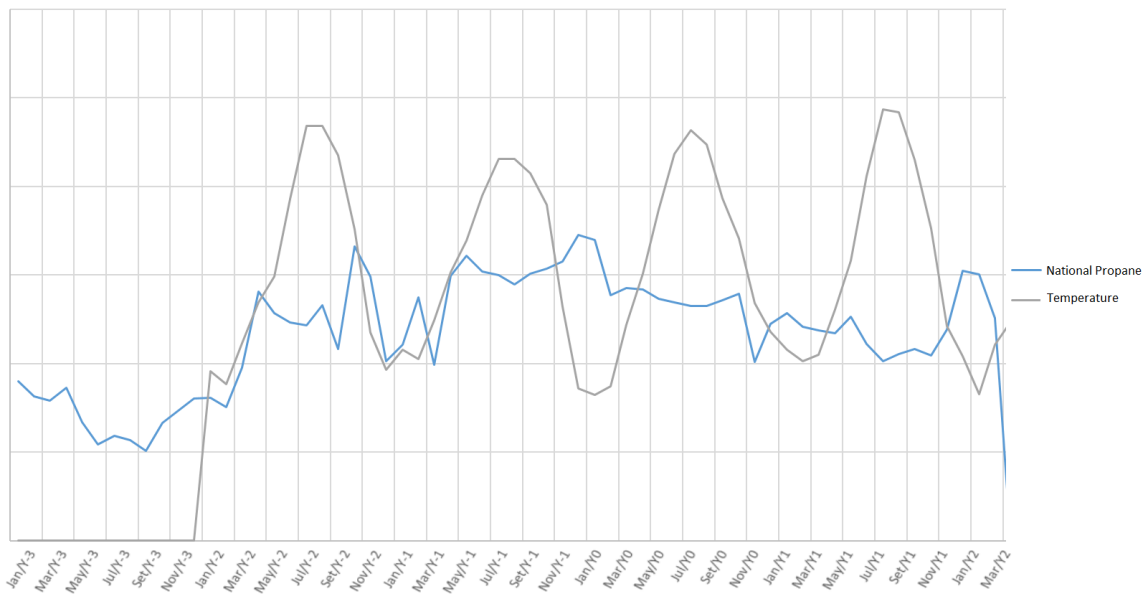

Figure 2: Average temperature and national sales.

In order to study the existence of seasonality in sales of type A and B cylinders, Figure 3 presents the sales for the three years. In this figure an increasing linear trend of ALPHA's sales, due to the company's market expansion, is observed. There is also some indicators of seasonality, because over the years the variations appear to be similar. In order to analyse the seasonality, moving averages seasonality coefficients (e.g. [4,10]) and exponential smoothing forecasts (for review see e.g. [2, 3, 5]), are calculated in the next Section.

3 Bottled propane gas sales forecast

3.1 Estimating seasonality coefficients

To study the seasonality of the data, the seasonality coefficients for total propane sales of ALPHA (in tons); sales of type A and B ALPHA assets; and sales of butane, propane and total in Portugal were calculated.

Let us consider, without loss of generality, ALPHA sales of propane between January Year 0 and December Year 2. The number of observations is given by $N = k \times s$, where k is the number of years and s the number of periods in the year, i.e. months. In this case $N = 3 \times 12 = 36$. Using the centered moving averages method, it is possible to calculate 12 seasonal indexes (one for each month) that express the amount of sales in each month

 ISBN: 978-84-617-8694-7

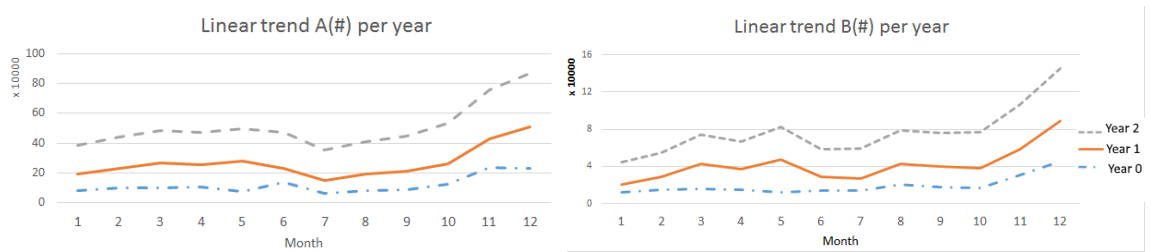

Figure 3: ALPHA sales of type A and B cylinders.

that are superior (or inferior) to the global mean sales. Using the multiplicative method, the seasonal indexes work as a percentage. The non-normalized estimates of the seasonal component at time i of each year are:

$$\bar{S}_i = \frac{1}{k-1}\sum_{j=1}^{k} S^*_{i+s(j-1)}\ , \qquad i = 1, 2, \ldots, s,$$

with

$$S^*_t = \frac{X_t}{M_t},$$

where M_t are the centered moving averages of the sales series X_t:

$$M_t = \frac{1}{s}\left(\frac{1}{2}X_{t-\frac{s}{2}} + X_{t-\frac{s}{2}+1} + \ldots + X_{t+\frac{s}{2}-1} + \frac{1}{2}X_{t+\frac{s}{2}}\right), \quad t = \frac{s}{2}+1, \ldots, N-\frac{s}{2}.$$

Finally, the standardized estimates of the seasonal components are:

$$\hat{S}_i = \bar{S}_i \cdot \frac{s}{\sum_{j=1}^{s}\bar{S}_j}\ , \qquad 1, 2, \ldots, s.$$

Using these formulas it is possible to estimate the seasonal indexes of the demand and sales (see Figure 4).

Similarly, the seasonal coefficients presented in Table 1 were obtained. The national coefficients (PT butane, PT propane, PT total) do not have significant variations from month to month. In fact, for the national sales, the PT butane seasonal coefficients present a minimum of 84% in October and a maximum of 111% in May, while for PT propane and PT total the minimum is attained in September with 92% and 91%, respectively, and the maximum occurs in April with 111% and 110% 92%.

On the other hand, ALPHA sales show more significant variations. The seasonal coefficients of the total sales vary from 59% in July to 172% in December, while for type A

 ISBN: 978-84-617-8694-7

	Seasonal coefficient
January	84%

November	88%	99%	96%	135%	144%	124%
December	108%	98%	101%	172%	163%	183%

Therefore, forecast for sales can be done using these seasonal coefficients.

 ISBN: 978-84-617-8694-7

3.2 Exponential smoothing forecast

Exponential smoothing forecast is a widely used method for time series forecast, including sales forecasting [1, 5, 6, 12].

Using the seasonal coefficients obtained in the previous subsection to desseasonalize the data, then Holt's method was used to forecast type A bottles sales. The model obtained using Holt's method [11] was such that: AIC = 671.9332, BIC = 678.5942, RMSE = 25697.11 for the training set, level coefficient $\alpha = 0.0253$ and trend coefficient $\beta = 0.0253$. Further details of this model are depicted in Table 2). In Figure 5, the observed values of the type A bottles sales (from Jan/Y0 to Apr/Y2) are presented alongside with the estimated values (from Jan/Y0 to Apr/Y2), and the forecast sales for May/Y2 until Dec/Y3.

sigma:	25697.11						
	AIC	AICc	BIC				
	671.9332	674.6605	678.5942				
Error measures:

4 Conclusions and future work

The goal of this work was to forecast the sales of propane gas cylinders in order to plan the assets acquisition necessity of a Portuguese company of the energy sector. In this work the time series techniques exponential smoothing and moving averages were used to forecast the demand.

This approach allowed to see that the national seasonal coefficients are quite distinct from the ones observed for the sales of the company. ALPHA's sales present a larger variability in the seasonal coefficients than the total national sales. For the company the higher coefficients were observed in May, November and December, while the smaller were in July.

Since national and ALPHA seasonality coefficients are different, some other possible explanatory variables should be considered in order to forecast the demand with better accuracy. For that reason, several data has been collected, such as atmospheric temperatures, demand in previous periods, objectives of sales, expectation of price increase, and among others variables. In an extended version of this paper the focus will be in using approaches to forecast sales that take into account this data.

Abstract

A Markov model is defined through its associated stochastic transition matrix whose entries are deterministic values representing the so-called transition probabilities between two possible states. In practice, these quantities are not known in a deterministic manner since they need to be fixed from sampling, therefore, it is more realistic to consider them as random variables (RV's) rather than deterministic quantities. This paper is addressed to give a generalization of the classical Markov methodology allowing the treatment of the entries of the transition matrix as RV's. The randomization of the classical Markov model permits the computation of the first probability density function (1-PDF) of the solution stochastic process taking advantage of the so-called Random Variable Transformation (RVT) technique. From the 1-PDF relevant probabilistic information about the evolution of the model described by Markov models can be calculated including all one-dimensional moments (mean, variance, symmetry, kurtosis, etc). As it is shown, RVT method also allows us the computation of the PDF's of the time instant until a certain proportion of the total population reaches a specific value of interest and of the steady state. All theoretical results are established under fairly general assumption since the PDF's of the randomized transition probabilities are assumed to be arbitrary. Finally, our theoretical findings are illustrated by means of a numerical example.

Key words: Binary Markov chain, random variable transformation technique, first probability density function

1 Introduction

A stochastic process (SP) is a mathematical representation that permits to describe how evolves a phenomenon over time in a probabilistic manner. Discrete Markov models, also referred to as Markov chains, are particular SP's where the outcome of an experiment depends only on the outcome of the previous experiment [5, 1]. Markov chains are applied in many different realms including Economy, Sociology, Reliability, Medical Decision Making, for instance. Markov chains are often chosen as a suitable tools for modelling very different phenomena because they are fairly general and adaptable to many contexts [4]. Moreover, excellent numerical techniques exist for computing its statistics.

This contribution is addressed to give a generalization of classical Markov chains by randomizing the entries of the transition matrix as random variables (RV's). To the best of our knowledge, this problem has not been considered yet in the extant literature. As a first step, we here will concentrate on the simplest type of Markov chains, usually referred to as binary Markov chains which are those having just two possible states.

Let $\{x_n,\, n = 0, 1, \dots\}$ be a Markov chain, where $n = 0, 1, 2, \dots$, denotes the cycle or period. As early indicated, we will consider binary Markov chains whose two possible states will be denoted by x_n^1 and x_n^2, being n the period or cycle. It is assumed that $0 < x_n^1, x_n^2 < 1$, thus x_n^1 and x_n^2 can be interpreted as percentages. As a key feature of Markov chains, it is assumed that $x_n^1 + x_n^2 = 1$ for every n. This means that the system is closed, that is, if for example, x_n^1 and x_n^2 represent the percentage of susceptibles and infected persons of a population, then it is implicitly assumed that any person can neither leave nor join the population. The evolution of the number of individuals in each cycle n is determined by the initial state $(x_0^1, x_0^2)^\top$ and the transition matrix while the long-term behaviour of the Markov chain only depends on the transition matrix. This matrix is a constant matrix whose entries represent the probabilities to change either from one state to another or to remain in the same state between to consecutive cycles. In practice, this entries are assumed to be deterministic quantities. In this contribution we generalize this feature by considering that the entries of the transition matrix are RV's rather than deterministic constants. Naturally, these RV's are assumed to take values in the interval $[0, 1]$, thus representing probabilities. In Figure 1, we show the flow diagram with the transitions among states.

In the classical context, a Markov chain is described as follows

$$x_{n+1} \;=\; a\, x_n, \quad n = 0, 1, 2, \dots, \quad a = \begin{pmatrix} p & 1-q \\ 1-p & q \end{pmatrix}, \tag{1}$$

where a is termed the (deterministic) transition matrix and $x_0 = (x_0^1, x_0^2)^\top = (x_0^1, 1 - x_0^1)^\top$ is the initial condition, i.e. the initial percentage of individuals in each group.

As indicated above, we will consider the entries of the transition matrix, p and q, as well as the initial condition, x_0, as RV's. For sake of clarity, in the following these quantities will

 ISBN: 978-84-617-8694-7

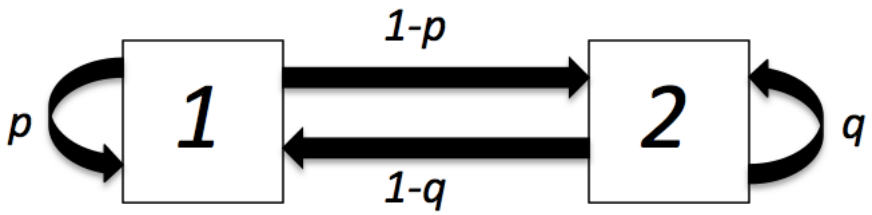

Figure 1: Flow diagram to a binary Markov chain.

be written using capital letters. The randomized Markov chain is then written as follows

$$\begin{aligned} X_{n+1} &= A\,X_n, \quad n=0,1,2,\ldots, \quad A=\begin{pmatrix} P & 1-Q \\ 1-P & Q \end{pmatrix}, \\ X_0 &= (X_0^1, 1-X_0^1)^\top, \end{aligned} \tag{2}$$

where X_0^1, P and Q are assumed to be absolutely continuous RV's defined on a common probability space $(\Omega, \mathcal{F}, \mathbb{P})$.

Solving a randomized Markov chain means not only to obtain its solution discrete SP, $X_n = (X_n^1, X_n^2)^\top = (X_n^1, 1-X_n^1)^\top$, but also to compute its mean, $\mathbb{E}[X_n]$ and its variance, $\mathbb{V}[X_n]$, for each cycle n. A more general purpose is the computation of its first probability density function (1-PDF), $f_1(x;n)$. This function provides a full probabilistic description of the solution SP in every cycle n. The aim of this paper is to obtain the 1-PDF of the solution SP for randomized binary Markov chains under very general hypotheses. To reach this objective, we will apply the Random Variable Transformation (RVT) method. This is a powerful technique that has been recently used by the authors to construct random phase portrait for planar systems [2] and to model the stroke disease [3]. The RVT technique permits to compute the PDF of a RV which results from mapping of another RV whose PDF is known. The multidimensional version of the RVT technique is stated in Theorem 1.

Theorem 1 *(Multidimensional version, [6, pp. 24–25]). Let* $\mathbf{U} = (U_1, \ldots, U_n)^\top$ *and* $\mathbf{V} = (V_1, \ldots, V_n)^\top$ *be two n-dimensional absolutely continuous random vectors. Let* $\mathbf{r} : \mathbb{R}^n \to \mathbb{R}^n$ *be a one-to-one deterministic transformation of* $\mathbf{U}$ *into* $\mathbf{V}$*, i.e.,* $\mathbf{V} = \mathbf{r}(\mathbf{U})$*. Assume that* $\mathbf{r}$ *is continuous in* $\mathbf{U}$ *and has continuous partial derivatives with respect to* $\mathbf{U}$*. Then, if* $f_{\mathbf{U}}(\mathbf{u})$ *denotes the joint probability density function of vector* $\mathbf{U}$*, and* $\mathbf{s} = \mathbf{r}^{-1} = (s_1(v_1, \ldots, v_n), \ldots, s_n(v_1, \ldots, v_n))^\top$ *represents the inverse mapping of* $\mathbf{r} = (r_1(u_1, \ldots, u_n), \ldots, r_n(u_1, \ldots, u_n))^\top$*, the joint probability density function of vector* $\mathbf{V}$ *is given by*

$$f_{\mathbf{V}}(\mathbf{v}) = f_{\mathbf{U}}\left(\mathbf{s}(\mathbf{v})\right) |J|, \tag{3}$$

 ISBN: 978-84-617-8694-7

where $|J|$ is the absolute value of the Jacobian, which is defined by

$$J = \det\left(\frac{\partial \mathbf{s}^\top}{\partial \mathbf{v}}\right) = \det\begin{pmatrix} \dfrac{\partial s_1(v_1,\ldots,v_n)}{\partial v_1} & \cdots & \dfrac{\partial s_n(v_1,\ldots,v_n)}{\partial v_1} \\ \vdots & \ddots & \vdots \\ \dfrac{\partial s_1(v_1,\ldots,v_n)}{\partial v_n} & \cdots & \dfrac{\partial s_n(v_1,\ldots,v_n)}{\partial v_n} \end{pmatrix}. \tag{4}$$

As the two states of a binary Markov chain make up a closed system, $X_n^1 + X_n^2 = 1$, we shall see that once the 1-PDF of one of the two states has been computed, the 1-PDF of the other state can be straightforwardly determined taking advantage of the following key lemma. This result can be derived as direct application of Theorem 1.

Lemma 2 *Let X and Y be two absolutely continuous random variables, such as $Y = 1 - X$. Let $f_X(x)$ denote the probability density function of the random variable X, then the probability density function of the random variable Y is given by*

$$f_Y(y) = f_X\left(1 - y\right). \tag{5}$$

2 Solving the randomized binary Markov chain

This section is divided in two parts. In the first subsection we will compute the 1-PDF of the solution to the randomized binary Markov chain (2) under very general assumptions and the PDF of its steady state as well. The second subsection is addressed to determine the PDF of the RV representing the time until a given proportion of the population is reached. These goals will be achieved by applying the RVT technique.

Let us recall that the solution of problem (2) is given by

$$X_n = A^n X_0 = \begin{pmatrix} \dfrac{-1+Q+(-1+P+Q)^n\left(1-Q+(-2+P+Q)X_0^1\right)}{-2+P+Q} \\ \dfrac{-1+P+(-1+P+Q)^n\left(-1+Q-(-2+P+Q)X_0^1\right)}{-2+P+Q} \end{pmatrix},\ n = 0, 1, \ldots \tag{6}$$

As P and Q are absolutely continuous RV's, then $\mathbb{P}\left[\{\omega \in \Omega :\ P(\omega) + Q(\omega) - 2\}\right] = 0$, for all event $\omega \in \Omega$. As a consequence, the denominator of both components of (6) is well-defined.

 ISBN: 978-84-617-8694-7

2.1 First Probability Density Function

As previously indicated, in this subsection we will obtain the 1-PDF of (6) using the RVT method. To do this, we will apply Theorem 1 for the following choice of mapping $\mathbf{r}$

$$\begin{aligned} y_1 &= r_1\left(x_0^1,p,q\right) = \frac{-1+q+(-1+p+q)^n\left(1-q+(-2+p+q)x_0^1\right)}{-2+p+q},\\ y_2 &= r_2\left(x_0^1,p,q\right) = p,\\ y_3 &= r_3\left(x_0^1,p,q\right) = q. \end{aligned}$$

Then, we will obtain the PDF of X_n^1 for n fixed. This can be achieved by applying Theorem 1, but we first need to compute the inverse mapping $\mathbf{s}$ of mapping $\mathbf{r}$

$$\begin{aligned} x_0^1 &= s_1\left(y_1,y_2,y_3\right) = \frac{y_1\left(-2+y_2+y_3\right)+\left(-1+y_3\right)\left(-1+\left(-1+y_2+y_3\right)^n\right)}{\left(-1+y_2+y_3\right)^n\left(-2+y_2+y_3\right)},\\ p &= s_2\left(y_1,y_2,y_3\right) = y_2,\\ q &= s_3\left(y_1,y_2,y_3\right) = y_3, \end{aligned}$$

and its jacobian

$$|J| = \left|\frac{\partial s_1}{\partial y_1}\right| = \left|\frac{1}{\left(-1+y_2+y_3\right)^n}\right|.$$

Therefore, the PDF of the random vector (Y_1,Y_2,Y_3) defined through mapping $\mathbf{r}$ is

$$\begin{aligned} f_{y_1,y_2,y_3}\left(y_1,y_2,y_3\right) &= f_{x_0^1,P,Q}\left(\tfrac{y_1(-2+y_2+y_3)+(-1+y_3)(-1+(-1+y_2+y_3)^n)}{(-1+y_2+y_3)^n(-2+y_2+y_3)},y_2,y_3\right)\\ &\times \left|\tfrac{1}{(-1+y_2+y_3)^n}\right|. \end{aligned}$$

Finally, marginalizing this expression with respect to P and Q and letting n arbitrary, we obtain the 1-PDF of X_n^1

$$\begin{aligned} f_1^{x^1}(x;n) &= \iint_{\mathcal{D}(P,Q)} f_{x_0^1,P,Q}\left(\tfrac{x(-2+p+q)+(-1+q)(-1+(-1+p+q)^n)}{(-1+p+q)^n(-2+p+q)},p,q\right)\\ &\times \left|\tfrac{1}{(-1+p+q)^n}\right| \mathrm{d}q\,\mathrm{d}p, \end{aligned} \tag{7}$$

where $\mathcal{D}(P,Q)$ stands for the domain of the random vector (P,Q).

Now, taking into account that $X_n^2 = 1 - X_n^1$ for every n, and applying Lemma 2, the 1-PDF of X_n^2 is given by

$$\begin{aligned} &f_1^{x^2}(x;n) = f_1^{x^1}(1-x;n) =\\ &= \iint_{\mathcal{D}(P,Q)} f_{x_0^1,P,Q}\left(\tfrac{(1-x)(-2+p+q)+(-1+q)(-1+(-1+p+q)^n)}{(-1+p+q)^n(-2+p+q)},p,q\right)\left|\tfrac{1}{(-1+p+q)^n}\right| \mathrm{d}q\,\mathrm{d}p. \end{aligned} \tag{8}$$

 ISBN: 978-84-617-8694-7

An important issue in dealing with Markov chains is to determine the steady state. From the deterministic theory it is known that the steady state to the Markov chain (1) is

$$x_\infty = \begin{pmatrix} \dfrac{1-q}{2-p-q} \\ \dfrac{1-p}{2-p-q} \end{pmatrix}. \tag{9}$$

By defining an appropriate mapping based on the expression (9) and using RVT technique, it can be shown that the PDF corresponding to the first component of the steady state is

$$f_{x_\infty^1}(x) = \int_{\mathcal{D}(Q)} f_{P,Q}\left(\frac{-1-x(2+q)+q}{x}, q\right)\left|\frac{1-q}{x^2}\right| \mathrm{d}q. \tag{10}$$

2.2 Distribution of time until a given proportion of the subpopulation is reached

It is useful to know when the percentage of a group in the population will attain a certain level. This motivates the computation of the distribution of the time, N_i, $i = 1, 2$, until a given proportion, ρ_i, of the population of state i is reached. Now, we concentrate on the computation of N_1 corresponding to the first subpopulation. Then, let us consider the following relation obtained from the first component of equation (6) one gets

$$\rho_1 = \frac{-1+q+(-1+p+q)^{n_1}(1-q+(-2+p+q)x_0^1)}{-2+p+q}. \tag{11}$$

In order to obtain the 1-PDF, $f_{N_1}(n)$, we first isolate n_1 from equation (11) and use the capital letter notation for random inputs X_0^1, P and Q. This leads to

$$N_1 = \frac{\log\left(\frac{1-Q+(-2+P+Q)\rho_1}{1-Q+(-2+P+Q)x_0^1}\right)}{\log(-1+P+Q)}. \tag{12}$$

This RV represents the time until a percentage ρ_1 of the subpopulation 1 has been reached. Using the RVT technique with an appropriate mapping inspired in (11), it can be proved that

$$\begin{aligned} f_{N_1}(n) &= \iint_{\mathcal{D}(P,Q)} f_{x_0^1,P,Q}\left(\tfrac{(-1+p+q)^{-n}(1-q+(-1+q)(-1+p+q)^n+\rho_1(-2+p+q))}{-2+p+q}, p, q\right) \\ &\times \left|\tfrac{(-1+p+q)^{-n}(-1+q-(-2+p+q)\rho_1)\log(-1+p+q)}{-2+p+q}\right| \mathrm{d}q\,\mathrm{d}q. \end{aligned} \tag{13}$$

 ISBN: 978-84-617-8694-7

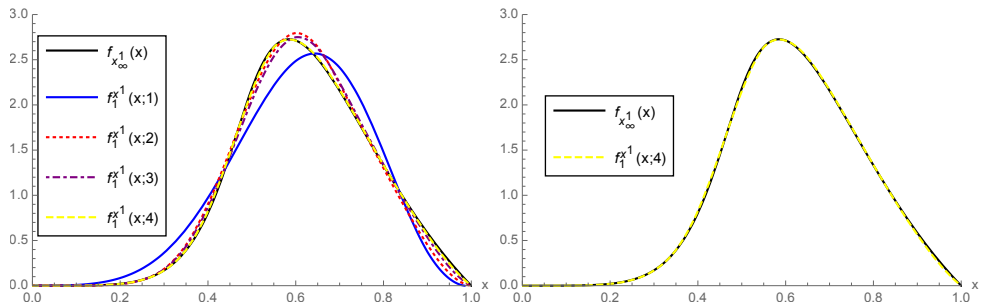

Figure 2: Left: 1-PDF of the solution SP, X_n^1, with $n \in \{1,2,3,4\}$ and the PDF of the equilibrium RV X_∞^1. Right: 1-PDF of the solution SP, X_n^1, with $n = 4$ and the PDF of the equilibrium RV X_∞^1.

3 Example

This section is addressed to show an example where the previous theoretical results are illustrated. With this aim, we need to choose the distributions of RV's X_0^1, P and Q. For the sake of clarity in the presentation, hereinafter we will assume that these RV's are independent. Therefore, its joint PDF can be factorized as the product of each individual PDF, $f_{X_0^1,P,Q}(x_0^1,p,q) = f_{X_0^1}(x_0^1)f_P(p)f_Q(q)$. On the one hand, as X_0^1 is the initial percentage of population in the state 1 (subpopulation 1), it lies between 0 and 1, then it is plausible to assume that X_0^1 has a Uniform distribution on the interval $[0,1]$. On the other hand, as P and Q represent the probabilities to remain in the states 1 (subpopulation 1) and 2 (subpopulation 2), respectively, then interval $[0,1]$ can represent their domains. Therefore, Beta is a flexible biparametric probability distribution for these two RV's, and this motivates that in the sequel we take $P \sim \text{Be}(3;2)$ and $Q \sim \text{Be}(3;5)$.

In Figure 2 the 1-PDF, $f_1^{X^1}(x;n)$, of the solution SP, X_n^1, for different values of $n \in \{1,2,3,4\}$ and the PDF, $f_{X_\infty^1}(x)$, of the equilibrium point, X_∞^1, are shown. As it has been previously pointed out, in this graphical representation one can observe that $f_1^{X^1}(x;n)$ tends to $f_{X_\infty^1}(x)$ when n increases. In Figure 2, we have plotted separately the PDF's $f_1^{X^1}(x;4)$ and $f_{X_\infty^1}(x)$ to better highlight this behaviour. On the right side of Figure 2, we can observe that both PDF's match. In Table 1, we report the total error of approximation $f_1^{X^1}(x;n)$ to $f_{X_\infty^1}(x)$ as n increases. This error is calculated as

$$e_n = \int_0^1 \left| f_1^{X^1}(x;n) - f_{X_\infty^1}(x) \right| \mathrm{d}x, \quad n = 1,2,\ldots \tag{14}$$

In Figure 3, the mean of the solution SP, X_n^1, and the threshold computed by the mean of the equilibrium have been represented. As it occurs with the 1-PDF, now we can observe

	$n=1$	$n=2$	$n=3$	$n=4$
e_n	0.155419	0.0508478	0.0405023	0.00884491

Table 1: Values of error e_n given by (14) for different cycles, $n \in \{1,2,3,4\}$.

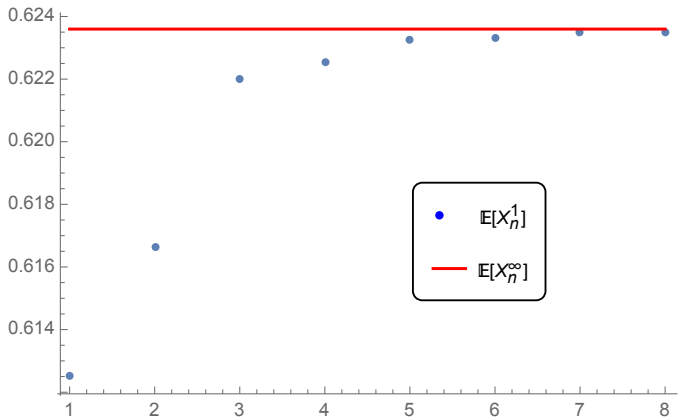

Figure 3: Blue points: $\mathbb{E}\left[X_n^1\right]$ for different $n \in \{1,2,\ldots,8\}$. Red line: $\mathbb{E}\left[X_\infty^1\right]$.

that $\mathbb{E}\left[X_n^1\right]$ tends to $\mathbb{E}\left[X_\infty^1\right]$ as n increases. This fact can be numerically observed in Table 2, where the error measured as the absolute value of the difference between $\mathbb{E}\left[X_n^1\right]$ and $\mathbb{E}\left[X_\infty^1\right]$, has been calculated for $n \in \{1,2,\ldots,8\}$.

	$n=1$	$n=2$	$n=3$	$n=4$

Table 2: Error between $\mathbb{E}\left[X_n^1\right]$ and $\mathbb{E}\left[X_\infty^1\right]$ for different cycles, $n \in \{1,2,\ldots,8\}$.

4 Conclusions

In this paper we have provided a full probabilistic description of random binary Markov chains under very general assumptions on the random inputs. These input are the probabilities of the transition matrix and the initial conditions. That description has been made

 ISBN: 978-84-617-8694-7

through the first probability density function of the discrete solution stochastic process and the probability density function associated to the steady state. Furthermore, the probability density function of a key time having specific interpretation in practice has been determined. Other quantities of great interest in the deterministic context of Markov chains, like first passage time, can be randomized using our approach. This permits the applications of the theoretical results established in this contribution when dealing with real models.

Abstract

Linear differential equations are important to model problems in many disciplines. When its input parameters are treated as random variables, the solution of a random differential equation is a stochastic process. Apart from obtaining the solution stochastic process, it is also important to determine its first probability density function. The first probability density function is important because it provides a comprehensive probabilistic description of the solution and from it one can calculate the mean and the variance functions and other important moments as well. In this paper we deal with the computation of approximations of the first-order probability density function to homogeneous variable-coefficient linear differential equations. This problem is studied under very general assumptions on both the diffusion coefficient and the initial conditions, which are assumed to be a stochastic process and a random variable, respectively. To achieve this goal, the Karhunen-Loève expansion and Random Variable Transformation technique will be applied. Our findings are illustrated by means of a numerical example.

Key words: Random non-autonomous linear differential equations, Random Variable Transformation, Karhunen-Loève expansion.

1 Introduction

Linear differential equations, which depend on a number parameters, are important to model some problems in many disciplines as Physics or Engineering, for example [1]. Although

most of differential equations that appear in practice are nonlinear, linearization can be used to study the local stability of an equilibrium point of a system of nonlinear differential equations or discrete dynamical systems [2]. This method is commonly used in fields such as engineering, Physics, Economics, Ecology, etc.

Coefficients and initial conditions of differential equations are treated as deterministic constants in spite of being usually obtained by measurements and experiments. Then, they contain errors. For this reason, it is more realist to treat these quantities as random variables (RVs) or, when depending on other variables as time and/or space, as stochastic processes (SPs).

A great part of the extant literature dealing with differential equations with uncertainty focuses on the study of Stochastic Differential Equations (SDEs). In that case, randomness is considered by means of special classes of SPs like markovian processes or, even more specific as the Wiener process (also designed as brownian motion). This latter case restricts the uncertainty to gaussian processes with irregular sample behaviour. This class of SDEs are usually referred to as Itô-type SDEs. Solving SDEs is based on Itô calculus [3, 4]. Apart from obtaining the solution SP, solving a SDE also means to determine the mean and the variance of the solution. Complementary to SDEs, uncertainty can be considered through a wider type of probabilistic distributions as binomial, Poisson, beta, gamma, etc. including gaussian, but having milder sample behaviour. This class of equations are referred to as Random Differential Equations (RDEs) and their rigorous analysis is usually based on a he so-called Mean Square calculus [5, 6] whose convergence is termed mean square convergence.

It is worthy to point out that the extension of results of deterministic differential equations to RDEs is not immediate at all. With the aim of motivating this assertion, and to justify our subsequent study for the linear non-autonomous RDE, next we state some well-know in the deterministic framework that do not fulfil in the random context unless additional assumptions are included. Indeed, let us consider the first-order linear RDE

$$x'(t;\omega) = a(\omega)x(t;\omega),\ t \geq 0; \quad x(0;\omega) = 1,$$

where $a = a(\omega)$ is a second-order RV, i.e. having finite variance defined on a complete probability space $(\Omega, \mathcal{F}, \mathbb{P})$. In [5, 7], it has been shown that the extension of the classical Lipschitz condition to mean square calculus in order to prove the uniqueness of the solution to random initial problem (IVP) is satisfied if, and only if, $a = a(\omega)$ is bounded almost surely. As a consequence, this important result is not applicable when $a = a(\omega)$ assumes a Gaussian or a Poisson probability distribution. As another example that highlights deep differences between deterministic and random differential equations, let us consider the following non-homogeneous linear RDE

$$x'(t;\omega) = a(t;\omega)x(t;\omega) + b(t;\omega), \quad x(t_0;\omega) = x_0(\omega). \tag{1}$$

Then, the mean of the solution, $\mu_x(t) = \mathbb{E}[x(t;\omega)]$, does not satisfy the averaged differential

 ISBN: 978-84-617-8694-7

equation (see [5, 8])

$$\frac{\mathrm{d}\,\mu_x(t;\omega)}{\mathrm{d}\,t} = \mathbb{E}[a(t;\omega)]\mu_x(t) + \mathbb{E}[b(t;\omega)], \quad \mu_x(t_0;\omega) = \mathbb{E}[x_0(\omega)].$$

In [9] a random power series solution to random IVP (1) is constructed and the main statistical functions (mean and variance) are calculated using mean square calculus as well.

Besides the calculation of first statistical moments, such as the mean and the variance, the computation of the first probability density function (1-PDF) of the solution SP is much more desirable since, from it, one can compute all the statistical moments. Furhtemore, the 1-PDF provides a comprehensive probabilistic description of the solution SP for each time instant t and it permits compute the probability that the solution lies on a certain set of specific interest.

In a previous contribution [10], some of the authors have provided a closed-form expression for the 1-PDF of the solution SP to first-order autonomous linear RDE whose input parameters (coefficients and initial condition) are assumed to be RVs rather than deterministic constants. This contribution is based on the application of the so-called Random Variable Transformation (RVT) technique. Now, we will reach the next level by considering that the diffusion coefficient of an homogeneous linear RDE is a SP instead of a RV. Therefore, the problem is formulated as follows

$$\left.\begin{array}{rcl} x'(t,\omega) & = & a(t,\omega)x(t,\omega), \quad t \in \mathcal{T} \subset \mathbb{R}^+ \\ x(t_0,\omega) & = & x_0(\omega), \end{array}\right\} \tag{2}$$

where $a : \mathcal{T} \times \Omega \to \mathbb{R}$ is a real-valued SP and $x_0 : \Omega \to \mathbb{R}$ is a real-valued RV. Hereinafter, $\mathrm{L}^2(\Omega, \mathrm{L}^2(\mathcal{T}))$ will denote the Hilbert space of square integrable real-valued SPs [11]. Our main goal is to obtain the 1-PDF, $f_1(x,t)$, of the solution SP, $x(t;\omega)$, to the random IVP (2). This objective will be achieved by applying RVT method together with Karhunen-Loève expansion. Despite of the simplicity in the statement of random IVP (2), as it shall be seen later the answer to this question is far from trivial. Moreover, as far as we know this problem has not be treated yet.

Karhunen-Loève expansion (KLE) is a Fourier type series that permits to represent a SP in $\mathrm{L}^2(\Omega, \mathrm{L}^2(\mathcal{T}))$ by a denumerable set of uncorrelated RVs, $\{\xi_i\}_{i=1}^{\infty}$, with mean zero and unit variance. KLE is a generalization of the spectral decomposition of real-valued symmetric matrices [11].

Theorem 1 (L^2 convergence of Karhunen-Loève) *([11, p.202]) Consider a stochastic process $\{y(t), t \in \mathcal{T}\}$ and suppose that $y(t) \in \mathrm{L}^2(\Omega, \mathrm{L}^2(\mathcal{T}))$. Then,*

$$y(t,\omega) = \mu_y(t) + \sum_{j=1}^{\infty} \sqrt{\nu_j}\phi_j(t)\xi_j(\omega), \quad \omega \in \Omega, \tag{3}$$

 ISBN: 978-84-617-8694-7

where the sum converges in $\mathrm{L}^2(\Omega, \mathrm{L}^2(\mathcal{T}))$,

$$\xi_j(\omega) := \frac{1}{\sqrt{\nu_j}} \left\langle y(t,\omega) - \mu_y(t), \phi_j(t) \right\rangle_{\mathrm{L}^2(\mathcal{T})},$$

being $\mu_y(t) = \mathbb{E}[y(t)]$ *the mean of* $y(t)$ *and* $\{\nu_j, \phi_j\}$ *denote, respectively, the eigenvalues with* $\nu_1 \geq \nu_2 \geq \cdots \geq 0$ *and eigenfunctions of the covariance function,* $C_y(s,t)$ *in*

$$(\mathfrak{C}f)(t) := \int_{\mathcal{T}} C_y(s,t) f(s) \mathrm{d}s, \quad \textit{for } f \in L^2(\mathcal{T}),$$

where $\mathfrak{C}$ *is the integral operator.*

Random variables $\xi_j(\omega)$ *have mean zero, unit variance and are pairwise uncorrelated. If the process is Gaussian, then* $\xi_j \sim N(0,1)$ *i.i.d.*

To apply the RVT technique, we will need to consider the truncation of order N of the infinite series (3), i.e.

$$y_N(t,\omega) = \mu_y(t) + \sum_{j=1}^{N} \sqrt{\nu_j} \phi_j(t) \xi_j(\omega), \quad \omega \in \Omega. \tag{4}$$

In this manner, only the following $N+1$ RVs, $x_0(\omega)$ and $\{\xi_i(\omega) : 1 \leq i \leq N\}$, will be involved in dealing with our approximate problem thas results after substituting the diffusion coefficient $a(t,\omega)$ by the truncated KLE of order N in the original random IVP (2). Then, we will obtain the 1-PDF, $f_1^N(x,t)$, of the solution to the approximate random IVP. The last step will be to prove that $f_1^N(x,t)$ converges to the exact 1-PDF $f_1(x,t)$ under mild conditions. To do this, the following result will be required.

Theorem 2 (Uniform convergence of Karhunen-Loève) *[11, p.203] Consider a stochastic process* $y(t,\omega) \in \mathrm{L}^2(\Omega, \mathrm{L}^2(\mathcal{T}))$, *and let* $y_J(t,\omega)$ *be the stochastic process defined in* (4). *If* $\mathcal{T} \subset \mathbb{R}$ *is a closed and bounded set and the covariance function of* $y(t,\omega))$, $C_y(s,t)$ *is continuous,* $C_y \in \mathbf{C}(\mathcal{T} \times \mathcal{T})$, *then* $\phi_j \in \mathbf{C}(\mathcal{T})$ *and the series expansion of* C_y *converges uniformly. In particular,*

$$\sup_{s,t \in \mathcal{T}} |C_y(s,t) - C_{y,J}(s,t)| \leq \sup_{t \in \mathcal{T}} \sum_{j=J+1}^{\infty} \nu_j \phi_j(t)^2 \to 0, \quad \textit{as } J \to \infty,$$

where $C_{y,J}$ *is the covariance function of the SP* $y_J(t,\omega)$ *defined by*

$$C_{y,J}(s,t) = \sum_{j=1}^{J} \nu_j \phi_j(s) \phi_j(t).$$

Moreover,

$$\sup_{t \in \mathcal{T}} \mathbb{E}\left[(y(t,\omega) - y_J(t,\omega))^2 \right] \to 0, \quad \textit{as } J \to \infty.$$

 ISBN: 978-84-617-8694-7

For the sake of completeness, now we state the RVT technique that will be used throughout our analysis. As previously indicated this result will allow us to determine the 1-PDF $f_1^N(x,t)$ of the truncated solution SP in terms of the joint PDF of the random vector $(x_0(\omega), \xi_1(\omega), \ldots, \xi_N(\omega)$, which will be assumed known.

Theorem 3 (Random Variable Transformation method) *([5, 12]) Let us consider* $\mathbf{x}(\omega) = [x_1(\omega), \ldots, x_m(\omega)]^{\mathsf{T}}$ *and* $\mathbf{y}(\omega) = [y_1(\omega), \ldots, y_m(\omega)]^{\mathsf{T}}$ *be two* m*-dimensional absolutely continuous random vectors defined on a complete probability space* $(\Omega, \mathfrak{F}, \mathbb{P})$*. Let* $\mathbf{r} : \mathbb{R}^m \to \mathbb{R}^m$ *be a one-to-one deterministic transformation of* $\mathbf{x}(\omega)$ *into* $\mathbf{y}(\omega)$*, i.e.,* $\mathbf{y}(\omega) = \mathbf{r}(\mathbf{x}(\omega))$ *for each* $\omega \in \Omega$*. Assume that* $\mathbf{r}$ *is continuous in* $\mathbf{x}(\omega)$ *for every for each* $\omega \in \Omega$ *fixed, and has continuous partial derivatives with respect to each* $x_i \equiv x_i(\omega)$*,* $1 \leq i \leq m$*, for every* $\omega \in \Omega$*. Then, if* $f_{\mathbf{x}(\omega)}(\mathbf{x})$ *denotes the joint probability density function of random vector* $\mathbf{x}(\omega)$*, and* $\mathbf{s} = \mathbf{r}^{-1} = (s_1(y_1, \ldots, y_m), \ldots, s_m(y_1, \ldots, y_m))$ *represents the inverse mapping of* $\mathbf{r} = (r_1(x_1, \ldots, x_m), \ldots, r_m(x_1, \ldots, x_m))$*, the joint probability density function of vector* $\mathbf{y}(\omega)$ *is given by*

$$f_{\mathbf{y}(\omega)}(\mathbf{y}) = f_{\mathbf{x}(\omega)}\left(\mathbf{s}(\mathbf{y})\right) |J_m| \,, \tag{5}$$

where $|J_m|$*, which is assumed to be different from zero, denotes the absolute value of the Jacobian defined by the determinant*

$$J_m = \det \begin{bmatrix} \dfrac{\partial s_1(y_1, \ldots, y_m)}{\partial y_1} & \cdots & \dfrac{\partial s_m(y_1, \ldots, y_m)}{\partial y_1} \\ \vdots & \ddots & \vdots \\ \dfrac{\partial s_1(y_1, \ldots, y_m)}{\partial y_m} & \cdots & \dfrac{\partial s_m(y_1, \ldots, y_m)}{\partial y_m} \end{bmatrix} . \tag{6}$$

The paper is organized as follows. Section 2 is addressed to compute the 1-PDF, $f_1^N(x,t)$, of the truncated solution SP and also to study under what conditions there is convergence in distribution to the 1-PDF of the exact solution SP, $f_1(x,t)$. Our findings are illustrated with a numerical in Section 3. Conclusions are drawn in Section 4.

2 Computing the 1-PDF of the truncated solution stochastic process

It is known that the exact closed solution to the IVP (2) is

$$x(t,\omega) = x_0(\omega) \mathrm{Exp}\left[\int_{t_0}^{t} a(s,\omega) \mathrm{d}s\right], \quad \omega \in \Omega. \tag{7}$$

It is important to note that given a SP $a(t)$, in general nothing is known about the distribution of the random integral $\int_{t_0}^{t} a(s)\,\mathrm{d}s$. An exception is the integrand is a Gaussian

 ISBN: 978-84-617-8694-7

SP. In this case, the integral is also a Gaussian SP, see [5]. This is the reason why Karhunen-Loève expansion is used here.

Let us first consider the truncated Karhunen-Loève expansion of SP $a(t,\omega)$ (see (1))

$$a_N(t,\omega) = \mu_a(t) + \sum_{j=1}^{N} \sqrt{\nu_j}\phi_j(t)\xi_j(\omega), \quad \omega \in \Omega, \tag{8}$$

where $\mu_a(t)$ represents the mean of the SP $a(t,\omega)$.

Secondly, we substitute (8) in (7). Then, the approximated solution SP of the random IVP (2) is

$$\begin{aligned} x_N(t,\omega) &= x_0(\omega)\mathrm{Exp}\left[\int_{t_0}^{t} a_N(s,\omega)\mathrm{d}s\right] \\ &= x_0(\omega)\mathrm{Exp}\left[\int_{t_0}^{t}\left(\mu_a(s) + \sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)\xi_j(\omega)\right)\mathrm{d}s\right]. \end{aligned} \tag{9}$$

Now, fixed $t \in \mathcal{T}$, we will apply the RVT method (see Theorem 3), to obtain the PDF of the approximate solution SP (9) in function of the joint PDF of the random vector $\boldsymbol{\xi}_{N+1}(\omega) = (x_0(\omega), \xi_1(\omega), \ldots, \xi_N(\omega))$, $f_{\boldsymbol{\xi}_{N+1}(\omega)}(\boldsymbol{\xi}_{N+1})$, which is assumed to be known. To this end, we consider the following mapping $\mathbf{r} : \mathbb{R}^{N+1} \to \mathbb{R}^{N+1}$, whose components are r_i, $1 \le i \le N+1$,

$$\begin{aligned} y_1 &= r_1(x_0,\xi_1,\ldots,\xi_N) &&= x_0\ \mathrm{Exp}\left[\int_{t_0}^{t}\left(\mu_a(s) + \sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)\xi_j\right)\mathrm{d}s\right], \\ y_2 &= r_2(x_0,\xi_1,\ldots,\xi_N) &&= \xi_1, \\ &\vdots \\ y_{N+1} &= r_{N+1}(x_0,\xi_1,\ldots,\xi_N) &&= \xi_N. \end{aligned}$$

Its inverse transformation, $\mathbf{s} = \mathbf{r}^{-1}$, is

$$\begin{aligned} x_0 &= s_1(y_1,y_2,\ldots,y_{N+1}) &&= y_1\ \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s) + \sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)y_{j+1}\right)\mathrm{d}s\right], \\ \xi_1 &= s_2(y_1,y_2,\ldots,y_{N+1}) &&= y_2, \\ &\vdots \\ \xi_N &= s_{N+1}(y_1,y_2,\ldots,y_{N+1}) &&= y_{N+1}. \end{aligned}$$

It can be checked that the absolute value of the Jacobian is

$$|J_{N+1}| = \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s) + \sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)y_{j+1}\right)\mathrm{d}s\right] \neq 0.$$

 ISBN: 978-84-617-8694-7

Applying the RVT method (see Theorem 3), we obtain the joint PDF of the random vector $\mathbf{y}_{N+1} = (y_1(\omega), y_2(\omega), \ldots, y_{N+1}(\omega))$ in function of the joint PDF of the random vector $\boldsymbol{\xi}_{N+1}(\omega)$

$$\begin{aligned} f_{\mathbf{y}_{N+1}(\omega)}(\mathbf{y}_{N+1}) &= f_{\boldsymbol{\xi}_{N+1}(\omega)}\left(y_1 \ \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s)+\sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)y_{j+1}\right)\mathrm{d}s\right], y_2, \ldots, y_{N+1}\right) \\ &\quad \times \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s)+\sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)y_{j+1}\right)\mathrm{d}s\right]. \end{aligned} \tag{10}$$

Finally, taking $t \in \mathcal{T}$ arbitrary and marginalizing expression (10), we obtain the 1-PDF of the truncated solution SP

$$\begin{aligned} f_1^N(x,t) &= \int_{\mathcal{D}(\boldsymbol{\xi}_N)} f_{\boldsymbol{\xi}_{N+1}}\left(x \ \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s)+\sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)\xi_j\right)\mathrm{d}s\right], \xi_1, \ldots, \xi_N\right) \\ &\quad \times \mathrm{Exp}\left[-\int_{t_0}^{t}\left(\mu_a(s)+\sum_{j=1}^{N}\sqrt{\nu_j}\phi_j(s)\xi_j\right)\mathrm{d}s\right] \mathrm{d}\xi_N \cdots \mathrm{d}\xi_1, \end{aligned} \tag{11}$$

where $\mathcal{D}(\boldsymbol{\xi}_N)$ denotes the domain of random vector $\boldsymbol{\xi}_N(\omega) = (\xi_1(\omega), \ldots, \xi_N(\omega))$.

The uniformly convergence of the sequence $\{f_1^N(x,t)\}$ in $\mathbb{R} \times \mathcal{T}$, i.e.

$$\lim_{N\to\infty} f_1^N(x,t) = f_1(x,t), \quad \forall (x,t) \in \mathbb{R} \times \mathcal{T}.$$

can be established.

3 Example

In this section we show a numerical example where the main results previously established are illustrated. In this example we assume that $a(t,\omega)$ is the standard Brownian motion, $B(t)$, and $t_0 = 0$, [11, 13]. Then, it is known that is mean, $\mu_a(t) = 0$, and its variance, $\mathbb{V}[a(t)] = 1$, $\forall t \in \mathcal{T} = [0,T]$. Also, the covariance function is given by

$$C_a(s,t) = \min(s,t), \quad (s,t) \in \mathcal{T} \times \mathcal{T},$$

 ISBN: 978-84-617-8694-7

which has the following eigenvalues and normalized eigenfunctions

$$\nu_j = \frac{4T^2}{\pi^2(2j-1)^2}, \quad \phi_j(t) = \sqrt{\frac{2}{T}} \sin\left(\frac{t\pi(2j-1)}{2T}\right), \quad j = 1, 2, \ldots \tag{12}$$

Then according to (11), the 1-PDF of the truncated solution SP, $x_N(t,\omega)$, is

$$f_1^N(x,t) = \int_{\mathcal{D}(\boldsymbol{\xi}_N)} f_{\boldsymbol{\xi}_{N+1}(\omega)} \left(x \prod_{j=1}^{N} \mathrm{e}^{-K_j(t)\xi_j}, \xi_1, \ldots, \xi_N \right) \prod_{j=1}^{N} \mathrm{e}^{-K_j(t)\xi_j} \, \mathrm{d}\xi_N \cdots \mathrm{d}\xi_1, \tag{13}$$

where

$$K_j(t) = \frac{4\sqrt{2}T^2}{\sqrt{T}\pi^2(2j-1)^2} \left(1 - \cos\left(\frac{t\pi(2j-1)}{2T}\right)\right).$$

In this example the 1-PDF of the exact solution SP, $x(t,\omega)$, can be computed. This allows us to check the accuracy of approximations constructed using our approach. Applying RVT technique and as $Z(t) = \int_0^t B(s)\mathrm{d}s \sim \mathrm{N}(0, t^3/3)$, the 1-PDF is given by

$$f_1(x,t) = \int_{-\infty}^{\infty} f_{X_0,Z}(x\,\mathrm{e}^{-z}, z)\,\mathrm{e}^{-z}\,\mathrm{d}z. \tag{14}$$

Hereinafter we will take $\xi_j(\omega)$, $j = 1, 2$, truncated standard Gaussian RVs in the interval $[-10, 10]$, $x_0(\omega)$ a uniform RV on the interval $[0, 1]$, $x_0(\omega) \sim \mathrm{Un}[0, 1]$ and we will assume that $x_0(\omega)$, $\xi_1(\omega)$ and $\xi_2(\omega)$ are independent RVs. In Table 1 the error given by the expression (15) is calculated for different times levels, $t \in \{0.1, 1, 2\}$ and truncation orders, $N = 1, 2$. We observe that the 1-PDF of the first truncation is close to the 1-PDF of the exact solution. Moreover, if the order of truncation increases this error decreases.

$$\mathrm{e}_N(t) = \int_{-\infty}^{\infty} \left| f_1(x,t) - f_1^N(x,t) \right| \mathrm{d}x. \tag{15}$$

$\mathrm{e}_N(t)$	$N=1$	$N=2$
$t=0.1$	0.019319	0.016788
$t=1$	0.077919	0.008663
$t=2$	0.005310	0.000832

Table 1: Error measure $\mathrm{e}_N(t)$ defined by (15) for different time instants, $t \in \{0.1, 1, 2\}$, and truncation orders, $N \in \{1, 2\}$.

 ISBN: 978-84-617-8694-7

4 Conclusions

In this paper we have proposed a method in order to compute the first probability density function of the solution stochastic process to the non-autonomous linear random differential equation with a random initial condition. The method is based on the application of both the Random Variable Transformation technique and the Karhunen-Loève expansion. To the best of our knowledge, thisis the first time that this approach has been considered. The method has been successfully tested through an example where the exact expression of the first probability density function of the solution is available. The proposed technique is promising, and we will study its application to complex random differential equations in our forthcoming research.

Abstract

The heliostat field of a solar power tower system, considering both its deployment cost and potential energy loss at operation, must be carefully designed. This procedure implies facing a complex continuous, constrained and large-scale optimization problem. Hence, its resolution is generally wrapped by extra distribution patterns or layouts with a reduced set of parameters. Griding the available surface is also an useful strategy. However, those approaches limit the degrees of freedom at optimization. In this context, the authors of this work are working on a new meta-heuristic for heliostat field optimization by directly addressing the underlying problem. Attention is also given to the benefits of modern High-Performance Computing (HPC) to allow a wider exploration of the search-space. Thus, a parallel genetic optimizer has been designed for direct heliostat field optimization. It relies on elitism, uniform crossover, static penalization of infeasible solutions and tournament selection.

Key words: heliostat field optimization, genetic algorithm, parallelization

1 Introduction

Solar central receiver systems, SCRS in what follows, are one the most promising flagships in the field of solar energy for large-scale electricity production. This is mainly due to the high thermodynamic efficiency and power output stability that can be achieved by these

 ISBN: 978-84-608-6082-2

systems [2, 6]. For the scope of this work, SCRS can be defined as a large set of high reflectance mirrors, called 'heliostats', and a radiation receiver on top of a tower. Heliostats feature an orientable structure and a tracking system that make them follow the apparent solar movement throughout days while also reflecting the incident radiation on the receiver. This energy is then progressively transferred to a working fluid which circulates inside the receiver. Finally, once the temperature of the fluid is high enough, it can be ultimately used in a turbine cycle to generate electricity. In Fig. 1, an illustrative depiction of this kind of systems is shown. Further information of SCRS can be found in [1, 16].

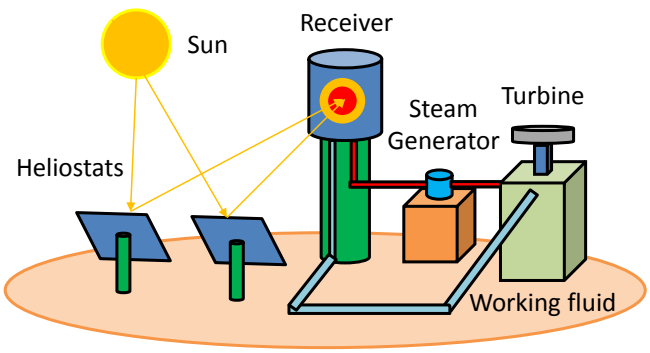

Figure 1: Scheme of a solar tower power plant.

The heliostat field supposes up to 50% of the initial investment costs and can cause up to 40% of energetic loss at operation [3, 6]. Consequently, its design must be carefully optimized. Some valid criteria to do so are the total intercepted power [8] (which is the objective chosen in this work), optical efficiency [3, 10] (which can be seen as a ratio between the really intercepted power and the theoretical maximum), land use [10, 15] and price of production [12]. Heliostat field optimization is a complex problem in which [5]: i) the coordinates of every heliostat should be directly considered (and commercial fields have, at least, several hundreds of heliostats) with placement constraints and ii) the objective function is computationally expensive and multi-modal without a direct solid approach. According to the concise and clear analysis done in [5, 8], most design methodologies relies on a) well-known parametric distribution patterns and b) selection of positions. Besides, these approaches could also be combined and expanded with what could be called 'special strategies'. Regarding known distribution patterns, there are some classic ones such as the popular radial-staggered scheme (used in [6, 10, 11]). There are also some recent and interesting proposals such as the parametric layout described in [12], which mainly expands the concept of radial staggering with more degrees of freedom. In [10], apart from trying to optimize a radial-stagger distribution, an innovative pattern is also proposed, a bio-inspired spiral later used in [3]. In relation to greedy selection of positions, the method of [15], in

 ISBN: 978-84-608-6082-2

which a grid is formed on the available surface, is widely known. The approach proposed in [5] is similar to that strategy. In fact, the concept of selection is also generally applied to pattern-based fields by generating larger layouts than needed and ultimately selecting the best heliostats as investigated in [3, 10, 11, 12]. Hence, layouts could be even seen as 'smart' ways of generating available positions. This is a good way to partially overcome the constrained perspective of parametric layouts as commented in [12]. Additionally, what has been tagged as 'special strategies', without considering some of the previous ones which also combine several ideas/steps, could contain the methods proposed in [4, 8] for their enhanced flexibility. In [4], an interesting procedure in which the refinement of a preliminary design is presented. In [8], based on some works exposing the sub-optimality of parametric approaches, the whole complexity of the problem is directly addressed with a classical optimization approach and a gradient-based method.

The authors of this work have defined a new meta-heuristic for heliostat field design. It aims to address the continuous and constrained large-scale problem of adjusting the coordinates of very heliostat through gradually altering the search-space shown to any selected optimizer. In this paper, the design of an optimizer specially designed for the problem at hand is described and commented. It is a genetic algorithm that has been designed with the main aim of keeping a simple but robust and parallel structure. We are aware that this type of algorithms have already been used for heliostat field optimization but i) their interesting theoretical principles worth its application in our specific context and, ii) their use is commonly focused on relatively reduced set of parameters as in [3, 4, 11, 12]. The underlying premise of design is: 'The more solutions can be explored per unit of time, the better results can be obtained'. In fact, the objective function is complex and requires simulating several candidate fields, which can be computationally expensive. Furthermore, as directly working with coordinates, it is expected that numerous cycles will be needed to achieve good solutions. Nevertheless, the procedure also relies on known principles to properly converge. Specifically, elitism, tournament selection and uniform crossover. Besides, points of potential knowledge-injection are also highlighted. This paper is organized as follows: In Section 2, the optimization problem is formally described in terms of maximizing the total power reflected on the receiver. Then, in Section 3, the genetic optimizer is described in detail. Finally, in Section 4, conclusions are drawn and future work is planned.

2 Problem statement

As introduced, the problem at hand consist in placing a certain number of heliostats on a flat ground so that, they reflect the maximum power on a known receiver. Let H be the total number of heliostats to deploy. All are assumed to be of the same size and specifications (as usual, to benefit from large-scale production). Specifically, their reflective surface is

 ISBN: 978-84-608-6082-2

rectangular and has a size of $l \times w$ (from length and width, respectively). Every heliostat h can be identified on the field by its central point, $C_h = (x_h, y_h)$ (assuming Cartesian coordinates). Hence, a field of H heliostats can be defined as a vector $F = (C_1, \cdots, C_H) = (x_1, y_1, \cdots, x_H, y_H)$ in $\mathbb{R}^{2H}$.

Considering the previous definitions, the problem to solve will have $2H$ dimensions, i.e., two coordinates per heliostat. Let $P_T(F)$ be the total power effectively reflected by a certain field F on the receiver throughout a fixed set of T instants of interest (i.e., defined apparent solar positions), $T = \{t_1, \cdots, t_T\}$. Depending on the final application requirements, T can vary from a single one (for design-point optimization) to many ones encompassing, for instance, a whole year (which increase the complexity and, specially, the computational cost). $P_T(F)$, which will be the objective function, can be analytically defined as expressed in Eq. (1) [8, 9].

$$P_T(F) = A \sum_{t=t_1}^{T} I_t \left(\sum_{h=h_1}^{H} \eta_h(t) \right) \tag{1}$$

In relation to A, it is the reflective area of the heliostat model (approximately $l \times w$ (m^2)) and I_t is the incident radiation density at instant t (kW/m^2). Regarding $\eta_h(t)$, it is the instantaneous efficiency factor of heliostat h at instant t (from 0 to 1, minimum and maximum efficiencies respectively). This factor depends on i) the instant, ii) the position of heliostat h in relation to the receiver and iii) the other heliostats due to potential interactions. Its computation implies both simulating and analyzing the behavior of the candidate field. As clearly explained in [3, 10, 16], this factor models different sources of energy loss at operation. In fact, it is composed by different sub-factors (also in range [0,1]). The abstract definition selected in this work is shown in Eq. (2), and it is the same selected in [3, 9, 10].

$$\eta_h = \eta_{cos} \eta_{sb} \eta_{itc} \eta_{aa} \eta_{ref} \tag{2}$$

A brief summary of the components of Eq. (2) and the way in which they are computed is shown next:

- η_{cos} **(Cosine loss)**: The effective reflective area of a heliostat is reduced by the cosine of angle of incidence of solar radiation. It is computed as described in [16].
- η_{sb} **(Shading and blocking loss)**: Every heliostat can partially obstruct the radiation either incident (shading) or reflected (blocking) from any other one. It is computed as recently proposed in [13] with the method for candidate filtering used in [10]. This is the most computationally expensive part pf the function.
- η_{itc} **(Interception loss)**: The reflected flux map of heliostats might not perfectly fit the desired zone of the receiver. It is computed according to the model proposed in [9] (which avoids its temporal component for computational efficiency).

 ISBN: 978-84-608-6082-2

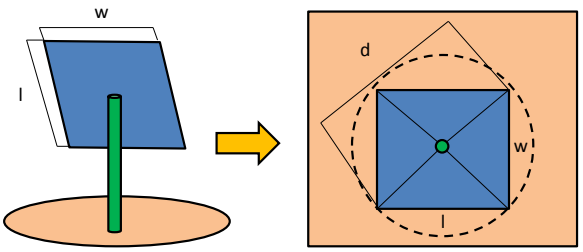

Figure 2: Characteristic safety distance for heliostats.

- η_{aa} **(Atmospheric attenuation loss)**: The atmosphere attenuates reflected radiation from heliostats along its trajectory. It is estimated by using the same model applied in [10] (which is also non-instant dependent).

- η_{ref} **(Reflectivity loss)**: Heliostats cannot grant a lossless reflection phenomenon. It is considered as a common fabrication constant as in [10].

Additionally, it must also be considered that: i) the receiver base will be at the origin of coordinates, ii) no heliostats can be neither nearer the receiver than R_{min} nor further than R_{max} and iii) heliostats should be able to freely move without colliding each other, where the safety distance d can be computed as $d = \sqrt{l^2 + w^2}$ (see Fig.2). At this point, the target optimization problem expressed in Eq. (3). Therefore, there are $H(H-1)/2 + 2H$ constrains to satisfy (as distance from any point a to b is the same that from b to a) and the potential problem dimensionality is really large.

$$\begin{aligned} \underset{F}{\text{maximize}} \quad & P_T(F) \\ \text{subject to} \quad & \sqrt{x^2+y^2} \geq R_{min} + \frac{d}{2}, \forall C = (x,y) \\ & \sqrt{x^2+y^2} \leq R_{max} - \frac{d}{2}, \forall C = (x,y) \\ & \sqrt{(x_i-x_j)^2+(y_i-y_j)^2} \geq d, \forall C_i = (x_i,y_i), C_j = (x_j,y_j) : (i \neq j) \end{aligned} \tag{3}$$

3 Method description

Genetic algorithms (GA), proposed by Holland in late seventies [7], are commonly used for complex global optimization problems. This is because their underlying theoretical principle is not linked to any particular problem but to the abstract evolution of species. Specifically,

 ISBN: 978-84-608-6082-2

a population of candidate solutions ('individuals') is generated and simulated to evolve (including interaction) until a certain halt condition met. In fact, as commented in Sec.1, they are usually considered for heliostat field optimization. In any case, the concept of GA (and even evolutionary computing in general) is quite wide and abstract. Hence, this kind of methods is ultimately adapted to the target problem, which usually determines both the selection of its base operators and their scope. Further information on population-based heuristic including GA, see [14].

In this work, a GA has been designed for the problem defined at Sec.2. Besides, as large populations are expected to be used it has the underlying aim of being able to run in parallel too. This strategy adapts the whole procedure to exploit modern high-performance environments, which is specially valuable to attenuate the potential cost of the objective function (specially for large fields and/or sets of instants).

The structure defined for the individuals is quite simple: They are vectors of length $2H$ with an additional field to record the fitness of that field design, i.e., the total power that it reflected on the receiver after simulation (evaluation of Eq. (1)). In Fig.3, the structure of individuals is depicted. Besides, it is important to remember, as included in that figure, that every pair of coordinates is linked to a certain heliostat. However, GA are mainly suited to unconstrained optimization [17] and as the problem at hand is constrained, some adaptations must be done. Specifically, the problem is treated as an unconstrained one and any unfeasible solution, i.e., those that does not respect all constraints, will be penalized with very low fitness. Penalization will only depend on the degree of violation, i.e., the more constraints are not respected (number and amount), the worse fitness is associated. This approach, which is quite common to handle constrained optimization problems with GA, is called 'static penalization' [17]. Thus, the designed method ignores the constraints shown in Eq. (3) but alter the evaluation of any candidate solution, F, as defined in Eq. 4. In that expression, m_c is the distance between heliostat c and the tower base, i.e., $m = \sqrt{x_c^2 + y_c^2}$, and I_T is the summation of solar radiation density at every instant in T. Finally, V is an abstract set which contains a record for every heliostat c in F and the constraints it violates (to compute only those factors). Every heliostat in V has also a special set linked, V_c listing any other heliostat z that is too near.

$$eval(F) = \begin{cases} P_T(F), & \text{if } V = \emptyset \\ 0 - AI_T \left(\frac{(R_{min}+d/2)-m_c}{(R_{min}+d/2)} + \frac{m_c-(R_{max}-d/2)}{m_c} \right. & \\ \left. + \frac{d-dist(C_c,C_z)}{d} \right) ; \forall c \in V, \forall z \in V_c & \text{otherwise} \end{cases} \quad (4)$$

Once the definition of candidate solutions and how constraints are handled, the genetic procedure can be described. It takes the input parameters listed below:

- pop_{size}: the population size, which will be kept constant during the search.
- num_{pairs}: the number of pairs to form for crossover.

 ISBN: 978-84-608-6082-2

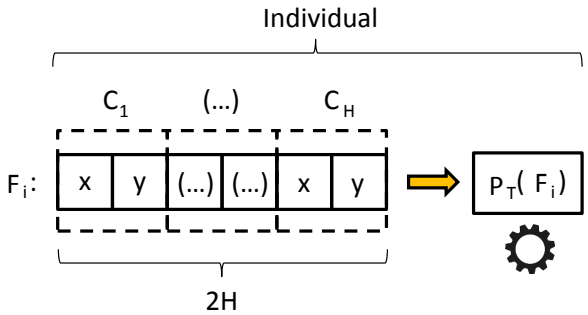

Figure 3: Diagram of an individual.

- $tourn_{size}$: the tournament size at any selection (both for crossover and replacement).
- ov_{mut}: the overall probability mutating a descendant.
- per_{mut}: the probability of altering every heliostat of a descendant once mutation started.
- *cycles*: the number of cycles, i.e., generations to run.

It must be noted that contextual information such as the description of the field, which is necessary to evaluate candidate solutions, is assumed implicitly available. With all this information, the algorithm described in Alg.1 is executed. As can be seen, it is a common evolutionary loop in which the parts that involve evaluating the objective function is distributed among concurrent threads (in a shared-memory environment). In fact, they all are forced to wait for the master to define the population of the next cycle before starting at line 12. By proceeding this way, threads can share the cost of evaluating the objective function (which is required at initialization (line 5), reproduction (line 9) and mutation (line 10)) while a consistent common population is maintained. Functions *createThreads*, *runInParallel* and *getChunkSize*, they are referred to the way in which a thread pool can be created and launched to work on different ranges of the population matrix. Similarly, tag *synchr* simple indicates that the update of that variable must be consistent. The tag *barrier_master_do* declares that the operation must be executed by the master while any other thread is forced to wait for him. Regarding the algorithmic behavior of the proposed GA, it is described next.

Function *GenerateInitialPop* (line 5) is expected to create as many candidate solutions, i.e., F vectors, as required by the population size. However, their evaluation according to Eq.4 is also required to form complete individuals. In fact, heliostats at this point are only forced to respect the constraints involving R_{min} and R_{max}, just to limit their position, but

Algorithm 1: Genetic algorithm for the first layer of the problem.

Input: Int $pop_{size}, num_{pairs}, tourn_{size}, cycles$, Real ov_{mut}, per_{mut}
Output: Vector F in $\mathbb{R}^{2H}$

1 IndividualSet *pop*, Individual *bestIndividual*; /* Shared among threads */
2 ThreadTeam $threads = createThreads()$; /* Create a team */
3 $threads.runInParallel()$; /* Thread-local below: */
4 Integers $range = getChunkSize()$; /* Get my zone of work as a thread */
5 $pop = GenerateInitialPop(pop_{size}, range, INJECT?)$;
6 $bestIndividual < synchr >= UpdateBest(pop)$;
7 **for** $i = 1$ ***to*** *cycles* **do**
8 IndividualSet $progs = SelectProgenitors(pop, range < num_{pairs} >, tourn_{size})$;
9 IndividualSet $desc = Reproduce(progs)$;
10 IndividualSet $descMut = Mutate(desc, ov_{mut}, per_{mut})$;
11 $bestIndividual < synchr >= UpdateBest(desc, descMut)$;
12 $pop < barrier\_master\_do >= Replace(pop, descMut, KEEP\_BEST)$;
13 **end**
14 **return** $bestIndividual.F$

collisions are not avoided. Thus, partially unfeasible solutions are possible from the very beginning. Nevertheless, its special label '$INJECT?$' declares the possibility of including some 'special individuals'. Specifically, it is referred to adding some fields obtained from any robust distribution pattern such as the biomimetic spiral proposed in [10]. This is a two-bladed option because it injects solid knowledge to the population from its origin, but also induces a serious influence in it because the fitness of those individuals will be much more higher than the other ones. Hence, it could lead to an important genetic drift and premature convergence. This option should be avoided or, at least, minimized when possible.

Function *SelectProgenitors* (line 8) simply looks for two different progenitors to form every pair. To do so, tournament selection is performed. This method is one of the most popular for GA as it can easily combine uniformity of exploration with adjustable selection pressure. Thus, every progenitor of each pair is selected out of a sample of $tourn_{size}$ participants. This is also the procedure applied in function *Replace* (line 12), in which the master selects every surviving individual out of $pop_{size} - 1$ tournaments. The previous -1 is caused because the best solution known so far is always left as part of the population (at it would not be guaranteed to participate at any tournament otherwise). This is called 'elitism' in the field of GA, and it is based on the idea that the structure of a very good solution could orientate the other ones to better zones of the search-space.

Function *Reproduce* (line 9) takes every pair and gets two descendant from each one.

 ISBN: 978-84-608-6082-2

To do so, uniform crossover is applied. This method is very popular because it features a high rate of mixing that tends to more complete explorations of the search-space. Its procedure consists in these steps: First, an auxiliary crossover mask is randomly defined. It is a binary string of length H (one per heliostat, i.e., pair of coordinates C) in which every bit had the same probability to be either a 0 or a 1. Second, a first descendant is formed by taking the heliostats (coordinates x and y) of its progenitor i for every position in which the auxiliary mask has a 1 while they taken from the progenitor $i+1$ otherwise. Third, the mask is inverted and a second descendant is obtained by applying the same rules. Any new individual must be ultimately evaluated according to Eq. 4.

Function $Mutate$ (line 10) is expected to allow the population to reach completely new zones of the search-space. To do so, every descendant has a probability of ov_{mut} of suffering any kind of mutation. Specifically, their set of heliostats is crossed and any of them has a probability of per_{mut} of being randomly repositioned. It must be noted that altered individuals must be evaluated as new ones. Besides, when applied, mutation can override promising solutions and make them worse. This is why a copy of the non-mutated ones is maintained to update the global reference of the best solution known so far.

Finally, the method returns to the best vector of coordinates defining a field that has been found during the search. That vector would be the solution that our meta-heuristic would receive for further processing.

4 Conclusions and future work

In this work, the problem of heliostat field optimization has been presented and formally stated. The field is not tried to be described by a reduced set of design variables, but the complete set of continuous coordinates is directly addressed. This approach maximizes the degrees of freedom at designing the field with respect to the use of parametric patterns. Increasing the mobility at search has been proven to lead to better designs. In fact, any final pattern can be seen just as a special case of a continuous pattern-free optimization. In this context, the authors of this paper are working on a meta-heuristic that can reduce the complexity of a complete resolution without significantly losing the achieved flexibility. However, as a meta-heuristic, it must be coupled with an optimizer to effectively solve the problem. Hence, a minimalist and parallel genetic algorithm has been designed for that purpose. Its aim is to perform a wide exploration of the search-space by using high-performance computing environments while also guiding the search. It relies on i) elitism, ii) uniform crossover, iii) static penalization and v) tournament selection. Additionally, the possibility of injecting distribution patterns as initial individuals is also allowed. It should be used with extreme care to avoid strong genetic drift and premature convergence.

Regarding future work, the most immediate one is to enhance the current preliminary implementation of the method. After that, it will included in our meta-heuristic and its real

 ISBN: 978-84-608-6082-2

performance for the problem at hand will be analyzed in depth. Hence, that some aspects might have to be further adapted.

Numerical solution of surface integral equations based on spline quasi-interpolation

Catterina Dagnino[1] and Sara Remogna[1]

[1] *Department of Mathematics, University of Torino, via C. Alberto, 10 - 10123 Torino, Italy*

emails: catterina.dagnino@unito.it, sara.remogna@unito.it

Abstract

In this paper we propose a modified version of the classical collocation method and two spline collocation methods with high order of convergence, for the solution of integral equations on surfaces of $\mathbb{R}^3$. Such methods are based on optimal superconvergent quasi-interpolants defined on type-2 triangulations and based on the Zwart-Powell quadratic box spline.

Key words: surface integral equation, spline quasi-interpolation
MSC 2000: 65R20, 65D07

1 Introduction

In this paper we consider the surface integral equation

$$\rho(\mathbf{P}_1) - \int_S K(\mathbf{P}_1, \mathbf{P}_2)\rho(\mathbf{P}_2)dS_{\mathbf{P}_2} = \psi(\mathbf{P}_1), \quad \mathbf{P}_1 \in S, \tag{1}$$

where S is a connected surface in $\mathbb{R}^3$, described by a sufficiently smooth map $\mathbf{F} : \Omega \to S$, with Ω a polygonal domain in $\mathbb{R}^2$, and the kernel $K(\mathbf{P}_1, \mathbf{P}_2)$ is continuous for $\mathbf{P}_1$, $\mathbf{P}_2 \in S$.

Therefore, (1) can be written as

$$\rho(\mathbf{F}(u,v)) - \int_\Omega K(\mathbf{F}(u,v), \mathbf{F}(s,t))\rho(\mathbf{F}(s,t)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(s,t)| \, ds \, dt = \psi(\mathbf{F}(u,v)), \ (u,v) \in \Omega,$$

where $|(D_s\mathbf{F} \times D_t\mathbf{F})(s,t)|$ is the Jacobian of the map $\mathbf{F}(s,t)$.

If we denote by $\mathcal{K} : C(S) \longrightarrow C(S)$ the integral operator defined by

$$\mathcal{K}\rho(\mathbf{F}(u,v)) := \int_{\Omega} K(\mathbf{F}(u,v), \mathbf{F}(s,t))\rho(\mathbf{F}(s,t)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(s,t)| \; ds \; dt,$$

for $(u,v) \in \Omega$, then we can write (1) in the following operator form

$$(\mathcal{I} - \mathcal{K})\rho = \psi. \tag{2}$$

We remark that (2) has a unique solution $\rho \in C(S)$ for any given $\psi \in C(S)$ [3].

In the literature, standard methods for solving (2) consist in Nyström, Galerkin and collocation methods. For instance, we recall the collocation ones based on a sequence of linear interpolatory projection operators onto finite dimensional subspaces $\mathcal{X}_{mn}$ of $C(S)$, converging to the identity operator pointwise. A classical choice of $\mathcal{X}_{mn}$ is the space of C^0 piecewise polynomials of a given degree d (usually $d = 2$) on a triangulation of Ω (see [3, 5]).

In this paper we propose three collocation methods for (2), based on a sequence of optimal superconvergent spline quasi-interpolating operators $\{Q_{mn}\}$, that are not projectors and are defined on the space $\mathcal{X}_{mn} = S_2^1(\Omega, T_{mn})$ of the C^1 quadratic splines on a uniform type-2 triangulation T_{mn} of Ω, with Ω a rectangular domain. We recall [12] that the above quasi-interpolating splines are expressed by means of the scaled/translates of the Zwart-Powell quadratic box spline (ZP-element) (see e.g. [4, Chap. 1], [14, Chap. 2]). From a computational point of view, this is more convenient than the use of other spanning sets, for instance formed by bivariate B-splines with support completely included in Ω [1, 7, 9, 13], that, having different supports, have different expressions in the domain, while the ZP-element is always the same.

Given a rectangular domain $\Omega = [a,b] \times [c,d]$, by dividing it into mn equal squares $\{\Omega_{ij}\}_{i=1,\ j=1}^{m\ \ n}$ with a given edge h, $m, n \geq 4$, each of them being subdivided into 4 triangles by its diagonals, we obtain a uniform type-2 triangulation T_{mn} of Ω. We denote by $S_2^1(\Omega, T_{mn})$ the space of C^1 quadratic splines on T_{mn}, whose dimension is $(m+2)(n+2) - 1$ ([14] and the reference therein).

This space is generated by the $(m+2)(n+2)$ B-spline functions $\{B_{i,j}, (i,j) \in A_{mn}\}$, where $A_{mn} = \{(i,j),\ 0 \leq i \leq m+1,\ 0 \leq j \leq n+1\}$, obtained by dilation/translation of the ZP-element. Moreover, in order to obtain a B-spline basis for $S_2^1(\Omega, T_{mn})$ we have to neglect one B-spline from the spanning set ([14] and the reference therein).

In the space $S_2^1(\Omega, T_{mn})$ we consider special optimal quasi-interpolants (abbr. QIs) of the form

$$Q_{mn}f := \sum_{(i,j)\in A_{mn}} \lambda_{i,j}(f) B_{i,j}, \tag{3}$$

with $\{\lambda_{i,j},\ (i,j) \in A_{mn}\}$ a family of local linear functionals defined in this way

$$\lambda_{i,j}(f) := \sum_{(k,l)\in F_{i,j}} \sigma_{i,j}(k,l) f(M_{k,l}), \tag{4}$$

 ISBN: 978-84-617-8694-7

where the finite set of points $\{M_{k,l},\ (k,l) \in F_{i,j}\}$, $F_{i,j} \subset A_{mn}$, lies in some neighbourhood of $\text{supp}B_{i,j} \cap \Omega$ and the $\sigma_{i,j}(k,l)$'s are chosen such that $Q_{mn}f \equiv f$ for all f in $\mathbb{P}_2$ (the space of bivariate polynomials of total degree two) and superconvergence is induced at some specific points, i.e. the vertices, the centers, the midpoints of horizontal and vertical edges of each subsquare of the partition. The coefficient functional expression (4) is given in [12] and we recall that $\|Q_{mn}\|_\infty \leq 2$. The points $M_{k,l}$ in (4) are the mn centers of the squares, the $2(m+n)$ midpoints of boundary segments and the four vertices of Ω.

We remark that the QIs (3) can also be written in quasi-Lagrange form

$$Q_{mn}f := \sum_{(i,j)\in A_{mn}} f(M_{i,j})L_{i,j},$$

by means of the fundamental functions $L_{i,j}$, obtained as linear combination of the $B_{i,j}$'s.

Standard results in approximation theory and other specific ones given in [6] allow us to deduce the following theorem, where $D^\beta = D^{\beta_1\beta_2} = \frac{\partial^{|\beta|}}{\partial x^{\beta_1}\partial y^{\beta_2}}$, with $|\beta| = \beta_1 + \beta_2$, $\|D^\nu f\|_\infty = \max\limits_{|\beta|=\nu} \left\|D^\beta f\right\|_\infty$, $\omega\left(D^\nu f, h\right) = \max\left\{\omega\left(D^\alpha f, h\right), |\alpha| = \nu\right\}$, where $\omega(f,h) = \max\left\{|f(P_1) - f(P_2)|\,; P_1, P_2 \in \Omega, \|P_1 - P_2\| \leq h\right\}$ is the modulus of continuity of $f \in C(\Omega)$, and $\|\cdot\|$ is the Euclidean norm.

Theorem 1 *Let $f \in C^\nu(\Omega)$, $0 \leq |\alpha| \leq \nu \leq 2$, $|\alpha| = 0, 1$ then*

$$\|D^\alpha(f - Q_{mn}f)\|_\infty \leq K_{\alpha,\nu}h^{\nu-|\alpha|}\omega\left(D^\nu f, h\right),$$

where the error constant $K_{\alpha,\nu}$ is independent of h and depends only on α and ν.

If, in addition, $f \in C^3(\Omega)$, then

$$\|D^\alpha(f - Q_{mn}f)\|_\infty \leq K_{\alpha,3}h^{3-|\alpha|}\left\|D^3 f\right\|_\infty.$$

We underline that Q_{mn} has superconvergence properties. In particular, for $f \in C^4(\Omega)$, we have that $|(f - Q_{mn}f)(P)| = O(h^4)$ at specific points P in Ω, that are the vertices, the centers, the midpoints of horizontal and vertical edges of each subsquare of Ω partition.

Finally, the above superconvergent QIs can be applied to numerical integration, getting cubature rules that we will use in Section 2.2.

For any function $f \in C(\Omega)$, we can numerically evaluate the integral

$$I(f) = \int_\Omega f(s,t)\, ds\, dt$$

by the cubature rule defined by

$$I(Q_{mn}f) = \sum_{(i,j)\in A_{mn}} w_{i,j}f(M_{i,j}), \tag{5}$$

 ISBN: 978-84-617-8694-7

where the weights

$$w_{i,j} = \int_\Omega L_{i,j}(s,t)\ ds\ dt.$$

are reported in [8].

From Theorem 1, we can easily deduce the following result.

Theorem 2 *Let $f \in C(\Omega)$ and $E(f) = I(f) - I(Q_{mn}f)$.*
Then, $|E(f)| \leq \bar{C}\omega(f,h)$, where $\bar{C}$ is a positive constant independent of m and n.
Moreover if $f \in C^\nu(\Omega)$, $\nu = 1,2,3$, then $E(f) = O(h^\nu)$.

We remark that the above cubature has precision degree at least 2, because Q_{mn} is exact on $\mathbb{P}_2$. However, since uniform partitions are special cases of the ones with symmetric knots with respect to the center of Ω, Corollary 1 of [10] can be generalized to our case, getting

$$I(f) = I(Q_{mn}f) \text{ for } f(s,t) = s^{r_1}t^{r_2},$$

with $0 \leq r_1, r_2 \leq 3$, $r_1 + r_2 = 3$ and $r_1, r_2 = 1,3$, with $r_1 + r_2 = 4$. Therefore the precision degree of the cubature (5) is 3 and, if $f \in C^4(\Omega)$, then $E(f) = O(h^4)$.

2 Collocation methods for surface integral equations

In this section we present and analyse three collocation methods (see [8] for details) based on the sequence $\{Q_{mn}\}$ of spline QI operators defined in Section 1.

2.1 Modified collocation method

In this method, that we call *modified collocation method*, in (2) we replace the operator $\mathcal{K}$ by $Q_{mn}\mathcal{K}$ and the right hand side ψ by $Q_{mn}\psi$. We remark that the idea of defining a collocation method by operators that are not projectors has been proposed in [2] for univariate integral equations.

Therefore, we approximate the integral equation (2) by

$$(\mathcal{I} - Q_{mn}\mathcal{K})\rho_{mn} = Q_{mn}\psi. \tag{6}$$

We write the approximated solution ρ_{mn}, belonging to $S_2^1(\Omega, T_{mn})$, as

$$\rho_{mn}(\mathbf{F}(u,v)) = \sum_{\alpha \in A_{mn}} X_\alpha L_\alpha(u,v), \quad \text{with} \quad \alpha = (i,j).$$

Substituting the expressions of Q_{mn} and ρ_{mn} into (6), by identifying the coefficients of L_α, we obtain

$$X_\alpha - \sum_{\beta \in A_{mn}} X_\beta \bar{L}_\beta(M_\alpha) = \psi(\mathbf{F}(M_\alpha)), \quad \alpha \in A_{mn},$$

 ISBN: 978-84-617-8694-7

with $\bar{L}_\beta = \mathcal{K} L_\beta$. This is a linear system of $(m+2)(n+2)$ equations, that can be written in the form

$$(I - A)\mathbf{X} = \mathbf{a} \tag{7}$$

where A is the matrix with entries

$$A_{\alpha\beta} := \bar{L}_\beta(M_\alpha) = \int_\Omega K(\mathbf{F}(M_\alpha), \mathbf{F}(s,t)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(s,t)| \, L_\beta(s,t) \; ds \; dt \tag{8}$$

and $\mathbf{a}$ is the vector with elements $\mathbf{a}_\alpha := \psi(\mathbf{F}(M_\alpha))$.

Concerning the convergence, we can state the following theorem.

Theorem 3 *Let $\rho \in C^3(\Omega)$, then $\|\rho - \rho_{mn}\|_\infty = O\left(h^3\right)$.*

2.2 Collocation methods with high order of convergence

In these methods, that we call *collocation methods with high order of convergence*, in (2) we replace $\mathcal{K}$ by one of the two following finite rank operators

$$\mathcal{K}_{mn,i} := Q_{mn}\mathcal{K} + \mathcal{K}^*_{mn,i} - Q_{mn}\mathcal{K}^*_{mn,i}, \qquad i = 1, 2,$$

where

1. $\mathcal{K}^*_{mn,1}$ is the degenerate kernel operator defined by

$$\begin{aligned} &\mathcal{K}^*_{mn,1}\rho(\mathbf{F}(u,v)) \\ &:= \int_\Omega Q_{mn}\left(K(\mathbf{F}(u,v), \mathbf{F}(s,t)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(s,t)|\right) \rho(\mathbf{F}(s,t)) \; ds \; dt \\ &= \sum_{\alpha \in A_{mn}} K(\mathbf{F}(u,v), \mathbf{F}(M_\alpha)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(M_\alpha)| \cdot \int_\Omega L_\alpha(s,t)\rho(\mathbf{F}(s,t)) \; ds \; dt, \end{aligned} \tag{9}$$

2. $\mathcal{K}^*_{mn,2}$ is the Nyström operator based on Q_{mn} and defined by

$$\mathcal{K}^*_{mn,2}\rho(\mathbf{F}(u,v)) := \sum_{\alpha \in A_{mn}} w_\alpha K(\mathbf{F}(u,v), \mathbf{F}(M_\alpha)) \, |(D_s\mathbf{F} \times D_t\mathbf{F})(M_\alpha)| \, \rho(\mathbf{F}(M_\alpha)), \tag{10}$$

according to (5).

We remark that such methods are defined by a logical scheme similar to that one used in [1] to construct methods for 2D integral equations, based on other quasi-interpolants.

Therefore, we approximate (2) by

$$\rho_{mn,i} - (Q_{mn}\mathcal{K} + \mathcal{K}^*_{mn,i} - Q_{mn}\mathcal{K}^*_{mn,i})\rho_{mn,i} = \psi, \qquad i = 1, 2. \tag{11}$$

 ISBN: 978-84-617-8694-7

that can be reduced to two systems of $2(m+2)(n+2)$ linear equations.

After some algebra, from (9) and (11), we can write the approximate solution $\rho_{mn,1}$ as:

$$\begin{aligned}\rho_{mn,1}(\mathbf{F}(u,v)) = \; & \psi(\mathbf{F}(u,v)) + \sum_{\alpha\in A_{mn}} X_\alpha L_\alpha(u,v) \\ & + \sum_{\alpha\in A_{mn}} Y_\alpha K(\mathbf{F}(u,v),\mathbf{F}(M_\alpha))\,|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\alpha)|\,,\end{aligned}$$

where the unknowns $\{X_\alpha\}$ and $\{Y_\alpha\}$, $\alpha\in A_{mn}$, are obtained by solving the linear system $(I-R)\mathbf{Z}=\mathbf{d}$, with

$$R := \begin{bmatrix} A & D-B \\ C & E \end{bmatrix}, \quad \mathbf{Z} := \begin{bmatrix} \mathbf{X} \\ \mathbf{Y} \end{bmatrix}, \quad \mathbf{d} := \begin{bmatrix} \mathbf{b} \\ \mathbf{c} \end{bmatrix} \tag{12}$$

and A, B, C, D, $E\in\mathbb{R}^{(m+2)(n+2)\times(m+2)(n+2)}$, $\mathbf{b}$, $\mathbf{c}\in\mathbb{R}^{(m+2)(n+2)}$, whose entries are given by

- $A_{\alpha,\beta} := \bar{L}_\beta(M_\alpha)$, see (8),
- $B_{\alpha,\beta} := K(\mathbf{F}(M_\alpha),\mathbf{F}(M_\beta))\,|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\beta)|$,
- $C_{\alpha,\beta} := \displaystyle\int_\Omega L_\alpha(s,t)L_\beta(s,t)\;ds\;dt$,
- $D_{\alpha,\beta} := \displaystyle\int_\Omega K(\mathbf{F}(M_\alpha),\mathbf{F}(s,t))|(D_s\mathbf{F}\times D_t\mathbf{F})(s,t)|K(\mathbf{F}(s,t),\mathbf{F}(M_\beta))|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\beta)|\;ds\;dt$,
- $E_{\alpha,\beta} := \displaystyle\int_\Omega K(\mathbf{F}(s,t),\mathbf{F}(M_\beta))\,|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\beta)|\,L_\alpha(s,t)\;ds\;dt$,
- $\mathbf{b}_\alpha := \mathcal{K}\psi(\mathbf{F}(M_\alpha)) = \displaystyle\int_\Omega K(\mathbf{F}(M_\alpha),\mathbf{F}(s,t))\,|(D_s\mathbf{F}\times D_t\mathbf{F})(s,t)|\,\psi(\mathbf{F}(s,t))\;ds\;dt$,
- $\mathbf{c}_\alpha := \displaystyle\int_\Omega \psi(\mathbf{F}(s,t))L_\alpha(s,t)\;ds\;dt$.

Similarly, from (10) and (11), we can get that the solution $\rho_{mn,2}$ is

$$\begin{aligned}\rho_{mn,2}(\mathbf{F}(u,v)) = \; & \psi(\mathbf{F}(u,v)) + \sum_{\alpha\in A_{mn}} X_\alpha L_\alpha(u,v) \\ & + \sum_{\alpha\in A_{mn}} w_\alpha Y_\alpha K(\mathbf{F}(u,v),\mathbf{F}(M_\alpha))\,|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\alpha)|\,,\end{aligned}$$

where the unknowns $\{X_\alpha\}$ and $\{Y_\alpha\}$, $\alpha\in A_{mn}$, are obtained by solving the linear system $(I-T)\mathbf{Z}=\mathbf{f}$, with

$$T := \begin{bmatrix} A & F-G \\ H & G \end{bmatrix}, \quad \mathbf{Z} := \begin{bmatrix} \mathbf{X} \\ \mathbf{Y} \end{bmatrix}, \quad \mathbf{f} := \begin{bmatrix} \mathbf{a} \\ \mathbf{e} \end{bmatrix} \tag{13}$$

and F, G, $H\in\mathbb{R}^{(m+2)(n+2)\times(m+2)(n+2)}$, $\mathbf{e}\in\mathbb{R}^{(m+2)(n+2)}$, whose entries are given by

- $F_{\alpha,\beta} := w_\beta \displaystyle\int_\Omega K(\mathbf{F}(M_\alpha), \mathbf{F}(s,t))|(D_s\mathbf{F}\times D_t\mathbf{F})(s,t)|K(\mathbf{F}(s,t), \mathbf{F}(M_\beta))|(D_s\mathbf{F}\times D_t\mathbf{F})(M_\beta)|\, ds\, dt,$
- $G_{\alpha,\beta} := w_\beta K(\mathbf{F}(M_\alpha), \mathbf{F}(M_\beta))\, |(D_s\mathbf{F} \times D_t\mathbf{F})(M_\beta)|,$
- $H_{\alpha,\beta} := L_\beta(M_\alpha),$
- $\mathbf{e}_\alpha := \psi(\mathbf{F}(M_\alpha).$

Concerning the convergence, we can state the following theorem.

Theorem 4 *If ρ is differentiable with bounded derivatives, $K(\cdot,\cdot) \in C^4(S \times S)$ and $\mathbf{F} \in C^5(\Omega)$, then $\|\rho - \rho_{mn,1}\|_\infty = O(h^7)$.*

If $\rho \in C^4(S)$, $K(\cdot,\cdot) \in C^4(S \times S)$ and $\mathbf{F} \in C^5(\Omega)$, then $\|\rho - \rho_{mn,2}\|_\infty = O(h^7)$.

3 Numerical results

By using the collocation methods (6) and (11), we have to evaluate many integrals and usually it must be done by suitable numerical integration formulas. Therefore, we have to discretize the proposed methods by introducing convenient cubatures and we denote by ρ^D_{mn}, $\rho^D_{mn,i}$, $i = 1, 2$, the corresponding solutions.

Here, we decide to compute the entries of the matrices and vectors appearing in (7), (12), (13), by using a composite Gaussian cubature on triangular domains (see [11]), implemented by the Matlab function `triquad` (see [15]), with N^2 nodes in each triangle of T_{mn} and with precision degree $2N - 1$. The number of nodes is chosen to preserve the approximation order of the method. Therefore, we choose $N = 2$ for the modified collocation method (6) and $N = 4$ for the two collocation methods with high order of convergence (11).

We test the performances of the proposed methods in the numerical solution of the surface integral equation from [3]

$$\rho(\mathbf{P}_1) - \frac{1}{30}\int_S \rho(\mathbf{P}_2)\frac{\partial}{\partial \mathbf{n}_{\mathbf{P}_2}}\left(\|\mathbf{P}_1 - \mathbf{P}_2\|^2\right) dS_{\mathbf{P}_2} = \frac{1}{30}\psi(\mathbf{P}_1),\ \mathbf{P}_1 \in S,$$

where S is the ellipsoidal surface given by $x^2 + \left(\frac{4y}{3}\right)^2 + (2z)^2 = 1$, $\mathbf{n}_{\mathbf{P}_2}$ is the inner normal to S at $\mathbf{P}_2$ and

$$\mathbf{F}(s,t) = \begin{bmatrix} \sin(s)\cos(t) \\ \frac{3}{4}\sin(s)\sin(t) \\ \frac{1}{2}\cos(s) \end{bmatrix}, \qquad (s,t) \in \Omega = [0,\pi] \times [0, 2\pi].$$

We choose $\rho(\mathbf{P}) = e^{\frac{1}{2}\cos(s)}$ and define ψ accordingly.

 ISBN: 978-84-617-8694-7

For each method we compute the maximum absolute errors

$$E_{mn} = \max_{(u,v)\in G} |\rho(u,v) - \rho^D_{mn}(u,v)|, \quad E_{mn,i} = \max_{(u,v)\in G} |\rho(u,v) - \rho^D_{mn,i}(u,v)|, \quad i = 1,2,$$

for increasing values of m and n, where G is a uniform grid of 100×100 points in Ω. We also compute the corresponding numerical convergence orders o_{mn}, $o_{mn,i}$, $i = 1,2$.

The results are shown in Table 1 and we can notice that they agree with the theoretical ones.

Table 1: Maximum absolute errors and numerical convergence orders.

Abstract

We consider an optimal order numerical approximation for the boundary layer adaptive solution of a system of reaction-diffusion problems. To generate the layer adaptive mesh, we use the equidistribution of a positive monitor function. This technique enables the mesh movement to follow the rapidly changing behavior of the solution. It is observed that the discrete solution is second-order uniformly convergent on this mesh and the convergence is optimal with respect to the discretization of the continuous problem. Numerical experiments validate the performance of the present method.

1 Introduction

In this work, we consider a system of reaction diffusion model which frequently rises in control theory [8]. For the numerical analysis, we consider the following singularly perturbed system of reaction-diffusion problems on $x \in \Omega = (0,1)$:

$$\boldsymbol{Lu}(x) = \boldsymbol{f}(x) \Leftrightarrow \begin{cases} L_1\boldsymbol{u}(x) \equiv -\varepsilon u_1''(x) + b_{11}(x)u_1(x) + b_{12}(x)u_2(x) = f_1(x), \\ L_2\boldsymbol{u}(x) \equiv -\varepsilon u_2''(x) + b_{21}(x)u_1(x) + b_{22}(x)u_2(x) = f_2(x), \\ u_1(0) = 0, \quad u_1(1) = 0, \quad u_2(0) = 0, \quad u_2(1) = 0, \end{cases} \tag{1}$$

where $0 < \varepsilon \ll 1$ is the singular perturbation parameter and $\boldsymbol{u}(x) = (u_1(x), u_2(x))^T$, $\boldsymbol{L} = (L_1,\ L_2)^T$ and $\boldsymbol{f}(x) = (f_1(x), f_2(x))^T$ which are assumed to be sufficiently smooth. The matrix $(b_{ij})_{i,j=1}^2$ is considered an L_0-matrix (*i.e.,* off-diagonals are nonpositive and diagonals are positive) with

$$\min_{x\in\overline{\Omega}=[0,1]} \left\{ \sum_{j=1}^{2} b_{mj}(x) \right\} \geq \beta > 0, \quad \text{for} \quad m = 1, 2, \tag{2}$$

and $\overline{\beta} > b_{ii}(x) > \beta > 0,\ i, j = 1, 2$, for some real number β, $\overline{\beta}$. Under these assumptions the equation (1) has a unique solution $\boldsymbol{u}(x)$ [3] with two boundary layers at $x = 0, 1$.

Numerical methods on a fixed uniform mesh do not capture boundary layer for an arbitrary value of ε, unless one uses the fitted operator technique. This technique is well developed in several works of Vigo-Aguiar et al. [9, 10]. In recent days, fitted mesh methods have shown its interest, where one needs to find an adaptive mesh which is dense inside the boundary layers. In [6], an almost second order convergence upto logarithmic term is observed on Shishkin's fitted mesh for (1). Here, our aim is to develop a numerical method for (1) which is exactly second order convergent. For this, we use the mesh equidistribution technique. A mesh $\{a = x_0 < x_1 < \cdots < x_N = b\}$ is said to be equidistributed [2, 4, 7], if

$$\int_{x_{i-1}}^{x_i} M\big(s, \boldsymbol{u}(s)\big) ds = \frac{1}{N} \int_a^b M\big(s, \boldsymbol{u}(s)\big) ds, \quad i = 1, \cdots, N, \tag{3}$$

where $M\big(x, \boldsymbol{u}(x)\big) (> 0)$ is called the error monitor function. This technique automatically adopts the mesh by equidistributing $M\big(s, \boldsymbol{u}(s)\big)$. Nowadays, several researchers have shown their interest on the moving mesh methods for scalar singularly perturbed reaction-diffusion [1, 3]. Here, our main goal is to obtain a parameter uniform optimal order convergent solution for a system of singularly perturbed reaction-diffusion problems using mesh equidistribution.

The paper is divided as follows. In Section 2, we propose an error monitor function whose equidistribution leads to an layer adaptive mesh. The finite difference discretization of (1) and its stability analysis is considered in Section 3. In Section 4, it is shown that the discrete solution is second-order parameter uniformly convergent on the equidistributed mesh. This order of convergence is optimal with respect to the discretization of the continuous problem. The numerical examples in Section 5 validates the theoretical prediction.

Throughout this paper, C denotes a generic positive constant, independent of ε, x_i (mesh points) and N (number of partitions of the domain $\overline{\Omega}$). We set $\phi_i = \phi(x_i)$ for any scalar function ϕ, while ϕ_i^N (or Φ_i^N for vector valued function) denote a numerical approximation of ϕ (analogously $\Phi = (\phi_1, \phi_2)^T \in \mathbb{R}^2$) at x_i. We denote $||\cdot||_\infty$ as $||\phi|| = ||\phi(x)||_D = \max_{\xi\in D} |\phi(\xi)|$ for any function ϕ defined on some domain D. Analogously for $\boldsymbol{\phi} \in \mathbb{R}^2$, $||\boldsymbol{\phi}||$ will be denoted as $||\boldsymbol{\phi}||_\infty = ||\boldsymbol{\phi}|| = \max_{x\in D} \{|\phi_1|, |\phi_2|\}$. In the analysis, we assume that ε satisfies $0 < \sqrt{\varepsilon} < N^{-1}$, as otherwise, the adaptive mesh is not required.

 ISBN: 978-84-617-8694-7

2 Derivative Bounds of the Solution

We decompose the analytical solution $\boldsymbol{u}$ into the smooth and singular components $\boldsymbol{v}$ and $\boldsymbol{w}$ resp. such that $\boldsymbol{u} = \boldsymbol{v} + \boldsymbol{w}$. The following lemma provides the derivative bounds of $\boldsymbol{v}$, $\boldsymbol{w}$.

Lemma 2.1 *The smooth component* $\boldsymbol{v} = (v_1, v_2)^T$, *where*

$$\boldsymbol{L}\boldsymbol{v}(x) = \boldsymbol{f}(x), \quad x \in \Omega, \quad \textit{where } \boldsymbol{v}(0) \textit{ and } \boldsymbol{v}(1) \textit{ are suitably chosen},$$

and the singular component $\boldsymbol{w} = (w_1, w_2)^T$, *where*

$$\boldsymbol{L}\boldsymbol{w}(x) = 0, \quad x \in \Omega, \quad \boldsymbol{w}(0) = \boldsymbol{u}(0) - \boldsymbol{v}(0), \quad \boldsymbol{w}(1) = \boldsymbol{u}(1) - \boldsymbol{v}(1),$$

satisfy

$$|\boldsymbol{v}^{(k)}(x)| \leq C(1 + \varepsilon^{(2-k)/2}), \textit{ for } k = 0, \cdots, 4, \tag{4}$$

and

$$|\boldsymbol{w}^{(k)}(x)| \leq C\varepsilon^{-k/2}\big(\exp(-x\sqrt{\beta/\varepsilon}) + \exp(-(1-x)\sqrt{\beta/\varepsilon})\big), \textit{ for } k = 0, \cdots, 4. \tag{5}$$

Proof. The proof of this lemma is given in [5]. For our error analysis, we shall use the leading order asymptotic expansion of the solution $\boldsymbol{u}(x)$ of (1) and its derivative bound. To find this, we use the decomposition of the solution $\boldsymbol{u}(x)$ into smooth component $\boldsymbol{v}(x)$ and the singular component $\boldsymbol{w}(x)$. To find this, we use the asymptotic expansion technique. For the smooth component $\boldsymbol{v}(x)$, we use the asymptotic expansion $\boldsymbol{v}(x) = \boldsymbol{v}_0(x) + \varepsilon\boldsymbol{v}_1(x) = (v_{01}(x) + \varepsilon v_{11}(x), v_{02}(x) + \varepsilon v_{12}(x))^T$ where $\boldsymbol{v}_1(0) = 0$ and $\boldsymbol{v}_1(1) = 0$. Hence the leading order term $\boldsymbol{v}_0(x)$ of $\boldsymbol{v}(x)$ satisfies (by putting $\varepsilon = 0$ in (1))

$$b_{11}(x)v_{01}(x) + b_{12}(x)v_{02}(x) = f_1(x), \quad b_{21}(x)v_{01}(x) + b_{22}(x)v_{02}(x) = f_2(x),$$

which ensures the ε uniform bound of $v_{01}(x)$ and $v_{02}(x)$. In a similar way, following the technique given in [6], we can obtain the derivative bounds in (4). Now, we decompose the singular/layer component $\boldsymbol{w}(x)$ as $\boldsymbol{w}(x) = \boldsymbol{w}^l(x) + \boldsymbol{w}^r(x)$ such that

$$\begin{cases} \boldsymbol{L}\boldsymbol{w}^l(x) = 0, \quad x \in \Omega, \\ \boldsymbol{w}^l(0) = \boldsymbol{w}(0), \quad \boldsymbol{w}^l(1) = 0, \end{cases} \quad \text{and} \quad \begin{cases} \boldsymbol{L}\boldsymbol{w}^r(x) = 0, \quad x \in \Omega, \\ \boldsymbol{w}^r(0) = 0, \quad \boldsymbol{w}^r(1) = \boldsymbol{w}(1). \end{cases}$$

Let us introduce the asymptotic expansions for the left-hand singular component $\boldsymbol{w}^l = (w_1^l, w_2^l)^T$ and the right-hand singular component $\boldsymbol{w}^r = (w_1^r, w_2^r)^T$ as

$$w_s^l(x) = w_{0s}^l(x) + \sqrt{\varepsilon}w_{1s}^l(x) + \varepsilon w_{2s}^l(x) + \cdots, \quad w_s^r(x) = w_{0s}^r(x) + \sqrt{\varepsilon}w_{1s}^r(x) + \varepsilon w_{2s}^r(x) + \cdots,$$

 ISBN: 978-84-617-8694-7

where $s = 1, 2$. To find the derivative bounds of $\boldsymbol{w}^l$, we shall use the transformation $\xi = x/\sqrt{\varepsilon}$. Using the Taylor series expansions of $b_{mn}(\xi\sqrt{\varepsilon})$, $m, n = 1, 2$, comparing the terms of order ε, it can be checked that the leading order terms of $\boldsymbol{w}^l(\xi)$ satisfies

$$\hat{L}_1 w_{01}^l + b_{12}(0) w_{02}^l = 0, \quad \hat{L}_2 w_{02}^l + b_{21}(0) w_{01}^l = 0,$$
$$w_{0k}^l(0) = -v_{0k}(0) \text{ with } \lim_{\xi\to\infty} w_{0k}^l(\xi) = 0, \text{ for } k = 1, 2,$$

where $\hat{L}_k \equiv -\dfrac{d^2}{d\xi^2} + b_{kk}(0)I$ and so on. In a similar way, the leading order terms of $\boldsymbol{w}^r(\xi)$ satisfies

$$\hat{L}_1 w_{01}^r + b_{12}(1) w_{02}^r = 0, \quad \hat{L}_2 w_{02}^r + b_{21}(1) w_{01}^r = 0,$$
$$w_{0k}^r(1) = -v_{0k}(1) \text{ with } \lim_{\xi\to-\infty} w_{0k}^r(\xi) = 0, \text{ for } k = 1, 2,$$

and so on. Now we can use a similar approach provided in [6] to have $|w_k^l(1)| < C\exp(-\beta/\varepsilon)$ and $|w_k^{l\ (p)}(x)| \le C\varepsilon^{-p/2}\exp\left(-x\sqrt{\beta/\varepsilon}\right)$, where $k = 1, 2$. By a similar way, using the asymptotic expansion technique, we can obtain the derivative bounds of the right-hand side of the boundary layer. This completes the proof of this lemma. ∎

From now onwards, we shall concentrate only on the finer bounds of the derivatives of $\boldsymbol{v}(x)$ and $\boldsymbol{w}(x)$. The *a priori* derivative bounds of the solution suggest that the boundary layer phenomena occurs from the singular component $\boldsymbol{w}(x) = (w_1(x), w_2(x))^T$ of the solution. Mesh equidistribution in (3) can also be thought of as a mapping $x = x(\xi)$ from a computational coordinate $\xi \in [0, 1]$ to the physical coordinate $x \in \overline{\Omega}$, defined by

$$\int_0^{x(\xi)} M\big(s, \boldsymbol{u}(s)\big) ds = \xi \int_0^1 M\big(s, \boldsymbol{u}(s)\big) ds. \tag{6}$$

To simplify the error analysis, we consider a monitor function, which only involves the singular component, since the derivatives of the singular component are not uniformly bounded with respect to ε. Here, we consider

$$M(x, \boldsymbol{u}(x)) = \alpha + |w_1''(x)|^{1/2} + |w_2''(x)|^{1/2}, \tag{7}$$

which involves the singular components (w_1, w_2) of $\boldsymbol{u}$. This choice will make the analysis simpler. Here α is a positive constant which is defined in Lemma 2.2. To approximate $w_k''(x)$, $k = 1, 2$, we use Lemma 2.1 with $0 < \varepsilon \ll 1$. Hence, the leading order expansion of $\boldsymbol{w}(x)$ follows

$$|w_m''(x)| \approx \begin{cases} \kappa_{m1}\varepsilon^{-1}\exp\left(-x\sqrt{\dfrac{\beta}{\varepsilon}}\right), & x \in [0, 1/2], \\ \kappa_{m2}\varepsilon^{-1}\exp\left(-(1-x)\sqrt{\dfrac{\beta}{\varepsilon}}\right), & x \in (1/2, 1], \end{cases}$$

 ISBN: 978-84-617-8694-7

where κ_{m1} and κ_{m2} for $m = 1, 2$, are constants which are independent of ε and x. Hence, we have

$$\int_0^1 (|w_1''(x)|^{1/2} + |w_2''(x)|^{1/2})dx \equiv K \approx 2\big[\sum_{i,j=1}^{2} |\kappa_{ij}|^{1/2}\big]/\sqrt{\beta}.$$

Substituting the approximate value of $w_k''(x)$ in (6), we obtain for $x(\xi) \leq 1/2$,

$$\xi\left(\frac{\alpha}{K}+1\right) = \alpha\frac{x(\xi)}{K} + \frac{2\sum_{i=1}^{2}|\kappa_{i1}|^{1/2}}{K\sqrt{\beta}}\left[1-\exp\left(-\frac{x(\xi)}{2}\sqrt{\frac{\beta}{\varepsilon}}\right)\right]. \tag{8}$$

Similarly, for $x(\xi) > 1/2$, we have

$$(1-\xi)\left(\frac{\alpha}{K}+1\right) = \alpha\frac{(1-x(\xi))}{K} + \frac{2\sum_{i=1}^{2}|\kappa_{i2}|^{1/2}}{K\sqrt{\beta}}\left[1-\exp\left(-\frac{(1-x(\xi))}{2}\sqrt{\frac{\beta}{\varepsilon}}\right)\right]. \tag{9}$$

Note that the equidistribution principle (6) is a mapping from the physical nonuniform coordinates $\{x_i\}_{i=0}^N$ to the computational coordinates of uniform meshes $\{\xi_i = i/N\}_{i=0}^N$. Hence, we have from (8) and (9) that

$$\frac{\alpha x_i}{K} + K_1\left[1-\exp\left(-\frac{x_i}{2}\sqrt{\frac{\beta}{\varepsilon}}\right)\right] = \frac{i}{N}\left(\frac{\alpha}{K}+1\right), \quad \text{for } x_i \leq 1/2, \tag{10}$$

and for $x_i > 1/2$

$$\frac{\alpha(1-x_i)}{K} + K_2\left[1-\exp\left(-\frac{(1-x_i)}{2}\sqrt{\frac{\beta}{\varepsilon}}\right)\right] = \left(1-\frac{i}{N}\right)\left(\frac{\alpha}{K}+1\right), \tag{11}$$

where

$$K_1 = \frac{\sum_{i=1}^{2}|\kappa_{i1}|^{1/2}}{\sum_{i,j=1}^{2}|\kappa_{ij}|^{1/2}} \quad \text{and} \quad K_2 = 1-K_1.$$

Hence, the adaptively generated mesh x_i is the solution of the nonlinear algebraic equations (10) and (11). Now let us denote the step sizes on an arbitrary mesh $\Omega^N \equiv \{0 = x_0 < x_1 < \cdots < x_N = 1\}$ as $h_i = x_i - x_{i-1}$. The following lemma provides the structure of the mesh distribution and a choice for α.

Lemma 2.2 *Let us assume that $\alpha = K$ in (10) and (11). Then the mesh points satisfy*

$$x_{k_l} < 2\sqrt{\frac{\varepsilon}{\beta}}\ln(N) < x_{k_l+1}, \text{ and } x_{k_r-1} < 1-2\sqrt{\frac{\varepsilon}{\beta}}\ln(N) < x_{k_r},$$

 ISBN: 978-84-617-8694-7

with $k_l = \left[\frac{K_1}{2}(N-1) + \sqrt{\frac{\varepsilon}{\beta}} N \ln(N)\right]$, $\quad k_r = \left[N - \frac{K_2}{2}(N-1) - \sqrt{\frac{\varepsilon}{\beta}} N \ln(N)\right] + 1$, *where* $[\cdot]$ *denotes the integral part of the inside quantity. In particular, the mesh widths within the boundary layers i.e., for* $i = 1, \cdots, k_l, k_r + 1, \cdots, N$, *satisfy* $h_i < C\sqrt{\varepsilon/\beta}$, *with*

$|h_{i+1} - h_i| \leq Ch_i^2, \quad i = 1, \cdots, k_l - 1$, *and* $|h_{i+1} - h_i| \leq Ch_{i+1}^2, \quad i = k_r + 1, \cdots, N-1$, *and*

$\exp\left(\frac{-x_i}{2}\sqrt{\frac{\beta}{\varepsilon}}\right) \leq CN^{-1}$, $i \geq k_l - 1$, $x_i \leq 1/2$, *and* $\exp\left(\frac{-(1-x_i)}{2}\sqrt{\frac{\beta}{\varepsilon}}\right) \leq CN^{-1}$, $i \leq k_r$, $x_i > 1/2$.

Proof. The proof of the above results on mesh structure follows from [1]. ∎

The following lemma provides upper bounds for the mesh spacings generated by (10-11).

Lemma 2.3 *Mesh spaces generated by the equidistribution of monitor function (7) satisfy*

$$h_i \leq CN^{-1}, \text{ for } i = 1, \cdots, N.$$

Proof. Note that (7) satisfies $M(x, \boldsymbol{u}(x)) \geq \alpha = K$. The derivative bounds of Lemma 2.1 follows $\int_0^1 M(x, \boldsymbol{u}(x))dx \leq C_1$ where C_1 is independent of ε. Hence, (3) implies

$$\alpha h_i \leq \int_{x_{i-1}}^{x_i} M(x, \boldsymbol{u}(x))dx = \frac{1}{N}\int_0^1 M(x, \boldsymbol{u}(x))dx \leq C_1 N^{-1}.$$

Therefore $h_i \leq CN^{-1}$. ∎

3 Discrete Problem

In this section, we consider the discrete problem and its stability for (1). We use the following finite difference schemes to discretize (1) on $\Omega^N \equiv \{0 = x_0 < x_1 < \cdots < x_N = 1\}$. For a given discrete function $\eta(x_i) = \eta_i$, we use the central difference operator

$$\delta^2\eta_i = \frac{(D^+\eta_i - D^-\eta_i)}{\hbar_i} \quad \text{where} \quad D^+\eta_i = \frac{\eta_{i+1} - \eta_i}{h_{i+1}} \text{ and } D^-\eta_i = \frac{\eta_i - \eta_{i-1}}{h_i},$$

where $\hbar_i = (h_i + h_{i+1})/2$ to discretize the problem (1). Therefore, the discrete problem corresponding to the continuous version (1) becomes:
Find $\boldsymbol{U} = (U_1, U_2)^T$ such that

$$\boldsymbol{L}^N \boldsymbol{U}_i = \boldsymbol{f}_i \Leftrightarrow \begin{cases} L_1^N \boldsymbol{U}_i \equiv -\varepsilon\delta^2 U_{1,i} + b_{11,i} U_{1,i} + b_{12,i} U_{2,i} = f_{1,i}, \\ L_2^N \boldsymbol{U}_i \equiv -\varepsilon\delta^2 U_{2,i} + b_{21,i} U_{1,i} + b_{22,i} U_{2,i} = f_{2,i}, \quad i = 1, \cdots, N-1, \\ U_{1,0} = U_{1,N} = U_{2,0} = U_{2,N} = 0, \end{cases} \quad (12)$$

 ISBN: 978-84-617-8694-7

where $\boldsymbol{L}^N = (L_1^N,\ L_2^N)^T$ is the discrete operator corresponding to the continuous operator $\boldsymbol{L}$ and $\boldsymbol{f}_i = (f_{1,i}, f_{2,i})^T$. By solving the system of linear algebraic equations in (12) on the adaptive equidistributed mesh obtained by the equidistribution of (7), we obtain the numerical solution $\boldsymbol{U}$ on the adaptive mesh $x_0, x_1, \cdots, x_N$. Observe that the discrete operator $\boldsymbol{L}^N$ satisfies the following comparison principle.

Lemma 3.1 *If two mesh functions $\boldsymbol{V}$ and $\boldsymbol{W}$, where $\mathbf{V}_i = (V_{1,i}, V_{2,i})$ and $\mathbf{W}_i = (W_{1,i}, W_{2,i})$ satisfy $(\boldsymbol{L}^N \boldsymbol{V})_i \geq (\boldsymbol{L}^N \boldsymbol{W})_i$, for $1 \leq i \leq N-1$, with $\boldsymbol{V}_0 \geq \boldsymbol{W}_0$ and $\boldsymbol{V}_N \geq \boldsymbol{W}_N$, then $\boldsymbol{V}_i \geq \boldsymbol{W}_i$, for $1 \leq i \leq N-1$.*

Proof. Let us assume $\mathbf{Z}_i = \mathbf{V}_i - \mathbf{W}_i$. Therefore, it is enough to show that $\mathbf{Z}_i \geq 0$ under the conditions stated above. Now, let us assume that the above result is not true, i.e., there exists $x_p \in \Omega^N$ such that $Z_{q,p} < 0$ for some q. Let $\boldsymbol{S}_i = (S_{1,i}, S_{2,i})^T$ where $S_{k,i} = 1$ for all i and k and assume $\phi = \max_k\{\max_i(-Z_k/S_k)(x_i)\}$. This implies that there exists a mesh point $x_* \in \Omega^N$ such that $(Z_t + \phi S_t)(x_*) = 0$ for some t. Note that $(Z_{k,i} + \phi S_{k,i}) \geq 0$ for all $i = 0, \cdots, N$. Therefore, the minimum of $Z_k + \phi S_k$ attains at x_*.

Again $(L_k^N \boldsymbol{S})_i = \sum_{j=1}^2 b_{kj,i} > 0$ from (2). Therefore

$$\begin{aligned} 0 < (L_t^N(\boldsymbol{Z} + \phi \boldsymbol{S}))_* &= -\varepsilon\delta^2(Z_t + \phi S_t)_* + \textstyle\sum_{j=1}^2 b_{tj,*}(Z_{j,*} + \phi S_{j,*}) \\ &= -\varepsilon\delta^2(Z_t + \phi S_t)_* + \textstyle\sum_{j=1, j\neq t}^2 b_{tj,*}(Z_{j,*} + \phi S_{j,*}) \leq 0 \end{aligned}$$

which is a contradiction. Therefore $\mathbf{Z}_i \geq 0$ for all i. ∎

An immediate consequence of the above lemma is the following stability result of (12).

Lemma 3.2 *If $\boldsymbol{U}_i = (U_{1,i}, U_{2,i})$, $0 \leq i \leq N$ is any discrete solution satisfying the problem (12), then*

$$\|\boldsymbol{U}\| \leq C \max\{\|\boldsymbol{U}_0\|, \|\boldsymbol{U}_N\|, \|\boldsymbol{L}^N \boldsymbol{U}_i\|\}. \tag{13}$$

Proof. Define the barrier function $\boldsymbol{U}_i^{\pm} = (U_{1,i}^{\pm}, U_{2,i}^{\pm})^T$ as $U_{k,i}^{\pm} = C_1 \pm U_{k,i}$, where $C_1 = C_2 \max\{\|\boldsymbol{U}_0\|, \|\boldsymbol{U}_N\|, \|\boldsymbol{L}^N \boldsymbol{U}_i\|\}$ where C_2 is a ε- independent positive user chosen constant. Then $\boldsymbol{U}_0^{\pm} \geq 0$ and $\boldsymbol{U}_N^{\pm} \geq 0$. Again,

$$(L_k^N \boldsymbol{U}^{\pm})_i = \pm L_k^N \boldsymbol{U}_i^N + C_1 \sum_{j=1}^2 b_{kj,i} \geq \pm L_k^N \boldsymbol{U}_i^N + C_1\beta > 0$$

for $C_2 \geq 1/\beta$. Therefore $\boldsymbol{U}_i^{\pm} \geq 0$ which proves the lemma. ∎

4 Convergence Analysis

Here, we describe the ε-uniform convergence analysis of the solution of (12). First, we decompose the numerical solution $\boldsymbol{U}$, into smooth and singular components $\boldsymbol{V}$ and $\boldsymbol{W}$

 ISBN: 978-84-617-8694-7

respectively, *i.e.,* $\boldsymbol{U} = \boldsymbol{V} + \boldsymbol{W}$, where $\boldsymbol{V}$ and $\boldsymbol{V}$ satisfy

$$\begin{cases} \boldsymbol{L}^N \boldsymbol{V}_i = \boldsymbol{f}_i, & i = 1, \cdots, N-1, \\ \boldsymbol{V}_0 = \boldsymbol{v}(0), \quad \boldsymbol{V}_N = \boldsymbol{v}(1), \end{cases} \text{ and } \begin{cases} \boldsymbol{L}^N \boldsymbol{W}_i = 0, & i = 1, \cdots, N-1, \\ \boldsymbol{W}_0 = \boldsymbol{w}(0), \quad \boldsymbol{W}_N = \boldsymbol{w}(1). \end{cases}$$

Therefore, using the triangle inequality, we can write that the error of the numerical solution $\boldsymbol{U}$ satisfies

$$||\boldsymbol{U}_i - \boldsymbol{u}(x_i)|| \leq ||\boldsymbol{V}_i - \boldsymbol{v}(x_i)|| + ||\boldsymbol{W}_i - \boldsymbol{w}(x_i)||, \tag{14}$$

in the region Ω^N. Now, consider the error of the smooth component $\boldsymbol{V}$. From (4) and Lemma 2.3, we have $|L_k^N(\boldsymbol{V}-\boldsymbol{v})(x_i)| = |(L_k - L_k^N)\boldsymbol{v}(x_i)| \leq C\varepsilon(h_i+h_{i+1})||v_k'''(x)||_{(x_{i-1},x_{i+1})} \leq CN^{-2}$, for $k = 1, 2$, since $\sqrt{\varepsilon} \ll N^{-1}$. Hence, we have

$$||\boldsymbol{L}^N(\boldsymbol{V} - \boldsymbol{v})(x_i)|| \leq CN^{-2}. \tag{15}$$

The consistency analysis of the singular component for $i = k_l, \cdots, k_r$, shows that the truncation error of the singular components W_1 and W_2 satisfy

$$|L_k^N(\boldsymbol{W} - \boldsymbol{w})(x_i)| \leq C\varepsilon|(\delta^2 w_k - w_k'')(x_i)| \leq C\varepsilon|w_k''(x)|_{[x_{i-1},x_{i+1}]}, \text{ for } k = 1, 2.$$

Now, Lemma 2.1 implies that $||\boldsymbol{L}^N(\boldsymbol{W} - \boldsymbol{w})(x_i)|| \leq C\exp(-x_{i-1}\sqrt{\beta/\varepsilon})$ for $x_i \leq 1/2$. Therefore, from Lemma 2.2 for $x_i \geq 1/2$ with $k_l \leq i$, we get

$$||\boldsymbol{L}^N(\boldsymbol{W} - \boldsymbol{w})(x_i)|| \leq C\exp\left(-x_{k_l-1}\sqrt{\beta/\varepsilon}\right) = C\left(\exp\left(-\frac{x_{k_l-1}}{2}\sqrt{\beta/\varepsilon}\right)\right)^2 \leq CN^{-2}.$$

In a similar manner, the case $x_i > 1/2$ with $k_r \geq i$ can be carried out. Hence, for $i = k_l, \cdots, k_r$,

$$||\boldsymbol{L}^N(\boldsymbol{W} - \boldsymbol{w})(x_i)|| \leq CN^{-2}. \tag{16}$$

Now, we consider the error estimate at the nodes corresponding to $i = 1, \cdots, k_l - 1$ and $i = k_r + 1, \cdots, N-1$. We only consider the left-hand boundary layer region as the analysis corresponding to right-hand boundary layer region can be derived by the same technique. Using Taylor's series expansion, we obtain

$$|L_k^N(\boldsymbol{W} - \boldsymbol{w})(x_i)| = \frac{\varepsilon|h_i^2 w_k'''(\eta_i^1) - h_{i+1}^2 w_k'''(\eta_i^2)|}{3(h_i + h_{i+1})}, \text{ where } \eta_i^1 \in (x_{i-1}, x_i) \text{ and } \eta_i^2 \in (x_i, x_{i+1}),$$

for $k = 1, 2$. Again $|h_i^2 w_k'''(\eta_i^1) - h_{i+1}^2 w_k'''(\eta_i^2)| \leq C(|h_i^2 - h_{i+1}^2||w_k'''(x_i)| + h_i^2(h_i+h_{i+1})|w_k^{(iv)}(x_i)|)$. Hence, Lemma 2.2 implies that

$$||\boldsymbol{L}^N(\boldsymbol{W} - \boldsymbol{w})(x_i)|| \leq C\varepsilon^{-1}h_i^2\exp\left(-x_i\sqrt{\frac{\beta}{\varepsilon}}\right) \leq C\varepsilon^{-1}\left(\int_{x_{i-1}}^{x_i}\exp\left(-\frac{s}{2}\sqrt{\frac{\beta}{\varepsilon}}\right)ds\right)^2.$$

 ISBN: 978-84-617-8694-7

It follows that

$$||\boldsymbol{L}^N(\boldsymbol{W}-\boldsymbol{w})(x_i)|| \leq C\varepsilon^{-1}\left(\sqrt{\varepsilon}\int_{x_{i-1}}^{x_i} M(t,\boldsymbol{u}(t))dt\right)^2 \leq CK^2N^{-2} \leq CN^{-2}.$$

where we have used the definition of the equidistribution principle (3) in the above inequality. Therefore, for $i = 1, \cdots, k_l - 1$ and $i = k_r + 1, \cdots, N-1$, we have

$$||\boldsymbol{L}^N(\boldsymbol{W}-\boldsymbol{w})(x_i)|| \leq CN^{-2}. \tag{17}$$

This completes the proof. ∎

Now, we write the main convergence result of the numerical solution $\boldsymbol{U}_i$.

4.1 The main convergence result

The following theorem shows that the discrete solution $\mathbf{U}$ of (12) is second-order uniformly convergent on the equidistributed mesh.

Theorem 4.1 *Let $\boldsymbol{u}$ be the solution of (1) and $\boldsymbol{U}$ be the solution of the discrete problem (12), on a mesh obtained by equidistributing the monitor function (7) with $\alpha = K$. Then, there exists a constant C, independent of ε, x_i and N, such that*

$$||\boldsymbol{u}-\boldsymbol{U}||_{\Omega^N} \leq CN^{-2}.$$

Proof. Lemma 3.2 implies that the inverse of the discrete operator $\boldsymbol{L}^N$ is ε-uniformly bounded. Therefore, using (15) and (17) in (14), we obtain that

$$|\boldsymbol{u}(x_i)-\boldsymbol{U}_i| \leq |\boldsymbol{V}_i - \boldsymbol{v}(x_i)| + |\boldsymbol{W}_i - \boldsymbol{w}(x_i)| \leq CN^{-2} \text{ for } i = 0, \cdots, N,$$

which is the required result. ∎

5 Computational Experiments

The layer adaptive meshes will be obtained by the equidistribution of the proposed monitor function (7) based on a moving mesh algorithm. We use the de Boor algorithm to move any user chosen mesh, whose convergence analysis is considered in [11]. For the convergence of this algorithm, it is sufficient to consider the following weak discrete version of (3):

$$M_i h_i \leq \frac{C_0}{N}\sum_{j=1}^{N} M_j h_j, \quad \text{for} \quad i = 1, \cdots, N$$

where M_i is the discrete approximation of the monitor function $M(x, \boldsymbol{u}(x))$ in the subinterval (x_{i-1}, x_i). In practice, we use the central difference approximation to discretize the second

 ISBN: 978-84-617-8694-7

order derivatives appeared in (7). Here $C_0 > 1$ is a user chosen constant. C_0 can be chosen large enough to get fewer iterations for the convergence of the algorithm.

Algorithm 1: (Mesh Generation and Adaptive Solution)

Step 1: Define the initial uniform mesh $\{x^{(0)} = i/N : 0 \le i \le N\}$ and go to Step 2 with $p = 0$.

Step 2: Solve the discrete problem $\boldsymbol{L}^N \boldsymbol{U}_i^{(p)} = \boldsymbol{f}_i^{(p)}$, defined in (12) for $(\boldsymbol{U}_0^{(p)}, \cdots, \boldsymbol{U}_N^{(p)})$ on the uniform mesh $\{x_i^{(p)} : i = 0, \cdots, N\}$. Define $h_i^{(p)} = x_i^{(p)} - x_{i-1}^{(p)}$ for $i = 1, \cdots, N$.

Step 3: Find the smooth component $\boldsymbol{V}_i^{(p)}$ by solving (1) with $\varepsilon = 0$. Denote the layer component of $\boldsymbol{U}_i^{(p)}$ as $\boldsymbol{W}_i^{(p)} = \boldsymbol{U}_i^{(p)} - \boldsymbol{V}_i^{(p)}$. Find the discretized monitor function $M_i^{(p)} = \left[\alpha^{(p)} + \sum_{k=1}^{2} |\overline{\delta}^2 W_{k,i}^{(p)}|^{1/2}\right]$ for $i = 1, \cdots, N$. by defining $\overline{\delta}^2 W_{k,i} = (\delta^2 W_{k,i} + \delta^2 W_{k,i-1})/2$ with $\overline{\delta}^2 W_{k,1} = \delta^2 W_{k,1}$ and $\overline{\delta}^2 W_{k,N} = \delta^2 W_{k,N-1}$, for $k = 1, 2$. where $\alpha^{(p)} = \sum_{i=1}^{N} h_i (\sum_{k=1}^{2} |\overline{\delta}^2 W_{k,i}|^{1/2})$. Compute the total length $\Phi_j^{(p)} = \sum_{i=1}^{j} h_i^{(p)} M_i^{(p)}$.

Step 4: Choose a constant $C_0 \ge 1$. The stopping criteria for iterative technique is $\max\limits_{i=1,\ldots,N} h_i^{(p)} M_i^{(p)} / \Phi_N^{(p)} \le C_0 N^{-1}$. If it holds, then go to Step 6, else continue with step 5.

Step 5: Generate a new mesh: Set $Y_i^{(p)} = i\Phi_N^{(p)}/N$ for $i = 0, \cdots, N$. Now interpolate $(Y_i^{(p)}, x_i^{(p+1)})$ to $(\Phi_i^{(p)}, x_i^{(p)})$ using piecewise linear interpolation. Generate a new mesh $x^{(p+1)} \equiv \{0 = x_0^{(p+1)} < x_1^{(p+1)} < \cdots < x_N^{(p+1)} = 1\}$ and return to Step 2.

Step 6: Set $x^* = \{0 = x_0^* < x_1^* < \cdots < x_N^* = 1\} = x^{(p+1)}$ and $\boldsymbol{U}^* = \boldsymbol{U}^{(p+1)}$, where x^* is the boundary layer adaptive mesh and $\boldsymbol{U}^*$ is our desired adaptive solution. Stop.

5.1 Numerical Examples

Now, we demonstrate two numerical examples to validate our monitor function (7).

Example 5.1 *Consider the following system of second-order reaction-diffusion problems:*

$$\begin{cases} -\varepsilon u_1''(x) + (10 + \exp(-x))u_1(x) - 6x^2 u_2(x) = 6 + 5x^2, \quad x \in \Omega = (0,1), \\ -\varepsilon u_2''(x) - x^4|x|u_1(x) + (7 + 2x^3)u_2(x) = 5 + x^3, \\ u_1(0) = u_1(1) = u_2(0) = u_2(1) = 0. \end{cases}$$

Example 5.2 *Consider the system of singularly perturbed second-order problems:*

$$\begin{cases} -\varepsilon u_1''(x) + 2(x+1)^2 u_1(x) - (1 + x^3)u_2(x) = 2\exp(x), \quad x \in \Omega = (0,1), \\ -\varepsilon u_2''(x) - 2\cos\left(\dfrac{\pi x}{4}\right) u_1(x) + 2.2\exp(1-x)u_2(x) = 10x + 1, \\ u_1(0) = u_1(1) = u_2(0) = u_2(1) = 0. \end{cases}$$

 ISBN: 978-84-617-8694-7

We compute the accuracy of the numerical solution by using the following double mesh principle: for any value of N, the maximum pointwise error $E^N_{m,\varepsilon}$, $m = 1, 2$, of the numerical solution is calculated by $E^N_{m,\varepsilon} = \max\limits_{0\le i\le N} |U^N_m - \overline{U}^{2N}_m|$, where $\boldsymbol{U}^N$ is the computed solution with N number of intervals and $\overline{\boldsymbol{U}}^{2N} = (\overline{U}^N_1, \overline{U}^N_2)$ is the numerical solution on a mesh, obtained by bisecting the original mesh such that the ith point of the original mesh coincides with the $2i$ th point of the newly obtained mesh. The uniform error, say E^N_m, for each fixed N is defined by $E^N_m = \max_{\varepsilon\in S} E^N_{m,\varepsilon}$, where the set $S = \{\varepsilon|\varepsilon = 1, 2^{-2}, \cdots, 2^{-30}\}$. The order of convergence is calculated by $r^N_m = \log_2\left(E^N_m/E^{2N}_m\right)$. We took $C_0 = 1.2$. in Algorithm 1.

The maximum ε-uniform errors E^N_m and the orders of convergence r^N_m of the (U_1, U_2) displayed in Tables 1, 2,3, 4 shows that the second order convergence hold true in practice. This rate is better than the rate of convergence on uniform mesh (where numerical solution diverges) and Shishkin mesh (where almost second order accuracy observed in [3]) which appear in Tables 6, 7 resp. The Shishkin mesh is constructed by dividing the domain $[0, 1]$ into three subdomains $[0, \tau]$, $[\tau, 1-\tau]$ and $[1-\tau, 1]$ with $\tau = \min\{1/4, 2\sqrt{\varepsilon/\beta}\log(N)\}$. Here each subdomain contains $N/4$, $N/2$ and $N/4$ number of mesh intervals respectively with

uniform step size. We take $\beta = .5$ to generate Table 7. Note that the present method also works for nonsingularly perturbed problems as the set S contains $\varepsilon = 1$. Table 5 presents the number of iterations taken by Algorithm 1 which shows the effectiveness our preferred monitor function.

Figures 1, 2 show the boundary layer phenomena and mesh density towards the boundary points $x = 0, 1$ of Examples 5.1 and 5.2. The mesh movements in Figure 3 shows the effectiveness of Algorithm 1 to generate layer adapted mesh. In addition, Figure 4 shows that the depicted second order convergence holds true in logarithmic scale as N increases.

6 Conclusion

In this paper, we have proposed a computational technique for a system of singularly perturbed reaction-diffusion problems exhibiting boundary layers by moving mesh methods. An error monitor function is proposed whose equidistribution will lead to a boundary layer adapted mesh. Through theoretical and numerical results, it is shown that the proposed numerical method is second order ε-uniform convergent.

On a generalized variable-coefficient Gardner equation with forcing term

R. de la Rosa[1], E. Recio[1], T.M. Garrido[1] and M.S. Bruzón[1]

[1] *Departamento de Matemáticas, Universidad de Cádiz*

emails: rafael.delarosa@uca.es, elena.recio@uca.es, tamara.garrido@uca.es, m.bruzon@uca.es

Abstract

Key words: Conservation laws, Equivalence transformations, Gardner equation, Nonlinear partial differential equations.

In the last decade, there has been an increasing interest in the research of several generalizations of some important dispersive wave equations such as the Korteweg-de Vries (KdV) equation, mKdV equations and the Burgers equation. Among these generalizations, special attention should be paid to variable-coefficient nonlinear equations because these describe a great number of nonlinear phenomena more realistically than their constant-coefficient counterparts. Specifically, the Gardner equation, also known as combined KdV-mKdV equation, is widely used in different branches of physics such as fluid dynamics, solid state physics or quantum field theory. Moreover, it describes interesting physical phenomena: the long wave propagation in an inhomogeneous two-layer shallow liquid, internal waves in a stratified ocean, ion acoustic waves in plasma with a negative ion...

In this paper, we consider a generalized variable-coefficient Gardner equation with nonlinear terms of any order and forcing term given by

$$u_t + a(t)u^n u_x + b(t)u^{2n}u_x + c(t)u_{xxx} + h(t)u_x + f(t)u = -r(t), \tag{1}$$

where n is a positive constant, $a(t)$ and $b(t)$ are not simultaneously equal to zero, $c(t) \neq 0$, $f(t)$, $h(t)$ and $r(t)$ are arbitrary functions. The Gardner equation has been recently studied by different authors [5, 6, 7, 8, 9]. In [9] a large number of solutions of equation (1)

ISBN: 978-84-617-8694-7

with $r(t) = 0$ were constructed. The authors obtained these solutions with the aid of two first-order nonlinear ordinary differential equations and a new generalized algebraic method. Later, in [6], exact solutions of equation (1) were obtained by using the general mapping deformation method which included soliton solutions, Jacobi elliptic wave solutions and Weierstrass elliptic function solution, among others. Finally, in [5] the authors performed an analysis of the classical and nonclassical symmetries admitted by the constant-coefficient counterpart of equation (1) and they constructed some exact travelling wave solutions by using the simplest equation method.

The problem lies in the fact that the study of variable-coefficient equations is often difficult. Equivalence transformations fit perfectly into the study of variable-coefficient partial differential equations (PDEs). Equivalence transformations allow us to determine those inessential elements of the class under consideration and to perform a transformation which maps these arbitrary elements to chosen simple values from the beginning. The use of these transformations often provides an alternative way to simplify a group classification problem and to show the results in a simple and clear manner.

An equivalence transformation of class (1) is a nondegenerate point transformation, (t, x, u) to $\left(\tilde{t}, \tilde{x}, \tilde{u}\right)$ in the augmented space $(t, x, u, a, b, c, h, f, r)$ with the property that it preserves the differential structure of the equation but with different arbitrary functions, $\tilde{a}(\tilde{t})$, $\tilde{b}(\tilde{t})$, $\tilde{c}(\tilde{t})$, $\tilde{h}(\tilde{t})$, $\tilde{f}(\tilde{t})$ and $\tilde{r}(\tilde{t})$.

The symmetry group of a PDE is the largest group of transformations acting on the space of independent and dependent variables which transforms solutions of the equation into other solutions. The method of Lie symmetry groups is one of the most powerful methods to analyse PDEs. Among its well-known applications, we highlight that symmetry groups can be used to obtain exact solutions or to construct conservation laws.

Given a PDE, a conservation law is a space-time divergence expression

$$D_t T + D_x X = 0, \tag{2}$$

that vanishes on all solutions of the PDE, where the conserved density T and the spatial flux X are functions of t, x, u and derivatives of u, whereas D_t and D_x denote the total derivative operators with respect to t and x respectively. This concept has its origin in physics, nevertheless it presents important applications in the study of differential equations or systems of differential equations. To begin with, the integrability of a differential equation is closely linked with the existence of a large number of conservation laws. Furthermore, these laws can be used to assess the accuracy and stability of numerical methods for the solutions of PDE.

 ISBN: 978-84-617-8694-7

Anco and Bluman [1, 2, 3] proved a general method to construct conservation laws for PDEs. This method makes use of the concept of multiplier. A multiplier is a non-singular function $Q(t, x, u, u_t, u_x, \cdots)$ on the set of solutions $u(t, x)$, which satisfies that $(u_t + a(t)u^n u_x + b(t)u^{2n}u_x + c(t)u_{xxx} + h(t)u_x + f(t)u + r(t))Q$ is a divergence expression not only for solutions of equation (1), but for any function $u(t, x)$.

A conservation law is called locally trivial if there is a function $\Theta(t, x, u, u_t, u_x, \ldots)$ so that the conserved vector $(T, X) = (D_x\Theta, -D_t\Theta)$ holds for every solution $u(t, x)$, therefore equation (2) becomes an identity. From this definition, two conservation laws are considered to be locally equivalent if they differ by a locally trivial conservation law. Any non-trivial conservation law can be expressed in a general form

$$\frac{d}{dt}\int_\Omega T dx = -X\Big|_{\partial\Omega},$$

where $\Omega \subseteq \mathbb{R}$ is a fixed spatial domain. Moving off of the set of solutions of equation (1), each conservation law can be stated by using the characteristic form

$$D_t\tilde{T} + D_x\tilde{X} = (u_t + a(t)u^n u_x + b(t)u^{2n}u_x + c(t)u_{xxx} + h(t)u_x + f(t)u + r(t))Q. \qquad (3)$$

In particular, from the characteristic form (3) it follows that each conserved vector given by (2) derives from a multiplier Q of equation (1). Multipliers Q are obtained by requiring that the divergence condition must be verified identically

$$\frac{\delta}{\delta u}\left((u_t + a(t)u^n u_x + b(t)u^{2n}u_x + c(t)u_{xxx} + h(t)u_x + f(t)u + r(t))Q\right) = 0,$$

where $\frac{\delta}{\delta u} = \partial_u - D_x\partial_{u_x} - D_t\partial_{u_t} + D_xD_t\partial_{u_{xt}} + D_x^2\partial_{u_{xx}} + ...$, represents the variational derivative. Divergence condition splits with respect to u_t, u_{xxx} and their differential consequences, yielding an overdetermined system in Q and the arbitrary functions which equation (1) involves. Once multipliers have been determined, the conserved vectors can be constructed by integrating the characteristic equation (3) [3, 4].

The aim of this work is to analyse the generalized Gardner equation (1) from the point of view of Lie symmetries and conservation laws. To achieve this objective, we will derive the continuous equivalence group of equation (1). The gauging of arbitrary functions by using equivalence transformations allows us to perform an exhaustive study of equation (1) and a clear presentation of the results. Moreover, we obtain a classification of the Lie symmetries of the reduced equation. Finally, we determine nontrivial conservation laws via the direct method of the multipliers [1, 2, 3].

Abstract

Big data field usually involves the use of Time Series (TS) datasets. In this scenario, the detection of complex TS events are rarely presented; thus, the learning algorithms need to tackle with the TS data balancing problem, which has been barely studied. This study addresses this issue, describing a very simple TS extension of the well-known SMOTE algorithm for balancing datasets where a preliminary study on the TS distances used in different parts of the extension of the SMOTE algorithm. Besides, as the study will carry out the experiments on a realistic TS dataset simulating epilepsy attacks, a proposal to force an erratic behavior is presented. A study on the characteristics of the dataset before and after the performance of this TS balancing algorithm is performed, showing evidence on the requirements for the research on this topic, the energy efficiency of the algorithm and the TS generation process among them.
Key words: Dataset balancing algorithms, SMOTE, Time Series, Time Series Distances

1 Introduction

Big data field usually involves the use of Time Series (TS) datasets. Such cases includes the management of the sensory systems located on wearable devices, like in the human activity recognition and the abnormal movement detection [1, 2]. Furthermore, the TS datasets have become into multivariate TS datasets, which makes the data analysis even more complex.

In this context, when leaning models for the detection of some complex events, the problem of lacking data balance arises: there are many more TS segments belonging to

normal class than to the abnormal class to detect. For instance, in the problem of epilepsy seizure detection [3, 4], the occurrence of a seizure might be once in a month or even less.

The main part of the literature concerning the dataset balancing problem is focused on classical datasets, where a sample includes an atomic value for each of the features. These balancing techniques can rely on oversampling the minority classes or undersampling the majority classes; however, as long as oversampling does not produce information losses, it is preferred over undersampling.

Some valid alternatives have also been published, coping with imbalanced problems specific algorithms [5], or proposing ensembles for the minority class together with a kind of undersampling of the majority classes [6]. Examples of oversampling techniques include well-known algorithms as SMOTE (Synthetic Minority Over-sampling Technique, [7, 8]), ADASYN (ADAptive SYNthetic Sampling, [9]), ADOMS (Adjusting the Direction Of the synthetic Minority clasS examples, [10]) or SPIDER (Selective Preprocessing of Imbalanced Data, [11]).

However, the problem of balancing TS datasets has not received much attention. In a TS datasets, each sample includes a TS for each feature. Moreover, the sample is assigned a class, but also a TS is attached as the labelling TS for that sample. From now on, we consider all the TS features from a sample with the same length and sampling frequency; however, the variability in these factors needs further study. Some approaches for TS datasets balancing have focused on univariate TS problems, either.

Several solutions studied how to classify the values in the incoming sequence [12, 13, 14, 15], where the known data sequence labels are clearly biased to the majority class. Therefore, the solutions rely on drawing new synthetic atomic values based on any of the above mentioned algorithms. On the other hand, Koknar et al proposed the balancing of univariate TS based on suggesting ghost points [16]. These ghosts points belong to the domain space of TS distances. With the distance matrix a SVM classifier is learned; allowing to generate a new TS and assigning a it a class. Different TS distance measurements were proposed, the Dynamic Time Warping (DTW) distance measurement along them.

Clearly, there is a need of tackling the multivariate TS datasets balancing problem. This study addresses this topic, extending the well-known SMOTE algorithm to cope with multivariate TS. Besides, our proposal use a simpler strategy to draw the synthetic TS than the one used by Koknar [16]. Current proposal includes the use of KNN algorithm to select the parents for new synthetic TS as well as the merging operator TS_AVERAGE presented in our previous work[17]. In addition, as the study will carry out the experiments on a realistic TS dataset simulating epilepsy attacks, a proposal to force an erratic behavior of the simulated TS is presented

The experimentation will analyze the distortion in the dataset due to the inclusion of the new TS samples. This study is structured as follows. Next section outlines the SMOTE algorithm, while the design issues are explained and possible solutions are given in Sect. 3.

 ISBN: 978-84-617-8694-7

Experimentation and the discussion on the results are coped in Sect. 4. Finally, the main conclusions are drawn.

2 The SMOTE algorithm

The SMOTE algorithm is an oversampling method [7], where each sample from the minority class is randomly combined with each of its nearest neighbors to balance the dataset. This method assumes a two-class problem, however, it can be easily extended to a multi-class problem.

Algorithm 1 reproduce the algorithm from the original paper for the sake of autocompletion. The parameters of this method include the number of nearest neighbor to consider (k, by default $k = 5$ has been proposed), the number of samples belonging to the minority class (T) and the number of synthetic samples to generate for each original sample from the minority class (N). This parameter N is given as a percentage; values smaller than 100% reduces the original minority subset and produces a new dataset of the same size as the original. Whenever $N > 100$ means that $N/100$ synthetic samples are to be generated for each sample from the minority class.

As can be seen, SMOTE takes a sample and searches for some neighbors; each synthetic sample is generated as random linear combination of the two considered samples. This method has been successfully tested on different domains; and plenty of different versions have been published [8]. One the most known version of SMOTE is*SMOTE-ENN*, a sort of de-noising version, that will not be considered in current work.

3 Tackling the TS balancing problem

Two main concerns, at least, have to be solved in order to allow the SMOTE algorithm to cope with TS datasets. The first concern is related to the method for choosing the parents TS to mate, the second focuses on the generation of the new TS sample.

Choosing the two TS samples that will be used in generating the new TS offspring should consider TS grouping according to some measurement. The original SMOTE randomly selects the parents for mating among those belonging to the minority class that are the nearest neighbours (KNN). However, different solutions can be considered; for instance, the solution proposed in ADASYN [9], where the parents are randomly chosen according to the distribution of the size of the neighborhood, is totally valid as well. It seems, according to the published results for the different SMOTE-based flavors, that problem-oriented heuristics might be the best solution for each problem. An example of such heuristic can be grouping the TS samples for the minority class using the mean value of the Phan et al distance[18]; afterwards, two different groups are randomly chosen; finally, one TS sample is chosen form

each of the two candidate groups. Nevertheless, this distance measurement suites the best when the length of the TS is bounded to less than, say, 30 values.

On the other hand, the generation of a new TS is not a simple task: as long as multivariate TS are considered, the new TS sample will need a TS for each of the available features. For each feature to generate, a combination of the parents' feature should be performed. Further, the combination must be coherent for all the features considered as a single sample. Finally, the class TS needs to be generated as well, which is much of a compromise. Again, general algorithms can be provided, but it should be expected that specific heuristic would eventually be needed in order to obtain a better performance.

In this study, the selection of the parents is performed using the same strategy than in the original SMOTE, using KNN with euclidean distance among the minority class samples. The euclidean distance between two multivariate TS X and Y (See equation 1) will be calculated on the average of all the features. In case the parents have different length, the shortest one will be considered.

$$KnnDistance_{X,Y} = \sqrt{\sum_{i=min\{\#X,\#Y\}} (\frac{\sum_{f \in features} X_i^f - Y_i^f}{\#features})^2} \quad (1)$$

The generation of a new TS sample is performed as follows, from now on, this proposal is referred as AVG_TS_SMOTE:

- For each feature, the average of the corresponding TS from the parents is computed.
- The class TS is calculated with the maximum of the values from the two parents.
- The length of the new TS sample, for every feature and for class TS, is bounded to the shortest of the two parents.

From now on, this new release of SMOTE will be referred as TS_SMOTE.

4 Experiments and results

4.1 Experimental setup

For this experimentation, a real world TS dataset obtained from the simulation of epileptic seizures is used; this dataset is publicly available at [3, 19]. This TS dataset was gathered following a previously defined and very strict protocol, defining a set of activities, namely, the simulation of the epileptic convulsions and three activities: running, sawing and walking -either gesturing while walking slowly or normal walking at different paces. A wearable triaxial accelerometer sensor (3DACM) included in a bracelet placed on the affected wrist measured the participant movements.

Transformation	**Calculation**
$SMA_t(\vec{s})$	$\frac{1}{w}\sum_{i=1}^{w-1}(\sum_{c\in\{x,y,z\}}\|b_{c,t-1}\|)$
$AoM_t(\vec{s})$	$\sum_{i=0}^{i=w-1}\sum_{c\in\{x,y,z\}}\|max(b_{c,t-i})$ $-min(b_{c,t-i})\|$
$TbP_t(\vec{s})$	Computed with the following algorithm: 1.- Find the sequences with value higher than mean+K*std within the window ($K = 0.9$) 2.- Keep the rising points from each of these sequences 3.- Measure the mean time between them

Table 1: The transformations of the components of the acceleration, where $b_{c,i}$ stands for the body acceleration.

The bracelets have wireless data sampling capabilities at a rate of 16 Hz, the 3DACM have a range of $2 \times g$. Up to 6 healthy participants, all of whom remained anonymous, successfully completed this experiment, each running 10 trials of each activity. The ages of the participants ranged from 22 to 47, with four participants of around 40 years old. One participant out of six was female, and the eldest was left-handed. An identification number was given to each Time Series (TS), including information fields on participant ID, the number of trials, the activity, etc.

The acceleration has been filtered and processed, becoming into a three variable TS dataset: the features are depicted in Table 1: the Signal-Magnitude Area (SMA), the Amount of Movement (AoM) and the Time between Peaks (TbP). The complete pre-processing have been described in [3].

This TS dataset, consisting on TS samples of three TS each -SMA, AoM and TbP- $\{\overline{TS}_s\}$, with the label for each activity $\{c_s\}$ and with the TS for each timestamp label $\{\overline{C}_s\}$, has been used in this experimentation. We denote this TS dataset as ORIG, while the TS dataset after applying AVG_TS_SMOTE is denoted as SMT.

To select the number of TS samples to introduce in the dataset we used the following criteria. In an imbalanced dataset, there exists $R = 3$ times more examples belonging to the MC class than to the mC class for the s data source. So, to balance the number of samples for both classes means injecting $(R1) \times |mC_s|$ new TS samples.

Finally, the α parameter was allowed to drift in the interval [-1.0, 1.0]. Although this is a rather wide interval, it was used to evaluate the robustness of the algorithm when the generation of the synthetic TS samples generate disperse samples. As stated in [8], this scenario highly penalizes the performance of balancing dataset algorithms; therefore, the conclusions can be extracted on adverse scenarios. The next experimentation focuses on

 ISBN: 978-84-617-8694-7

analyzing the correlation between each feature and the class for the ORIG and the SMT datasets.

4.1.1 Shifting process

As it was explained in section 4.1 a very strict protocol, with a high control of the timing in each stage, was carried out to gather the TS dataset, thus all the TSs corresponding to EPILEPSY class have the same timing (see figure 1.top). This is a problem when facing the same problem of generating synthetic TS in different domains, or even in the same domain, in different contexts -such as in everyday life- where the TS are not so similar, even totally different. So, in order to inject an erratic behavior in the datasets as in the daily live, a shifting procedure to induce more dispersion in the timing of the EPILEPSY class TS is proposed. This procedure consists of the following steps:

1. With a probability of **Pshift** (Pshift=50%) each Ts belonging to EPILEPSY class will be shifted.
2. Each chosen Ts will be shifted circularly **Sshift tics**to the right or to the left with a probability of 50% .
3. **Sshift** is the 75% of the number of NO_EPILEPSY class tics at beginning or at the end of the TS depending of the shifting direction, left or right respectively.

For the shake of example, a right shifted TS is shown in Figure 1bottom.

Once we have defined the shifting procedure, it will be carried out on the whole EPILEPSY class TS obtaining the Shifted Dataset. Thus we have two input datasets for our TS_SMOTE algorithm: the original dataset (ORIG) and the shifted dataset(SHIFTED), besides TS_SMOTE algorithm will be run with these two inputs obtaining the balanced datasets called ORIGSTM and SHIFTEDSTM respectively.

4.2 Correlation study

Two different measurements have been applied in this study in order to assess the relationship between the distribution of the ORIG and the SMT datasets, namely: the Pearson Correlation ($\rho_{X,Y}$, Eq. 2) coefficient and the Mutual Information ($MI(X,Y)$, Eq. 3); where cov is the covariance, σ_X is the standard deviation of X, $p(x)$ is the probability of the event x and $p(x,y)$ is the conditional probability of x given y.

$$\rho_{X,Y} = \frac{cov(X,Y)}{\sigma_X \sigma_Y} \tag{2}$$

$$MI(X,Y) = \sum_{y \in Y} \sum_{x \in X} p(x,y) \log \left(\frac{p(x,y)}{p(x)\, p(y)} \right) \tag{3}$$

 ISBN: 978-84-617-8694-7

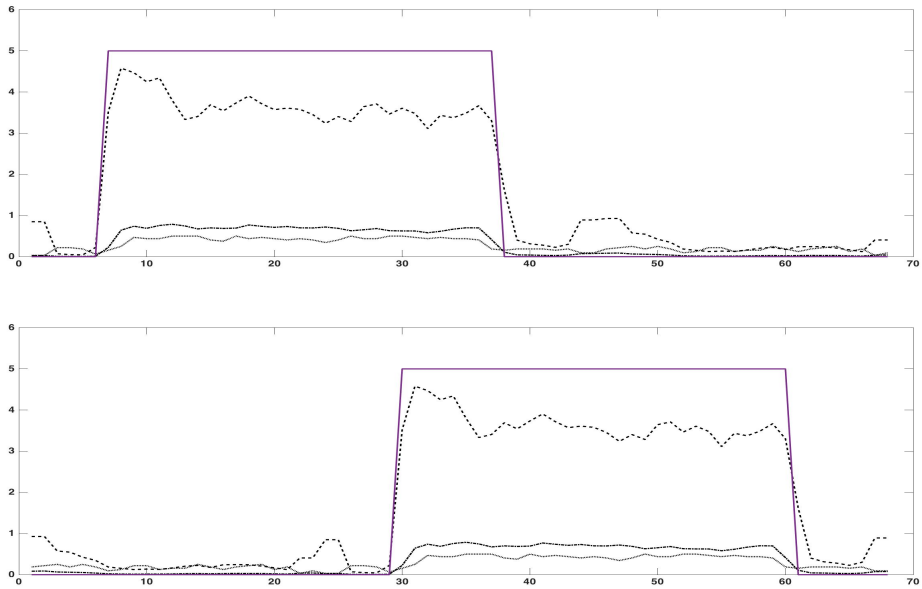

Figure 1: top) Case of EPILEPSY class TS where the solid line represents the class and the dashed, dotted and dashed-dotted lines represent the features SMA, AoM and TbP respectively, bottom) Right shifting of the top TS.

In order to analyze the robustness of the TS_SMOTE proposal, it's included a comparative study of correlation between the features and the class of each TS for the four datasets ORIG, SHIFTED, ORIGSMT and SHIFTEDSMT. For the sake of space restrictions only the detailed boxplot data for participant number 1 is depicted in Fig. 2. It can be noted that although the results for both flavors (shifted and not shifted datasets) are close similar it doesn't show the real differences between both results.

Let's see one the synthetic TS (Figure 3) from the SHIFTEDSMT dataset. It can be see that the synthetic TS (solid line) perverts totally at least one of the characteristics of the parent TSs (the dashed and the dotted lines), the length, which an important characteristic of a epilepsy attack.

Therefore, the table 2 includes a second correlation analysis, where every TS of not balanced dataset (ORIG or SHIFTED) will be compared with every TS of the corresponding balanced dataset (ORIGSMT or SHIFTEDSMT). It can be stated clearly that the balanced dataset obtained (SHIFTEDSMT) from the shifted dataset (SHIFTED) has a very low correlation with the respective not balanced dataset, with values of Pearson Correlation under 0.3-0.4 while the not shifted results are above 0.7-0.9.

Thus, we can conclude that the timing factor is a critical factor in the balancing process

 ISBN: 978-84-617-8694-7

The 6 left-most boxes correspond to the Pearson Correlation, while the 6 right-most correspond to the Mutual Information.

of TS, so it's necessary to consider a kind of TS distances independent of shifting like DTW or OSB.

5 Conclusions

This research, presents a simple extension of the datasets balancing SMOTE algorithm but adapted to TS (TS_SMOTE). Our proposal is based on the following points: a) the inclusion of KNN algorithm for multivariate TS to select the parents of the synthetic TSs, where the distance between TS is based on a combination of the features; b) the definition of the operator AVG_TS_SMOTE to obtain the synthetic TSs.

Besides a shifting process is presented in order to inject an erratic behavior in the

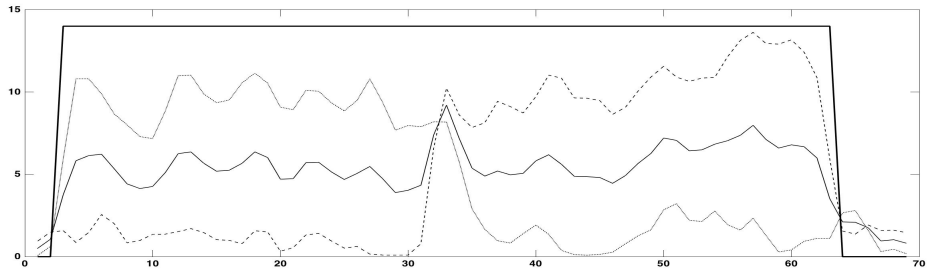

Figure 3: Example of SHIFTEDSMT Synthetic TS. From top to bottom, the two parents TS -the dashed and the dotted lines- and the synthetic TS -the solid line-.

datasets as in the daily live. So, the results of TS_SMOTE have been run on both unbalanced datasets (the original TS dataset and the shifted TS dataset) and we can conclude that timing is a critical factor in the balancing process of TS, so it's necessary to consider a kind of TS distances independent of shifting like DTW or OSB [20, 21].

Tricky Aspects of Kronecker Power Series in Constancy Adding Space Extention (CASE) Perspective

Metin Demiralp[1]

[1] *Computational Science and Engineering Department, Informatics Institute, İstanbul Technical University*

emails: metin.demiralp@gmail.com

Abstract

Kronecker power series is one of the fundamental elements of the Probabilistic Evolution Theory (PREVTH) developed in Demiralp group studies during the last decade. This is a concise representation of multivariate Taylor series where the independent variable is just a vector instead of many scalar independent variables and based on Kronecker powers. In contrast to Taylor series it is not unique because the greater than one Kronecker powers of a vector becomes orthogonal to certain constant vectors such that their population rapidly grows as the power increases. This property brings a lot of interesting flexibilities to change the structure of the series without changing the target function the Kronecker power series represents. These can be used at our favor to facilitate the analyses especially through the Constancy Adding Space Extension (CASE). This work focuses on these issues and basically on converting a Kronecker power multinomial to its highest power monomial which gains great importance to get a new extension to PREVTH.

Key words: Kronecker product, Kronecker power, Kronecker power series, Kronecker multinomial, Kronecker monomial, PREVTH.

1 Introduction: Kronecker Products, Kronecker Powers, Kronecker Power Series

Kronecker power series concept is somehow backbone of the Probabilistic Evolution Theory (PREVTH) which has been recently developed in Demiralp group studies, [1–16] for constructing analytic solutions to the first order ODEs under initial condition impositions. For better understanding of these series we need to start with Kronecker product of two

ordinary linear algebraic arrays (vectors, matrices). It is defined in a way such that each element of first (left) array is replaced by the product of second (right) array with that element. If we denote the factor arrays by $\boldsymbol{\mathcal{A}}_1$ $(m_1 \times n_1)$ and $\boldsymbol{\mathcal{A}}_2$ $(m_2 \times n_2)$ respectively then the Kronecker power can be symbolized as $\boldsymbol{\mathcal{A}}_1 \otimes \boldsymbol{\mathcal{A}}_2$ and its type is $m_1 m_2 \times n_1 n_2$. To be more explicit we can write the following equality for two given linear algebraic vectors, $\mathbf{a}$ and $\mathbf{b}$ with m_a and m_b elements respectively

$$\mathbf{a} \otimes \mathbf{b} \equiv \left[a_1 \mathbf{b}^T \;\; ... \;\; a_{m_a} \mathbf{b}^T \right]^T \tag{1}$$

where the product is a linear algebraic vector of $m_a m_b$ elements. This explicit definition can be extended to vector-matrix, matrix-vector, matrix-matrix products accordingly even though we are not going to get into further details. Kronecker power is not commutative generally for different factors. Throughout this presentation we use lower and upper letter bold symbols for ordinary linear algebraic vectors and matrices respectively. When we need to use just a single symbol for an entity which can be either vector or matrix depending on the situation we use bold calligraphic upper letters.

Now we can define the Kronecker power of an array (vector or matrix) as sufficient number of consecutive Kronecker products of that array. If we denote the array whose mth Kronecker power is under consideration by $\boldsymbol{\mathcal{A}}$ then we can write

$$\boldsymbol{\mathcal{A}}^{\otimes m} \equiv \underbrace{\boldsymbol{\mathcal{A}} \otimes \cdots \otimes \boldsymbol{\mathcal{A}}}_{m \text{ factors}}, \qquad m = 1, 2, ...; \qquad \boldsymbol{\mathcal{A}}^{\otimes 0} \equiv 1 \tag{2}$$

where we have used the algebraic convention dictating us that the zero power of something is just the constant 1.

Kronecker powers enable us to define the powers of ordinary algebraic vectors. This property can be used to much more concisely rewrite a multivariate Taylor series in a single infinite sum. If we consider a multivariate function f which depends on N number of independent variables then we can define the following vector

$$\mathbf{x} \equiv \left[x_1 - x_1^{(e)} \;\; ... \;\; x_N - x_N^{(e)} \right]^T \tag{3}$$

which can be called "System Vector" in system theoretical applications. Then the following infinite sum corresponds to multivariate Taylor series expanded at the position denoted by the vector whose elements $x_1^{(e)}$,..., $x_N^{(e)}$ respectively ((e) stands for recalling expansion) for the function $f(\mathbf{x})$.

$$f(\mathbf{x}) = \sum_{j=0}^{\infty} \mathbf{f}_j^T \mathbf{x}^{\otimes j} \tag{4}$$

where $\mathbf{f}_j$ stands for an N^j element constant vector whose elements can be evaluated from the f function's appropriate partial derivatives evaluated at $\mathbf{x} = \mathbf{0}_N$.

 ISBN: 978-84-617-8694-7

First two coefficient vectors, 1×1 type (scalar) f_0 and $N \times 1$ type f_1 vectors, are unique in this representation. However, all other f_j vectors are not unique because the greater than or equal to 2 Kronecker powers of the independent variable vector $\mathbf{x}$ is orthogonal to some finite number constant matrices. To explain this situation we can consider the Kronecker square of the vector $\mathbf{x}$. The vector $\mathbf{x}^{\otimes 2}$ has elements which are binary products like $a_i a_j$ $(i \neq j)$. The elements $a_i a_j$ and $a_j a_i$ are same even though their positions in element ordering are $(i-1)N + j$ and $(j-1)N + i$ respectively. So the vector whose elements are all zero except the ones at these locations have same magnitude but opposite signs is orthogonal to $\mathbf{x}^{\otimes 2}$. This implies that there are $N(N-1)/2$ constant vectors to which the vector $\mathbf{x}^{\otimes 2}$ is orthogonal. Hence the addition of the linear combination of these constant vector transposes with arbitrary linear combination coefficients does not change the contribution of the term proportional to f_2 to whole sum. Similar situations exist for other Kronecker powers greater than 2 such that the number of the constant vectors rapidly grows unboundedly as the power increases. All these discussions mean that Kronecker power series is not a unique entity and many appropriately defined constant vectors with arbitrary magnitudes can be added to the coefficients without changing the entire expansion.

2 Constancy Adding Space Extension (CASE)

The nonuniqueness of Kronecker power series in fact presents an important facilitation in the restructuring of Kronecker power series since certain arbitrary parameters can be introduced to the structure such that we can monitor the series coefficients by choosing appropriate values to these parameters. On the other hand, another important concept, "Space Extension" may take us to much better structures in Kronecker power series. Space extension means the definition of new independent variables in terms of the given ones to extend the space where the Kronecker power series basic vector $\mathbf{x}$ lies in such a way that the original Kronecker power series becomes having coefficients which are close to what we desire to have.

"Constancy Adding Space Extension" takes an important specific part amongst many other space extensions. It basically adds a constant function with an arbitrary value, as if a new independent variable. Let us now define an augmented independent variable vector from the independent variable of the Kronecker power series in (4) as follows

$$\mathbf{x}_{aug} \equiv \begin{bmatrix} \mathbf{x}^T & x_{n+1} - x_{n+1}^{(e)} \end{bmatrix}^T, \qquad x_{n+1} \equiv a \tag{5}$$

where we have assumed that the augmented expansion point component, $x_{n+1}^{(e)}$ vanishes and a is arbitrary at this moment. We can write the following Kronecker power series instead

 ISBN: 978-84-617-8694-7

of the one in (4)

$$f(\mathbf{x}) = \sum_{j=0}^{\infty} \mathbf{f}_{aug,j}^{T} \mathbf{x}_{aug}^{\otimes j} \tag{6}$$

where we need to express $\mathbf{f}_{aug,j}$ vectors in terms of $\mathbf{f}_j$ vectors. To accomplish this task we focus on the Kronecker powers $\mathbf{x}_{aug}^{\otimes j}$s. $\mathbf{x}_{aug}^{\otimes j}$ is a jth degree polynomial of a as can be noticed immediately even though this dependence may be considered quite complicated. A careful look at this vector reveals that each element is proportional to a nonengative integer power of a even though there seems to be existing rather a disordered ordering of these powers. However it is always possible that we can use permutations amongst the elements of this vector such that the new formed vector has vector blocks located as descending Kronecker powers of the vector $\mathbf{x}$ starting from the power j. Each block should be multiplied by a power of a such that the sum of this power with the Kronecker power of that term always remains equal to j. There is only one block containing jth Kronecker power of $\mathbf{x}$ which has no prefactor of an a power while the number of blocks proportional to the $(j-1)$th Kronecker power of $\mathbf{x}$ is j and they are multiplied by just a. The number of the other terms are relevant binomial coefficients and the degree of the a factors increases by one as the Kronecker power decreases by one. Therefore we can write

$$\mathbf{x}_{aug}^{\otimes j} \equiv \mathbf{\Pi}_j \left[\mathbf{x}^{\otimes j^T} \quad \underbrace{a\mathbf{x}^{\otimes (j-1)^T} \quad ... \quad a\mathbf{x}^{\otimes (j-1)^T}}_{j \text{ identical terms}} \quad \underbrace{a^2\mathbf{x}^{\otimes (j-2)^T} \quad ... \quad a^2\mathbf{x}^{\otimes (j-2)^T}}_{j(j-1)/2 \text{ identical terms}} \quad ... \quad a^j \right]^T \tag{7}$$

where $\mathbf{\Pi}_j$ is a permutation matrix of $(N+1)^j \times (N+1)^j$ type. Due to the specific nature of the permutation operation, this permutation matrix is unitary. We do not intend to explicitly give its analytic structure.

(7) implies that the relation $\mathbf{f}_{aug,j} = \mathbf{f}_{zpad,j}\mathbf{\Pi}^T$ can be constructed between the $\mathbf{f}_j$ and $\mathbf{f}_{aug,j}$ vectors where $\mathbf{f}_{zpad,j}$ stands for the $(N+1)^j$ element vector whose first N^j element block is equal to $\mathbf{f}_j$ while its remaining part is padded with zero.

3 Monomial Shifting In Constancy Adding Space Extension (CASE)

Abovementioned formulation shows that the use of CASE may not be considered so interesting unless certain extra actions are realized to facilitate the Kronecker Power Series utilization under consideration. To this end we can start with the following equalities: $1 \equiv a/a \equiv (1/a)\mathbf{e}_{N+1}^T \mathbf{x}_{aug},\ a \neq 0$ where $\mathbf{e}_{N+1}$ stands for the standard unit vector whose only nonzero element is 1 and located at the $(N+1)$th position, in $(N+1)$ dimensional

 ISBN: 978-84-617-8694-7

Cartesian space. The following extended form of this equality is much more facilitating for the term shifts in Kronecker power series.

$$1 \equiv \frac{a^m}{a^m} \equiv \frac{1}{a^m}\left(\mathbf{e}_{N+1}^T \mathbf{x}_{aug}\right)^m \equiv \frac{1}{a^m}\mathbf{e}_{N+1}^{\otimes m\ T}\mathbf{x}_{aug}^{\otimes m}, \qquad a \neq 0, \qquad m = 0, 1, 2, ... \tag{8}$$

This leads us to write

$$\begin{aligned}\mathbf{f}_{aug,j}^T \mathbf{x}_{aug}^{\otimes j} = 1\mathbf{f}_{aug,j}^T \mathbf{x}_{aug}^{\otimes j} 1 &= \frac{1}{a^m}\left(\mathbf{e}_{N+1}^{\otimes m_1\ T}\mathbf{x}_{aug}^{\otimes m_1}\right)\left(\mathbf{f}_{aug,j}^T \mathbf{x}_{aug}^{\otimes j}\right)\left(\mathbf{e}_{N+1}^{\otimes (m-m_1)^T}\mathbf{x}_{aug}^{\otimes (m-m_1)}\right) \\ &= \left(\mathbf{e}_{N+1}^{\otimes m_1} \otimes \mathbf{f}_{aug,j} \otimes \mathbf{e}_{N+1}^{\otimes (m-m_1)}\right)\mathbf{x}_{aug}^{\otimes (j+m)} = \mathbf{f}_{aug,j\to m_1+j+m-m_1}^T \mathbf{x}_{aug}^{\otimes (j+m)}\end{aligned} \tag{9}$$

where the $(N+1)^{j+m}$ type new coefficient vector can be given through the following identicality.

$$\mathbf{f}_{aug,j\to m_1+j+m-m_1} \equiv \mathbf{e}_{N+1}^{\otimes m_1} \otimes \mathbf{f}_{aug,j} \otimes \mathbf{e}_{N+1}^{\otimes (m-m_1)} \tag{10}$$

where the subscript component $j \to m_1 + j + m - m_1$ explains the shift from jth term to $(j+m)$th term in a way such that the total shift is partitioned to three elementary shifts: (i) first from constant to m_1 Kronecker power, (ii) then the next j step shift in power ascending direction, (iii) and finally, $(m - m_1)$ step in power ascending direction. This implies that there are $(m+1)$ number of three partitioned consecutive shifts from jth power to $(j+m)$th power.

Now, we can write the following equality from (9)

$$\begin{aligned}\mathbf{f}_{aug,j}^T \mathbf{x}_{aug}^{\otimes j} = \left(\sum_{m_1=0}^{m} \alpha_{m_1} \mathbf{f}_{aug,j\to m_1+j+m-m_1}\right)^T \mathbf{x}_{aug}^{\otimes (j+m)} &= \mathbf{f}_{aug,j\to j+m}\left(\boldsymbol{\alpha}\right)^T \mathbf{x}_{aug}^{\otimes j}, \\ \alpha_0 + \cdots + \alpha_m &= 1\end{aligned} \tag{11}$$

where $\boldsymbol{\alpha}$ stands for the set of the α parameters while the rightmost part coefficient is a concise notation not explicitly representing the partitioning and the coefficient of the $(j+m)$ Kronecker power of $\mathbf{x}_{aug}$ therein can be called the "Coefficient to m-Power-Shift". This means that m-power-shift introduces m arbitrary scalars as flexible parameters (if m vanishes then there is no inserted flexible parameter; however this means no shift and it is a trivial issue). These parameters can be determined to suppress certain array norms to get wider convergence domains.

The above analysis imposes no condition on the structure of the vector $\mathbf{f}_j$ and inserts a lot of arbitrary parameters to that vector during the m-power-shift such that the number of the parameters ascends up to infinity as j grows unboundedly. However, this number can be much more increased if the vector $\mathbf{f}_j$ has certain specific natures. To this end, first thing coming to mind, is the binary Kronecker product decomposition and we can write

$$\mathbf{f}_{aug,j} = \mathbf{f}_{aug,j_1}^{(1)} \otimes \mathbf{f}_{aug,j-j_1}^{(2)}, \qquad \mathbf{f}_{aug,j}\mathbf{x}^{\otimes j} = \left(\mathbf{f}_{aug,j_1}^{(1)}\mathbf{x}^{\otimes j_1}\right)\left(\mathbf{f}_{aug,j-j_1}^{(2)}\mathbf{x}^{\otimes (j-j_1)}\right) \tag{12}$$

 ISBN: 978-84-617-8694-7

where j_1 can take just a single or more-than-one values between 0 and j exclusive and each factor between parantheses can be parametrized by using m-power-shift formula given above. Since the total power shift will be considered as m, each paranthesed factor can be power shifted such that the total power shift remains as m-power-shift.

By using (11) and distributive property of matrix product over Kronecker product we can write

$$\begin{aligned}\mathbf{f}_j^T \mathbf{x}_{aug}^{\otimes j} &= \sum_{m_1=0}^{m} \gamma_{m_1} \left(\mathbf{f}_{aug,j_1\to j_1+m_1}\left(\boldsymbol{\alpha}_{m_1}\right) \otimes \mathbf{f}_{aug,(j-j_1)\to(j-j_1)+(m-m_1)}\left(\boldsymbol{\beta}_{m-m_1}\right)\right)^T \mathbf{x}_{aug}^{\otimes(j+m)} \\ &= \mathbf{f}_{j\to j+m;KPD}\left(\boldsymbol{\alpha},\boldsymbol{\beta},\boldsymbol{\gamma}\right)\mathbf{x}^{\otimes j+m} \end{aligned} \tag{13}$$

where subscript component KPD after semicolon stands for implying the Kronecker product decomposition of the vector $\mathbf{f}_j$ at two factor (binary) product level while the symbols $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ have been used to denote the unions of the sets over $\boldsymbol{\alpha}_{m_1}$s and the unions of the sets over $\boldsymbol{\beta}_{m_1}$s respectively whereas $\boldsymbol{\gamma}$ denotes the set composed of γs.

The set $\boldsymbol{\alpha}_{m_1}$ has (m_1+1) elements denoted by $\alpha_{m_1,0}$,...,α_{m_1,m_1} such that the sum of these elements separately vanish for all m_1 values between 1 and m inclusive as long as m does not vanish (otherwise trivial). Same thing is also valid for the set $\boldsymbol{\beta}_{m-m_1}$ whose elements can be denoted by $\beta_{m-m_1,0}$, ..., $\beta_{m-m_1,m-m_1}$ such that the sum of these elements separately vanish for each m_1 values between 0 and $m-1$ inclusive as long as m does not vanish (otherwise trivial). Hence, for a specific m_1 value between 0 and m, $\boldsymbol{\alpha}_{m_1}$ brings m_1 flexible parameters while the number of flexible parameters brought by the set $\boldsymbol{\beta}_{m-m_1}$ is $(m-m_1)$. Thus the number of flexible parameters entering the shift for a single given m_1 value from αs and βs is always m. This makes the total number of flexible parameters coming from αs and βs is $m(m+1)$. Since we have also used γs with indices between 0 and m inclusive as flexible parameters, the total number of flexible parameters is $m(m+2)$ because of the vanishing sum over γs. This means that the number of flexible parameters in (13) can be represented by a second degree polynomial of m. This proves the rapid increase in the parametrization when the vector $\mathbf{f}_j$ can be expressed as a Kronecker product of two appropriate subvectors. Here all these are true for just a single binary Kronecker product case. If there are more than one cases each of which leads us to a separate binary Kronecker power for the vector $\mathbf{f}_j$ then the number of the flexible parameters grows much more rapidly.

The latest analysis here in this section can be extended to the case where the vector $\mathbf{f}_j$ can be expressed as more than two factor Kronecker products. In those cases the number of the flexible parameters increases from second degree polynomials of m to much more higher polynomials of m even though we do not intend to proceed for giving much more informations for these cases since they are not primary items for this work.

In many cases the vector $\mathbf{f}_j$ may not be uniquely (but approximately) represented as the Kronecker products of some number of factors. In those cases, certain more sophisticated schemes, for example singular value decomposition like or enhanced multivariate products

 ISBN: 978-84-617-8694-7

representation like algorithms, to represent this vector can be brought to the stage. However, these algorithms alone may necessitate quite rigorous studies and we find them too detailed for this proceeding paper even though we have current research projects on these items.

The higher number of flexible parameters which can be inserted to Kronecker power terms during the shifts in Kronecker powers is quite important since their optimisation can be used to suppress the norm of the coefficient vector of shifted Kronecker power term. This suppression generally leads us to get wider convergence domain in the resulting-after-shift Kronecker power series and this is very important issue for practical applications. Hence high level parametrization of the m-power-shifts in Kronecker power series is perhaps most desired issue. We find this discussion sufficient for our goal in this work.

4 Converting Multinomiality to Highest Degre Monomiality via Power Shifts

Kronecker power series are somehow is the backbone of the Probabilistic Evolution Theory (PREVTH) as we pronounced at the beginning of this paper. PREVTH extensively uses the concept of space extension as unfamiliar reader can find sufficient information in our publications on this issue [1–16] and many practical cases have possibilities to get multinomiality (multinomial=polynomial of more than one independent variables) at the right hand side functions of the explicit ODEs in PREVTH. Until now we have also attempted to further reduce multinomiality to conicality (the second degree multinomiality) to get the analytical solution for PREVTH. Our recent considerations have shown that the Highest Degree Monomiality (just a single Kronecker power with highest degree together with its coefficient matrix or vector) can also facilitate the PREVTH analysis and may yield analytical solutions as again appropriate Kronecker power series.

Hence to proceed we can focus on the Kronecker power multinomial defined as follows

$$f\left(\mathbf{x}\right) = \sum_{j=0}^{N} \mathbf{f}_{aug,j}^{T} \mathbf{x}_{aug}^{\otimes j} \tag{14}$$

which is a restricted form of the Kronecker power series given in (6). Our purpose is now to use m-power-shifts to reduce this multinomial to a single power multinomial such that only the highest Kronecker power appears. To this end we can start with the following new form of (13)

$$\mathbf{f}_{j}^{T} \mathbf{x}_{aug}^{\otimes j} = \mathbf{f}_{j \rightarrow j+m;Dec}\left(\boldsymbol{\kappa}_{m}\right) \mathbf{x}^{\otimes j+m} \tag{15}$$

where the separately symbolized sets $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, and, $\boldsymbol{\gamma}$ have been combined to a single set denoted by κ_m (m specifies the shift) for brevity here. Beyond that the subscript string

 ISBN: 978-84-617-8694-7

KPD, which has been used to mean a very specific situation, can be interchanged with another string Dec to mean a more general vector decomposition.

We can now change m with $N-j$ in (15) to get the following more specific shift

$$\mathbf{f}_j^T \mathbf{x}_{aug}^{\otimes j} = \mathbf{f}_{j\to N;Dec}\left(\boldsymbol{\kappa}_{N-j}\right) \mathbf{x}^{\otimes N} \tag{16}$$

whose utilization in (14) produces

$$f\left(\mathbf{x}\right) = \left(\sum_{j=0}^{N} \mathbf{f}_{j\to N;Dec}\left(\boldsymbol{\kappa}_{N-j}\right) \right) \mathbf{x}^{\otimes N} \tag{17}$$

whose right hand side is apparently highest degree monomial of the original multinomial. This is a quite important relation and stands for opening new horizons to PREVTH. Here the number of elements in the set $\boldsymbol{\kappa}_{N-j}$ may be quite nonlinear in comparison to the term $(N-j)$ and therefore the total level of parametrization may be quite high and nonlinear in $(N-j)$ depending on the decomposition used in the parametrization. Even though this is an important issue in the sense of combinatorial analysis, we can consider this term as a secondary issue in this conceptual work. However, for further practicality this issue is quite important and we have launched a new peoject to reveal important aspects of this topic.

5 Concluding Remarks

The main goal of this work has been the conversion of a Kronecker multinomial to its highest degree monomial with a different coefficient. To this end we have basically used the Constancy Adding Space Extension (CASE) which principally adds a constant function with an unknown value to the existing unknowns such that the added constant function is considered as if it is a new unknown. This addition of course affects the existing coefficients of a Kronecker power series. However the most important aspect of CASE is the possibility of moving certain Kronecker powers to a higher Kronecker power and add to its existing value. This can be successed in such a way that the resulting affected higher Kronecker power coefficient includes some number of arbitrary parameters which can be used to suppress the relevant coefficient norms and therefore to obtain much wider convergence domain in the relevant Kronecker power series. The parametrization level (the number of the flexible parameters to be optimized) depends on the nature of the coefficients entering the shifts from certain Kronecker powers to higher degree Kronecker powers.

Kronecker power series appear comprehensively in PREVTH and are not unique expansions. This nonuniqueness shows up as flexible parameter insertion in Constancy Adding Space Extension (CASE). However, in PREVTH, the infinite Kronecker power series do not help us so much to facilitate the analysis and to get an analytical solution. On the other hand, in many practical applications the right hand sides of the explicit ODEs to

 ISBN: 978-84-617-8694-7

which PREVTH will be applied there exist certain functions of the unknown temporally changing functions such that the use of those functions as new unknowns with or without existing ones produces new extended set of ODEs having right hand sides in multinomials of the new unknowns. Once the multinomiality is obtained at the right hand side of the considered ODEs the rest is quite straightforward and the multinomiality can be converted to conicality as certain theorems guarantees. Even though the present widely used form of PREVTH uses conicality our brainstorming actions implied that highest degree monomial structured right hand sides even facilitate the PREVTH analysis pretty much and the power shifts mentioned in this paper permits us to convert a given Kronecker power multinomial to its highest degree monomial with a new coefficient and this brings another analytical solution having PREVTH version to applications.

Binary Kronecker Product Based Orthogonal Decompositions of Linear Algebraic Vectors

Metin Demiralp[1]

[1] *Computational Science and Engineering Department, Informatics Institute, İstanbul Technical University*

emails: metin.demiralp@gmail.com

Abstract

An algebraic vector which is a one way array can be decomposed to a linear combination of elements in a complete basis set. This is a quite ordinary idea for vector decomposition. However it becomes quite interesting when we take a basis set of orthonormal vectors each of which is a binary Kronecker product of same type. This work focuses on such decompositions each of which in fact uses appropriate matrix forms obtained from the target vector. We focus on singular value decomposition (SVD) and tridiagonal matrix enhanced multivariance products representation (TMEMPR) only in this work.

Key words: Kronecker product, Singular value decomposition, Tridiagonal Matrix Enhanced Multivariance Products Representation.

1 Introduction: Needs for Linear Algebraic Vector Decomposition

Probabilistic Evolution Theory (PREVTH) has been developed to get analytic solutions to explicit ODE(s) under initial value impositions recently in our group (Group for Science and Methods of Computing (G4SMC)) studies [1–16]. PREVTH solutions are given in Kronecker power series as long as the explicit ODE set at the focus has a conical right hand side. Space extension concept is also used to reduce the conicality to the highest degree monomial. The definition of Kronecker product, Kronecker power and Kronecker power series have been given in another paper [17] of this author in this conference proceeding.

 ISBN: 978-84-617-8694-7

Kronecker power series representation of a multivariate function is defined by using its multivariate Taylor series and therefore the partial derivative values evaluated at a specific expansion point denoted by the components $x_1^{(e)}$, ..., $x_N^{(e)}$ in N dimensional Cartesian space

$$f(\mathbf{x}) = \sum_{j=0}^{\infty} \mathbf{f}_j^T \mathbf{x}^{\otimes j} \tag{1}$$

where

$$\mathbf{x} \equiv \begin{bmatrix} x_1 - x_1^{(e)} & \dots & x_N - x_N^{(e)} \end{bmatrix} \tag{2}$$

which can be named "System Vector" in system theoretical point of view. In (1) f stands for a multivariate function depending on system vector $\mathbf{x}$ while the coefficient $\mathbf{f}_j$s are constant vectors of $N^j \times 1$ type, composed of constant elements in terms of the partial derivatives of f evaluated at the expansion point $\mathbf{x}^{(e)}$ in N-dimensional Cartesian space. These varying types of the coefficients are balanced by the types of the relevant Kronecker powers. Thus the jth monomial of the series has $1 \times N^j$ type array coefficient is balanced to a scalar by$N^j \times 1$ type $\mathbf{x}^{\otimes j}$. First two coefficients of the Kronecker power series in (1) are 1×1 type (scalar) $\mathbf{f}_0^T$ and $1 \times N$ type $\mathbf{f}_1$ vector transpose are unique in this representation. However, all remaining $\mathbf{f}_j$ vectors are not unique because the greater than or equal to 2 Kronecker powers of the independent variable vector $\mathbf{x}$ are orthogonal to certain finite number constant vectors. A detailed discussion on this issue has been given in another paper of this papers author [17]. Therein, these nonuniquenesses have been used for parametrization of the shifted coefficients through certain flexible parameters. Beyond these, certain decomposition relation additions have also been investigated up to certain level of detailing. Hence the decomposition of a vector to a linear combination of binary Kronecker products gains a lot of importance and we have devoted the remaining part of this presentation to this issue. We will present basically two decompositions: (i) Kronecker product based singular value decomposition, (ii) Tridiagonal Matrix Enhanced Multivariance Products Representation (TMEMPR) Based Decomposition.

2 Kronecker Product Based Singular Value Decomposition of Linear Algebraic Vectors

Singular Value Decomposition (SVD) of a matrix which can be even rectangular is formulated generally by using two mappings from one Cartesian space whose dimension matches target matrix column space dimension to another Cartesian space whose dimension matches target matrix row space dimension and its reverse such that each mapping somehow define a semi-eigenvalue problem to get a true eigenvalue problem when they are combined. We do not intend to repeat the details of this well-known formulation here. Beyond the

 ISBN: 978-84-617-8694-7

above formulation we can generate the SVD formula by optimizing the Euclidean distance between the target matrix and an outer product of two unit normed vectors whose number of elements match the row and column number of the target matrix scaled by an arbitrary constant where everything is considered real-valued for brevity. This gives some number of possibilities for the outer product and the scaling factor such that all solutions match one of the singular value decompositions additive terms as can be proven by using consecutive constrained optimizations until the Euclidean distance of the remaining target vanishes. We do not intend to detail this formulation since the following parts will reveal the same type actions for our present Kronecker product based singular value decomposition of a linear algebraic vector. Now for our current decomposition we will denote the target vector to be decomposed by $\mathbf{a}$ and assume that its number of element is mn where m and n are two positive integer numbers for convenience. We are going to propose the following cost functional for optimisation

$$\begin{aligned} \mathcal{J}\left(\sigma, \mathbf{u}, \mathbf{v}, \lambda_u, \lambda_v\right) &\equiv \left\|\mathbf{a} - \sigma \mathbf{u} \otimes \mathbf{v}\right\|^2 + \lambda_u \left(\mathbf{u}^T \mathbf{u} - 1\right) + \lambda_v \left(\mathbf{v}^T \mathbf{v} - 1\right) \\ &= \mathbf{a}^T \mathbf{a} - 2\sigma \mathbf{a}^T \left(\mathbf{u} \otimes \mathbf{v}\right) + \sigma^2 \mathbf{u}^T \mathbf{u} \mathbf{v}^T \mathbf{v} + \lambda_u \left(\mathbf{u}^T \mathbf{u} - 1\right) \\ &\quad + \lambda_v \left(\mathbf{v}^T \mathbf{v} - 1\right) \end{aligned} \tag{3}$$

where we have used the unit norm constraints on the vectors $\mathbf{u}$ of m elements and $\mathbf{v}$ of n elements. This cost functional depends on three scalars, σ, λ_u, λ_v and two vectors, $\mathbf{u}$ and $\mathbf{v}$. Its optimization necessitates the setting of its partial derivatives with respect to σ, λ_u and λ_v equal to zero and setting its gradients with respect to the vectors $\mathbf{u}$ and $\mathbf{v}$ equal to $\mathbf{0}_m$ and $\mathbf{0}_n$, the zero vectors of m and n elements respectively. We can at first write

$$\frac{\partial \mathcal{J}}{\partial \sigma} = 2\sigma \mathbf{u}^T \mathbf{u} \mathbf{v}^T \mathbf{v} - 2\mathbf{a}\left(\mathbf{u} \otimes \mathbf{v}\right) \tag{4}$$

$$\frac{\partial \mathcal{J}}{\partial \lambda_u} = \mathbf{u}^T \mathbf{u} - 1 \tag{5}$$

$$\frac{\partial \mathcal{J}}{\partial \lambda_v} = \mathbf{v}^T \mathbf{v} - 1 \tag{6}$$

These form three scalar equations for solving unknowns. We need two additional vector equations. To this end we have to evaluate the gradients of additive terms in the expression of the cost functional. We can write first

$$\mathbf{a} \equiv \left[\, \mathbf{a}_1^T \;\; \ldots \;\; \mathbf{a}_N^T \,\right] \tag{7}$$

where $\mathbf{a}_i$s stand for n-element subvector components of $\mathbf{a}$. This takes us to the following equality

$$\mathbf{a}^T \left(\mathbf{u} \otimes \mathbf{v}\right) = \sum_{i=1}^{m} u_i \mathbf{a}_i^T \mathbf{v} = \mathbf{u}^T \mathbf{A} \mathbf{v} \tag{8}$$

 ISBN: 978-84-617-8694-7

where $\mathbf{A}$ stands for the $m \times n$ type matrix defined as follows

$$\mathbf{A} \equiv [\, \mathbf{a}_1 \;\; ... \;\; \mathbf{a}_m \,]^T \tag{9}$$

All these enable us to rewite the explicit expression of the cost functional as follows

$$\begin{aligned} \mathcal{J}\left(\sigma, \mathbf{u}, \mathbf{v}, \lambda_u, \lambda_v\right) &= \mathbf{a}^T\mathbf{a} - 2\sigma\mathbf{a}^T\left(\mathbf{u} \otimes \mathbf{v}\right) + \sigma^2\mathbf{u}^T\mathbf{u}\mathbf{v}^T\mathbf{v} + \lambda_u\left(\mathbf{u}^T\mathbf{u} - 1\right) \\ &\quad + \lambda_v\left(\mathbf{v}^T\mathbf{v} - 1\right) \end{aligned} \tag{10}$$

which permit us to write

$$\boldsymbol{\nabla}_{\mathbf{u}}\mathcal{J} = -2\sigma\mathbf{A}\mathbf{v} + 2\sigma^2\mathbf{v}^T\mathbf{v}\mathbf{u} + 2\lambda_u\mathbf{u} = \mathbf{0}_m \tag{11}$$

$$\boldsymbol{\nabla}_{\mathbf{v}}\mathcal{J} = -2\sigma\mathbf{A}^T\mathbf{u} + 2\sigma^2\mathbf{u}^T\mathbf{u}\mathbf{v} + 2\lambda_v\mathbf{v} = \mathbf{0}_n \tag{12}$$

Premultiplication of (11) and (12) with the transposes of vectors $\mathbf{u}$ and $\mathbf{v}$ results in the following scalar equations

$$-2\sigma\mathbf{u}^T\mathbf{A}\mathbf{v} + 2\sigma^2 + 2\lambda_u = 0, \qquad -2\sigma\mathbf{v}^T\mathbf{A}^T\mathbf{u} + 2\sigma^2 + 2\lambda_v = 0 \tag{13}$$

where we have used (5) and (6). On the other hand, the combination of (8) with (4), (5) and (6) makes the following equality valid.

$$\sigma = \mathbf{u}^T\mathbf{A}\mathbf{v} \tag{14}$$

The employment of this intermediate result in (13) takes us to the conclusion that the Lagrange parameters of optimization, λ_u and λ_v, vanish. This implies that optimisation could have been conducted without imposing the unit norm condition on $\mathbf{u}$ and $\mathbf{v}$ through the constraints. Instead we could straightforwardly impose to the construction of cost functional by taking the norms of these vectors directly equal to 1. This achievement is quite natural for spectral-decomposition-like or SVD-like formulations.

Now we can reorganize (11) and (12) by setting λ_u and λ_v equal to 0 while setting the norms of the vectors $\mathbf{u}$ and $\mathbf{v}$ equal to 1. This gives

$$\mathbf{A}\mathbf{v} = \sigma\mathbf{u}, \qquad \mathbf{A}^T\mathbf{u} = \sigma\mathbf{v} \tag{15}$$

which implies that the σ parameter can take the singular values of $\mathbf{A}$ while $\mathbf{u}$ and $\mathbf{v}$ correspond to the relevant singular vectors of same matrix. The matrix $\mathbf{A}$ is composed of rows each of which is equal to one of $\mathbf{a}_i$s. Hence it is rowwise folding of the original vector $\mathbf{a}$. For this folding the vectors $\mathbf{v}$ and $\mathbf{u}$ are the relevant right and left singular vectors of the matrix $\mathbf{A}$ to the singular value σ. All these mean that we can define the Kronecker product

 ISBN: 978-84-617-8694-7

based singular value decomposition as the singular value decomposition of the matrix $\mathbf{A}$. We can therefore write

$$\mathbf{a} = \sum_{i=1}^{\min(m,n)} \sigma_i \mathbf{u}_i \otimes \mathbf{v}_i \tag{16}$$

where σ_i, $\mathbf{u}_i$, $\mathbf{v}_i$ are the ith Kronecker Product Based SVD singular value, normalized right singular vector, normalized left singular vector respectively as long as the multiple singular states are counted separately.

3 Kronecker Product Based Tridiagonal Matrix Enhanced Products Representation for an Ordinary Linear Algebraic Vector

We have been able to develop many extensions to the High Dimensional Model Representation (HDMR) and Enhanced Multivariance Products Representation (EMPR) [18–21] takes a very important place in these extensions. We have even brought new extensions to EMPR such that the Bivariate EMPR has been used as the backbone of the new methodology and its utilization is repeated with different support functions which are the basic additional components of EMPR. Bivariate EMPR can be written as follows for a given matrix $\mathbf{A}$ of $m \times n$ type

$$\mathbf{A} = \alpha \mathbf{u}\mathbf{v}^T + \overline{\mathbf{a}}_1 \mathbf{v}^T + \mathbf{u}\overline{\mathbf{a}}_2^T + \overline{\mathbf{A}}_{1,2} \tag{17}$$

where m-element $\mathbf{u}$ and n-element $\mathbf{v}$ vectors are given and called "Left" and "Right" "Support Vectors". They have unit norms and can be optimised to increase the descending dominance of right hand side additive terms. The right hand side entities, α, $\overline{\mathbf{a}}_1$, $\overline{\mathbf{a}}_2$ and $\overline{\mathbf{A}}_{1,2}$, stand for a scalar, an m-element vector, an n-element vector and an $m \times n$ type matrix. They are called in a way such that "constant component" for α, "univariate components for $\overline{\mathbf{a}}_1$ and $\overline{\mathbf{a}}_2$, and finally, "remainder matrix component" for $\mathbf{A}$. These are determined in such a way that additive terms become mutually orthogonal in Frobenius matrix inner product. We do not give further details since the basic content of this section will reveal all these details parallel to the formulations of this section.

Now as being inspired by Bivariate EMPR for a given matrix we can propose the following expression for a given vector $\mathbf{a}$ with mn elements where m and n are given positive integers.

$$\mathbf{a} = \alpha \mathbf{u} \otimes \mathbf{v} + \overline{\mathbf{a}}_1 \otimes \mathbf{v} + \mathbf{u} \otimes \overline{\mathbf{a}}_2^T + \overline{\mathbf{a}}_{1,2} \tag{18}$$

where the remainder term can be considered as the agent to be suppressed in norm. We can define the following Euclidean Distance cost functional by considering support vectors

 ISBN: 978-84-617-8694-7

as given entities while EMPR components are considered as the items to be optimised.

$$\begin{aligned}\mathcal{J}_{cd}\left(\alpha,\overline{\mathbf{a}}_1,\overline{\mathbf{a}}_2\right) &\equiv \left\|\mathbf{a}-\alpha\mathbf{u}\otimes\mathbf{v}-\overline{\mathbf{a}}_1\otimes\mathbf{v}-\mathbf{v}\otimes\overline{\mathbf{a}}_2\right\|^2\\ &= \mathbf{a}^T\mathbf{a}+\alpha^2+\overline{\mathbf{a}}_1^T\overline{\mathbf{a}}_1+\overline{\mathbf{a}}_2^T\overline{\mathbf{a}}_2+2\alpha\mathbf{u}^T\overline{\mathbf{a}}_1+2\alpha\mathbf{v}^T\overline{\mathbf{a}}_2+2\mathbf{u}^T\overline{\mathbf{a}}_1\mathbf{v}^T\overline{\mathbf{a}}_2\\ &\quad -2\mathbf{a}^T\left(\mathbf{u}\otimes\mathbf{v}\right)-2\mathbf{a}^T\left(\overline{\mathbf{a}}_1\otimes\mathbf{v}\right)-2\mathbf{a}^T\left(\mathbf{v}\otimes\overline{\mathbf{a}}_2\right)\\ &= \mathbf{a}^T\mathbf{a}+\alpha^2+\overline{\mathbf{a}}_1^T\overline{\mathbf{a}}_1+\overline{\mathbf{a}}_2^T\overline{\mathbf{a}}_2+2\alpha\mathbf{u}^T\overline{\mathbf{a}}_1+2\alpha\mathbf{v}^T\overline{\mathbf{a}}_2+2\mathbf{u}^T\overline{\mathbf{a}}_1\mathbf{v}^T\overline{\mathbf{a}}_2\\ &\quad -2\mathbf{u}^T\mathbf{A}\mathbf{v}-2\overline{\mathbf{a}}_1^T\mathbf{A}\mathbf{v}-2\mathbf{u}^T\mathbf{A}\overline{\mathbf{a}}_2 \end{aligned} \tag{19}$$

where we have used the fact that each support function has unit norm by definition. This may not be considered as the cost functional to be used in optimisation because of certain constraints on the right hand side components.

(18) imposes just a single vector equation amongst one scalar, two vectors, and, one matrix components and is not sufficient to uniquely determine the right hand side components. To get uniqueness the extended forms of Sobol conditions in High Dimensional Model Representation are needed to be used. They are called vanishing product conditions and two of them dictates us that $\overline{\mathbf{a}}_1$ and $\overline{\mathbf{a}}_2$ need to be orthogonal to the support vectors, $\mathbf{u}$ and $\mathbf{v}$, respectively. Thus using these vanishing inner products as constraints we can define the following new cost functional instead of the one in (19) as follows

$$\begin{aligned}\mathcal{J}\left(\alpha,\overline{\mathbf{a}}_1,\overline{\mathbf{a}}_2,\lambda_1,\lambda_2\right) &\equiv \mathcal{J}_{cd}\left(\alpha,\overline{\mathbf{a}}_1,\overline{\mathbf{a}}_2\right)+\lambda_1\mathbf{u}^T\overline{\mathbf{a}}_1+\lambda_2\mathbf{v}^T\overline{\mathbf{a}}_2\\ &= \mathbf{a}^T\mathbf{a}+\alpha^2+\overline{\mathbf{a}}_1^T\overline{\mathbf{a}}_1+\overline{\mathbf{a}}_2^T\overline{\mathbf{a}}_2-2\mathbf{u}^T\mathbf{A}\mathbf{v}-2\overline{\mathbf{a}}_1^T\mathbf{A}\mathbf{v}-2\mathbf{u}^T\mathbf{A}\overline{\mathbf{a}}_2\\ &\quad +\lambda_1\mathbf{u}^T\overline{\mathbf{a}}_1+\lambda_2\mathbf{v}^T\overline{\mathbf{a}}_2\end{aligned} \tag{20}$$

By setting the first partial derivative of this cost functional with respect to α equal to zero and then solving the resulting equation we can obtain

$$\alpha=\mathbf{u}^T\mathbf{A}\mathbf{v} \tag{21}$$

On the other hand, by setting the first partial derivatives of this cost functional with respect to λ_1 and λ_2 equal to zero and then solving the resulting equations we can obtain

$$\mathbf{u}^T\overline{\mathbf{a}}_1=0 \qquad \mathbf{v}^T\overline{\mathbf{a}}_2=0 \tag{22}$$

The remaining equations can be obtained by setting the gradients of the cost functional with respect to the vectors $\overline{\mathbf{a}}_1$ and $\overline{\mathbf{a}}_2$ equal to m element and n element zero vectors respectively. We can write

$$2\overline{\mathbf{a}}_1-2\mathbf{A}\mathbf{v}-\lambda_1\mathbf{u}=\mathbf{0}_m, \qquad 2\overline{\mathbf{a}}_2 2\mathbf{A}^T\mathbf{u}-\lambda_2\mathbf{v}=\mathbf{0}_n \tag{23}$$

 ISBN: 978-84-617-8694-7

whose equations can be premultiplied by the transposes of the vectors, $\mathbf{u}$ and $\mathbf{v}$, respectively; and then the resulting scalar equations can be solved for λ_1 and λ_2. This action produces

$$\lambda_1 = \lambda_2 = 2\mathbf{u}^T\mathbf{A}\mathbf{v} = 2\alpha \tag{24}$$

This takes us from (23) to the following results

$$\overline{\mathbf{a}}_1 = \mathbf{A}\mathbf{v} + \alpha\mathbf{u}, \qquad \overline{\mathbf{a}}_2 = \mathbf{A}^T\mathbf{u} + \alpha\mathbf{v} \tag{25}$$

(21) and (25) shows that α, $\overline{\mathbf{a}}_1$, $\overline{\mathbf{a}}_2$ components of the vector $\mathbf{a}$ match the Bivariate EMPR components of the matrix $\mathbf{A}$ which is a specific folded form of the vector $\mathbf{a}$. This implies that the remainder vector $\overline{\mathbf{a}}_{1,2}$ should give the remainder matrix, $\mathbf{A}_{1,2}$ when it is folded in accordance with the folding of the target vector $\mathbf{a}$.

TMEMPR is based on consecutive Bivariate EMPR (BEMPR) application to the target matrix. The remainder matrix of first BEMPR can be taken as a new target and then the univariate components of the first BEMPR can used as the new support vectors after they are scaled such that their norms become 1. This produces new α and new univariate components together with a new remainder matrix. Then a new BEMPR is launched with this remainder at the focus by using the new univariate vectors as the new support vectors. As the number of consecutive BEMPRs increases the newly formed remainder matrix becomes having decreasing ranks such that after some number of consecutive steps the remainder becomes disappearing. This builds Tridiagonal Matrix Enhanced Multivariance Products Representation (TMEMPR) whose explicit structure is given below

$$\mathbf{A} = \sum_{i=1}^{n_\alpha} \alpha_i \mathbf{u}_i \mathbf{v}_i^T + \sum_{i=1}^{n_\beta} \beta_i \mathbf{u}_{i+1} \mathbf{v}_i^T + \sum_{i=1}^{n_\gamma} \mathbf{u}_i \mathbf{v}_{i+1}^T \tag{26}$$

where n_α stands for $\min(m, n)$, the minimum of the positive integer row and column numbers, while n_β characterizes $(m-1)$ when $m < n$ and m when $m > n$. Similarly, n_γ represents m when $m < n$ and $(m-1)$ when $m > n$. In the case where $m = n$ both n_β and n_γ take the common value, $(m-1)$. Curious readers can refer to our basic relevant publications [18–21] for much more detailed information on TMEMPR.

Above analysis and the most recently given formula can be parallelly adapted to the case of vector decomposition through TMEMPR as follows

$$\mathbf{a} = \sum_{i=1}^{n_\alpha} \alpha_i \mathbf{u}_i \otimes \mathbf{v}_i^T + \sum_{i=1}^{n_\beta} \beta_i \mathbf{u}_{i+1} \otimes \mathbf{v}_i^T + \sum_{i=1}^{n_\gamma} \mathbf{u}_i \otimes \mathbf{v}_{i+1}^T \tag{27}$$

where all entities, α, β, and, γ parameters together with the support vectors, $\mathbf{u}$s and $\mathbf{v}$s, are known in terms of the target vector $\mathbf{a}$ and the initially given support vectors. This completes the construction of our basic goal, the vector decomposition via TMEMPR.

4 Concluding Remarks

This work has been devoted to the linear algebraic vector decomposition by using binary Kronecker product terms. Our important remarks are enumerated below

1. We have focused on Singular Value Decomposition (SVD) of an ordinary linear algebraic vector such that each additive term is proportional to the Kronecker product of two vectors each of which has been taken from an orthonormal vector set, each of which is from a different Cartesian vector space.

2. We have also focused on Tridiagonal Matrix Enhanced Multivariance Products Representation (TMEMPR). We have immediately noticed that each additive term outer product should be changed with the Kronecker product of the same factors of the relevant outer product.

3. Kronecker Product Based SVD and TMEMPR are not the only possible ordinary linear algebraic vector decompositions. However, these are the most basic two of standing approaches based on powerful theoretical backgrounds.

4. These two decompositions can be used for shifting from a Kronecker power to a another higher Kronecker power. This inserts quite many arbitrary parameters to shifted Kronecker power coefficient and enable us to suppress the norms of coefficient vectors or matrices as much as possible. Even though the handling of these parameter evaluations stands rather comprehensive it has the power of monitoring the Kronecker power series convergences.

5. By having convergence monitoring powers of these decompositions we are now at an important point that we can extend the Probabilistice Evolution Theory (PREVTH) we have developed for conical systems in last decade to highest power monomiality. This will form the content of our very near future publication. We have been now equipped very much to this end.

Highest Monomiality Based Probabilistic Evolution Theoretical (PREVTH) Solutions to Explicit Ordinary Differential Equations

Metin Demiralp[1]

[1] *Computational Science and Engineering Department, Informatics Institute, İstanbul Technical University*

emails: metin.demiralp@gmail.com

Abstract

This work can be regarded as the most contemporary and important development realized in most recent Demiralp group studies, nine of which are reported in this conference's presentations. A well developed Probabilistic Evolution Theory (PREVTH) has been developed by us in the last decade through step by step, maybe small but quite important, developments. However, that theory basically constructed to solve the explicit ODE(s) whose autonomous right hand side functions are conical (second degree multinomial) in unknown temporal functions. The obtention of conicality is generally based on certain space extension procedures which mostly increase the dimensionality of the space of unknowns. Our recent efforts have revealed that the conicality is not the only important facilitation to get rather simple analytic series solutions. It is also almost equivalently possible to develop similar algorithms to one for conicality case for any multinomiality in the right hand sides since as we have caught the fact that any multinomial can be converted to highest degree monomial by using some shift operations. This work is designed to focus on these issues by also referring to other two important papers of the author in this conference contributions.

Key words: Kronecker product, Kronecker power series, PREVTH, PREVTH recursions.

1 Introduction: Probabilistic Evolution Theory (PREVTH) in its Contemporary Form

In last decade of our group (Group for Science and Methods of Computing (G4SMC)) studies [1–16], we have developed a productive structure we have called Probabilistic Evolution

Theory (PREVTH) to obtain analytic solutions to first order autonomous explicit ODE(s) under initial value impositions. As long as the explicit ODE set at the focus has a conical right hand side PREVTH solutions are given in Kronecker power series even though the coefficient matrices or vectors may not be analytically found. The "Space Extension" concept can also be used to convert the conicality to the highest (second) degree monomiality to get analytically evaluable coefficient arrays (matrices or vectors). Curious readers can refer to our relevant publications [1–16]. We do not intend to repeat the details of solution construction procedure since almost same thing will be realized for the PREVTH's present form solution in this work.

2 Probabilistic Evolution Theory (PREVTH) on Highest Power Multinomiality

Let us consider the following vector ODE

$$\dot{\mathbf{x}}(t) = \mathbf{F}\mathbf{x}(t)^{\otimes n}, \qquad \mathbf{x}(0) = \mathbf{a} \tag{1}$$

where $\mathbf{x}(t)$ stands for the N-element system vector while n stands for a positive integer whereas $\mathbf{F}$ is a constant rectangular matrix of $N \times N^n$ type. Even though we can construct a Kronecker power series solution to this vector ODE it opens a new formalism from scratch. Instead of that construction it seems to be better to use an ODE over not system vector but its $(n-1)$th Kronecker power. To this end, we can write the following equality via simple temporal differentiation.

$$\begin{aligned} \frac{d\mathbf{x}(t)^{\otimes (n-1)}}{dt} &= \sum_{j=0}^{n-2} \mathbf{x}(t)^{\otimes j} \otimes \dot{\mathbf{x}}(t) \otimes \mathbf{x}(t)^{\otimes (n-j-2)} = \mathbf{G}\mathbf{x}(t)^{\otimes (2n-2)}, \\ \mathbf{G} &\equiv \sum_{j=0}^{n-2} \mathbf{I}_N^{\otimes j} \otimes \mathbf{F} \otimes \mathbf{I}_N^{\otimes (n-j-2)}, \qquad \mathbf{x}(0)^{\otimes (n-1)} = \mathbf{a}^{\otimes (n-1)} \end{aligned} \tag{2}$$

where $\mathbf{G}$ matrix is of $N^{n-1} \times N^{2n-2}$ type. Now we can write

$$\dot{\mathbf{y}}(t) = \mathbf{G}\mathbf{y}(t)^{\otimes 2}, \qquad \mathbf{y}(0) = \mathbf{a}^{\otimes (n-1)} \equiv \mathbf{b}, \qquad \mathbf{y}(t) \equiv \mathbf{x}(t)^{\otimes (n-1)} \tag{3}$$

where $\mathbf{y}$ is an N^{n-1} element vector. The ordinary differential equation herein allows us to use conicality based Probabilistic Evolution Theory (PREVTH) to construct a Kronecker Power Series solution. We are going to give intermediate steps explicitly for better explanation.

 ISBN: 978-84-617-8694-7

We can write the following equality from this purely conical ODE set.

$$\begin{aligned}\frac{d\mathbf{y}(t)^{\otimes j}}{dt} &= \sum_{k=0}^{j-1}\mathbf{y}(t)^{\otimes k}\otimes\dot{\mathbf{y}}(t)\otimes\mathbf{y}(t)^{\otimes(j-k-1)} = \mathbf{M}_j\mathbf{y}(t)^{\otimes j+1},\\ &\mathbf{M}_j \equiv \sum_{k=0}^{j-1}\mathbf{I}_{\overline{\mathrm{N}}}^{\otimes k}\otimes\mathbf{G}\otimes\mathbf{I}_{\overline{\mathrm{N}}}^{\otimes(j-k-1)},\quad \overline{\mathrm{N}}\equiv N^{n-1}\qquad \mathbf{y}(0)^{\otimes j}=\mathbf{b}^{\otimes j}\end{aligned}\tag{4}$$

where $\overline{N}^j\times\overline{N}^{j+1}$ type array, $\mathbf{M}_j$, can be called "Monocular Matrix" as we have done in Conicality Based Probabilistic Evolution Theory (PREVTH). The temporal integration of both sides in (4) takes us to the following integral equation

$$\mathbf{y}(t)^{\otimes j}=\mathbf{b}^{\otimes j}+\int_0^t d\tau\mathbf{M}_j\mathbf{y}(\tau)^{\otimes(j+1)},\qquad j=1,2,3,...\tag{5}$$

First J equations of this recursion can be used to get the following equality by eliminating the integrals over the Kronecker powers (except the highest one) of the system vector and performing all remaining intermediate simple integrations

$$\begin{aligned}\mathbf{y}(t) &= \sum_{j=0}^{J-1}\frac{t^j}{j!}\mathbf{T}_j\mathbf{b}^{\otimes(j+1)}+\int_0^t dt_1...\int_0^{t_{J-1}}dt_J\mathbf{T}_J\mathbf{y}\left(t_J\right)^{\otimes(J+1)},\qquad J=1,2,3,...\\ &\mathbf{T}_k\equiv\prod_{\ell=1}^{k}\mathbf{M}_\ell,\qquad k=0,1,2,...\end{aligned}\tag{6}$$

where $t_0\equiv t$ and the finite product over Monocular Matrices, whose upper limit is less than the corresponding lower limit, is assumed to be $\overline{N}$ element identity matrix. The multifold integral term in the first part of this formula tends to vanish as long as its integrand's norm tends to decrease as J increases unboundedly. However, this is equivalent to the convergence of the preceding multinomial part in the first equation of this formula. If this convergence happens to exist then we can write the solution as follows

$$\mathbf{y}(t)=\sum_{j=0}^{\infty}\frac{t^j}{j!}\mathbf{T}_j\mathbf{b}^{\otimes(j+1)},\tag{7}$$

As have done in Conicality Based Probabilistic Evolution Theory, the matrix $\mathbf{T}_j$ is called "j-th Telescope Matrix" and it is somehow consistent cascaded form of the Monocular Matrices.

The solution given through (7) is a denumerable infinite linear combination of $\overline{N}$ element vectors, jth of which is in fact the image of the $(j+1)$th augmented initial vector ($\mathbf{b}$) Kronecker power under the jth Telescope matrix ($\mathbf{T}_j$). The conicality coefficient matrix $\mathbf{G}$

is defined as a sum of certain left and right Kronecker products of the matrix $\mathbf{F}$ with appropriate identity matrices. Hence it is rather sparse and the sparsity dramatically increases as the positive integer n increases. On the other hand, Monocular Matrices add more sparsity because of their structures connecting them to the matrix $\mathbf{G}$. A similar sparsity addition comes from the relations of the Telescope Matrices to Monocular matrices. All these imply that the sparsity is a quite undesired happening because it consumes much more memory and execution times in computer applications, and hence, must be avoided. To this end a new compaction method we call squarification has been proposed in Demiralp group studies. Basic definition of the squarification is as follows

$$\mathbf{T}_j \mathbf{b}^{\otimes (j+1)} \equiv \mathbf{S}_j (\mathbf{b}) \mathbf{b}, \qquad j = 0, 1, 2, ... \tag{8}$$

where $\mathbf{S}_j (\mathbf{b})$ stands for a matrix of $\overline{N} \times \overline{N}$ with elements depending on initial vector. The square matrices, $\mathbf{S}_j (\mathbf{b})$s can be evaluated by using specific procedure we call "Squarification". Since $\mathbf{T}_0 = \mathbf{I}_{\overline{N}}$ there is specific need for squarification and we take $\mathbf{S}_0 \equiv \mathbf{I}_{\overline{N}}$. However for $\mathbf{S}_1 (\mathbf{b})$ we can write first

$$\mathbf{T}_1 \mathbf{b}^{\otimes 2} = \mathbf{G}\mathbf{b}^{\otimes 2} \equiv \left[\mathbf{G}_1 \ \ ... \ \ \mathbf{G}_{\overline{\mathrm{N}}} \right] \mathbf{b}^{\otimes 2} = \left(\sum_{j=1}^{\overline{\mathrm{N}}} b_j \mathbf{G}_j \right) \mathbf{b} \tag{9}$$

which urges us to define the following "Squarification" procedure

$$\lfloor \mathbf{G}, \mathbf{b} \rceil = \left(\sum_{j=1}^{\overline{\mathrm{N}}} b_j \mathbf{G}_j \right) \mathbf{b}, \qquad \mathbf{S}_1 (\mathbf{b}) \equiv \lfloor \mathbf{G}, \mathbf{b} \rceil \tag{10}$$

where the leftmost symbol can be called "Squarification of $\mathbf{G}$ by $\mathbf{b}$", or briefly, "Squarification" while the matrix $\mathbf{G}$ and the vector $\mathbf{b}$ are called "Squarificant" and "Squarifier" respectively. The essential points in this squarification are the rules on the types of the squarificant and the squarifier. The matrix column number must be square of its row number which must also be equal to the number of elements in the squarifier. Beyond these, the matrices, $\mathbf{S}_j (\mathbf{b})$ are called "Squarified Telescope Matrices (SquTelMats)". These are vald only when the rectangular matrix to be squarified acts on a Kronecker square. If the rectangular matrix acts on a rather general entity, a Kronecker product of two different vectors then the rules may change accordingly. We are going to encounter such cases at the end of this section.

Even though the first SquTelMat, $\mathbf{S}_1 (\mathbf{b})$ is coincidentally a sole squarification, the other higher indexed SquTelMats generally have nested and powered squarifications. The expressions of these entities rapidly become quite complicated as the index of the SquTelMat tends to increase unboundedly. And, as a matter of fact, the determination of these expressions become formidable tasks even computer facilites are appropriately used. These facts have

 ISBN: 978-84-617-8694-7

urged us to seek a recursion amongst the SquTelMats. After comprehensive studies we have been able to get

$$\mathbf{S}_j(\mathbf{b}) = \sum_{k=0}^{j-1} \binom{j-1}{k} \lfloor \mathbf{G}, \mathbf{S}_k(\mathbf{b})\,\mathbf{b} \rceil\, \mathbf{S}_{j-k-1}(\mathbf{b}), \qquad j = 1, 2, ... \qquad \mathbf{S}_0(\mathbf{b}) = \mathbf{I}_{\overline{\mathbb{N}}} \tag{11}$$

whose validity had been shown by using some number of first SquTelMat expressions even though the general induction stage of the mathematical induction proof method has not been realized. Quite recently we could have been able to prove the validity of this recursion for all positive integer j values [21].

Although this recursion is constructed on square matrices, it is much better to convert it to a vector recursion for facilitating the computer algebra. To this end we can write

$$\mathbf{v}_j(\mathbf{b}) = \sum_{k=0}^{j-1} \binom{j-1}{k} \lfloor \mathbf{G}, \mathbf{v}_k(\mathbf{b}) \rceil\, \mathbf{v}_{j-k-1}(\mathbf{b}), \quad j = 1, 2, ... \quad \mathbf{v}_0(\mathbf{b}) = \mathbf{b} \tag{12}$$

where

$$\mathbf{v}_j(\mathbf{b}) \equiv \mathbf{S}_j(\mathbf{b})\,\mathbf{b} \tag{13}$$

Now the utilization of the last definition in (7) gives the ultimate PREVTH solution of (3) as follows

$$\mathbf{y}(t) = \sum_{j=0}^{\infty} \frac{t^j}{j!} \mathbf{v}_j(\mathbf{b}) \tag{14}$$

Now we can rewrite (1) as follows in the light of our most recent findings

$$\dot{\mathbf{x}}(t) = \mathbf{F}\mathbf{x}(t)^{\otimes n} = \mathbf{F}\left(\mathbf{y}(t) \otimes \mathbf{x}(t)\right) \qquad \mathbf{x}(0) = \mathbf{a} \tag{15}$$

which urges us to write the following much more general squarification where two vector Kronecker product appears instead of a single vector's Kronecker square.

$$\mathbf{F} \equiv [\,\mathbf{F}_1 \;\; ... \;\; \mathbf{F}_{N^{n-1}}\,], \qquad \lfloor \mathbf{F}, \mathbf{y}(t) \rceil \equiv \sum_{j=1}^{N^{n-1}} y_j(t) \mathbf{F}_j \tag{16}$$

The first vector factor of the Kronecker product must have same number of elements as the number of square blocks in the rectangular matrix squarificant while the second vector factor of the Kronecker product must have same number elements as the number of the rows of the squarificant. We do not distinguishly symbolize this squarifier for brevity and this does not create any confusion as long as the Kronecker product factors' and squarificant's

 ISBN: 978-84-617-8694-7

row and column numbers are incompatible for multiplication. This squarification enables us to finally write

$$\dot{\mathbf{x}}(t) = \lfloor \mathbf{F}, \mathbf{y}(t) \rceil \, \mathbf{x}(t) \qquad \mathbf{x}(0) = \mathbf{a} \tag{17}$$

This is a linear vector ODE with variable known coefficient and can be at least numerically solved since we have assumed that $\mathbf{y}(t)$ has been found from the PREVTH solution of the auxiliary vector ODE. On the other hand, this equation can also be handled by using a PREVTHwise recursion.

3 Solving Previous Section's Linear Vector ODE via Recursion Construction

We can now proceed to get the solution of (17) by proposing the following expansions

$$\mathbf{x}(t) \equiv \sum_{j=0}^{\infty} \frac{t^j}{j!} \mathbf{x}_j, \qquad \lfloor \mathbf{F}, \mathbf{y}(t) \rceil = \sum_{j=1}^{\infty} \frac{t^j}{j!} \lfloor \mathbf{F}, \mathbf{y}_j \rceil \tag{18}$$

which allows us to write

$$\dot{\mathbf{x}}(t) \equiv \sum_{j=0}^{\infty} \frac{t^j}{j!} \mathbf{x}_{j+1}, \qquad \lfloor \mathbf{F}, \mathbf{y}(t) \rceil \, \mathbf{x}(t) = \sum_{j=1}^{\infty} \frac{t^j}{j!} \sum_{k=0}^{j} \binom{j}{k} \lfloor \mathbf{F}, \mathbf{y}_k \rceil \, \mathbf{x}_{j-k} \tag{19}$$

as long as the convergences permit us. The plugging into (17) produces

$$\mathbf{x}_{j+1} = \sum_{k=0}^{j} \binom{j}{k} \lfloor \mathbf{F}, \mathbf{y}_k \rceil \, \mathbf{x}_{j-k}, \qquad j = 0, 1, 2, ...; \qquad \mathbf{x}_0 \equiv \mathbf{a}. \tag{20}$$

This is an infinite linear recursion whose solution's convergence characteristics can be investigated by using, for example, majorant series.

Let us consider the linear vector space spanned by the matrices of $N \times N^{n-1}$ type and denote it by $\mathcal{M}_{N \times N^{n-1}}$. We are going to consider the Frobenius inner product and relevant induced norm which can be explicitly defined over this space as follows

$$(\mathbf{M}_1, \mathbf{M}_2) \equiv Tr\left(\mathbf{M}_1^T \mathbf{M}_2\right), \qquad \|\mathbf{M}\| \equiv (\mathbf{M}, \mathbf{M}), \qquad \mathbf{M}_1, \mathbf{M}_2, \mathbf{M} \in \mathcal{M}_{N \times N^{n-1}} \tag{21}$$

Now we can write the following norm equality from the second equality in (16)

$$\|\lfloor \mathbf{F}, \mathbf{y}(t) \rceil\| \leq \sum_{j=1}^{N^{n-1}} |y_j(t)| \, \|\mathbf{F}_j\| \leq \left(\sum_{j=1}^{N^{n-1}} y_j(t)^2 \right)^{\frac{1}{2}} \left(\sum_{j=1}^{N^{n-1}} \|\mathbf{F}_j\|^2 \right)^{\frac{1}{2}} \equiv \|\mathbf{y}(t)\| \, \|\mathbf{F}\| \tag{22}$$

 ISBN: 978-84-617-8694-7

where we have used the Cauchy-Schawarz inequality when we write the rightmost inequality. On the other hand, we can also write

$$\|\mathbf{y}(t)\| \le \sum_{j=0}^{\infty} \frac{|t|^j}{j!} \|\mathbf{y}_k\| \equiv Y(t), \qquad \|\lfloor \mathbf{F}, \mathbf{y}(t) \rceil\| \le \|\mathbf{F}\| \, Y(t) \tag{23}$$

$$\|\mathbf{x}(t)\| \le \sum_{j=0}^{\infty} \frac{|t|^j}{j!} \|\mathbf{x}_k\| \equiv X(t), \qquad \|\lfloor \mathbf{F}, \mathbf{y}(t) \rceil \mathbf{x}(t)\| \le \|\mathbf{F}\| \, Y(t) X(t) \tag{24}$$

The first one of this couple of equation imply the following formulae when it is considered together with the second one of the same couple of equations

$$\|\dot{\mathbf{x}}(t)\| \le \sum_{j=0}^{\infty} \frac{|t|^j}{j!} \|\mathbf{x}_{k+1}\|, \qquad \dot{X}(t) = \|\mathbf{F}\| \, Y(t) X(t) \tag{25}$$

where we have converted the inequality to equality at the second formula since $X(t)$ has been considered as a majorant function. It should be accompanied with the initial imposition $X(0) = \mathbf{a}$. Then the resulting simple scalar ODE can be solved as follows

$$X(t) = \mathrm{e}^{\|\mathbf{F}\| \int_0^t d\tau Y(\tau)} \mathbf{a}, \qquad t \ge 0 \tag{26}$$

In accordance with this majorant function $\mathbf{x}(t)$ should converge in the same temporal interval as $Y(t)$ converges. This means that the essential point is the temporal convergence of the vector $\mathbf{y}(t)$. This convergence has been investigated under sufficient rigor in our relevant publications. [1–16]. Curios readers can refer to them.

4 Conicality Matrix and Convergence of Auxiliary Solution

We have used an auxiliary conicality based PREVTH solution in the previous sections. Therein the auxiliary vector $\mathbf{y}(t)$ has played an important role in the construction of the main solution. Hence its temporal series convergence is also a very important issue in the quality of the PREVTH solution for the highest monomiality based ODEs. On the other hand, our conicality based PREVTH solution convergence is basically determined by the matrix $\mathbf{G}$ we may call "Conicality Matrix" and also initial vector $\mathbf{b}$. We are not going to repeat the details of this issue. However, we may consider to investigate the specific structure of conicality in the sense of coefficient nonuniquenesses and the relevant flexibilities.

Second equality of (2) defines the conicality matrix, $\mathbf{G}$ explicitly. The structure of this matrix includes many different types identity matrices each of which is multiplied by a (generally) different Kronecker powers of the system vector such that these powers are

 ISBN: 978-84-617-8694-7

orthogonal to certain number of constant vectors. This enables us to add certain number of specific constant matrices to these identity matrices with arbitrary coefficients. So it is quite possible to insert many flexible parameters to the conicality matrix, **G**. Same thing happens not only to identity matrices but also to the core matrix (highest monomiality matrix), **F**. All these flexible parameters can be determined in such a way that the norm of the Conicality Matrix, **G** can be suppressed as much as possible to get a close quality to desired convergence rate. We do not intend to go beyond this point in this issue.

5 Concluding Remarks

We have presented how to construct a Kronecker power series solution to an explicit autonomous first order ODE set with a monomial at the right hand side and to this end we have used the fact that the right hand side multinomial's highest degree monomial can be considered as the only Kronecker power at the right hand side of the focused ODE set without any loss of generality due to our findings [27, 28]. Since we believe that our basic task has been completed in this work, we are not willing to repeat all details here.

Beside this work we have some other papers reporting most recent developments about PREVTH in this conference. One paper [21] focuses on the proof of the conicality based PREVTH and that development is a milestone as we believe.

Another paper [22] includes the solution of sensitivity coefficient evaluation problem and has been one of the basic motivation agent to put this work on the loom if the statement holds.

The quantum expectation value dynamics is a quite important issue in the solution of the quantum dynamical problems and until now we have used the Ehrenfest or Ehrenfest-like analysis. This was presenting a lot of undesired negativities. Now in three different papers [23–25], Heisenberg picture related concepts have been used first time and a set of operator equatons we call "Evolver Dynamical Equations" have been constructed. We believe that this development opens a new horizon in PREVTH use for quantum dynamical problems.

Finally, in our another paper [26] we have attempted to get analytic continuations to PREVTH solutions by using Padé approximants.

Abstract

In this work, a predator-prey model considering a non-differentiable functional response similar to the Cobb-Douglas type production function. We show that this function has a strong influence on the locally and globally dynamics of the model.

The non-uniqueness of solutions on the coordinate axis for any initial conditions is proved, i.e. the system is non-lipchitzian. Moreover, the model has at least one small amplitude limit cycles generated by Hopf bifurcation of a fine focus.

Tthe existence of a homocinic curve on the phase plane (threshold curve), which divides the behavior of the trajectories, iimplying that two solutions, to distinct side of this curve have different $\omega-limit$; so, the solutions highly sensitive to initial conditions.

Key words: predator-prey model, stabiity, separatrix curve, limit cycles,
MSC 2000: AMS codes 92D25; 34C23; 58F14; 58F21

1 Introduction

We analyzed a predator-prey model, in which the following aspects are considered: i) the prey natural growth is the logistic equation, [17],

ii) the functional response is a non-differentiable [4, 7, 11], and

iii) the equation for predator growth is the logistic type [1, 15, 17].

This last assumption characterize to the Leslie-Gower type models, in which the conventional environmental carrying capacity for predators K_y is a function of the available prey quantity [1, 10, 13].

We will consider that the predator consumption function or functional response is expressed by the $H(x,y) = qx^{\alpha}y^{\beta}$, known in Economy Sciences as a Cobb-Douglas type function [4]. This function is more realistic than the bilinear functional response $H(x,y) = qxy$, proposed in the Lesie-Gower predator-prey model [8, 9, 13].

To establish the local stability of the equilibrium points, the standard methodoogy cannot be used, [2, 3, 12], due the non-uniqueness of solutions over the coordinates axis. Thus, new methods must be proposed for the analysis of the singuarities over the axis.

2 The model

The predator-prey model is described by a family of vector fields or by autonomous bidimensional differential equations system of the Kolmogorov type [6] given by

$$X_{\mu}: \left\{ \begin{array}{ll} \frac{dx}{dt} & = r\left(1-\frac{x}{K}\right)x - qx^{\alpha}y^{\beta} \\ \frac{dy}{dt} & = s\left(1-\frac{y}{nx+c}\right)y \end{array} \right. \tag{1}$$

where $x(t)$ and $y(t)$ denote the prey and predator population size, respectively, of densities as functions of time, and the vector of parameters

$$\mu = (r, K, q, s, n, c, \alpha, \beta) \in \mathbb{R}^6_+ \times]0,1]^2$$

having different ecological meanings.

In order to make an adequate description of the behaviour of system (1) and to simplify calculus, we follow the methodology used in [8, 9, 10], making a change in variables and a time rescaling given by

$$\varphi : \mathbb{R}^2_+ \times \mathbb{R} \to \mathbb{R}^2_+ \times \mathbb{R},$$

such that

$$\varphi(u,v,\tau) = \left(ku, nkv, \frac{(u+C)}{r}\tau\right) = (x,y,t)$$

with

$$detD\varphi(u,v,\tau) = \left| \begin{pmatrix} k & 0 & 0 \\ 0 & nk & 0 \\ \frac{\tau}{r} & 0 & \frac{(u+C)}{r} \end{pmatrix} \right| = \frac{nk^2(u+C)}{r} > 0.$$

Then, φ is a diffeomorphism preserving time orientation; hence, in the new coordinates, the topologically equivalent vector field [5, 3] to X_{μ} is

$$Y_{\eta}: \left\{ \begin{array}{ll} \frac{du}{d\tau} & = \left((1-u)u - Qu^{\alpha}v^{\beta}\right)(u+C) \\ \frac{dv}{d\tau} & = S(u+C-v)v \end{array} \right. , \tag{2}$$

where $\eta = (Q, C, S, \alpha, \beta) \in \mathbb{R}^3 \times]0,1]^2$ with $Q = \frac{q}{r}k^{\alpha+\beta-1}n^{\beta}$, $C = \frac{c}{nk}$ and $S = \frac{s}{r}$.

 ISBN: 978-84-617-8694-7

The equilibrium points of system (2) or singularities of vector field Y_η are: $(0,0)$, $(1,0)$, $(0,C)$ and $(u_e,v_e)\in\mathbb{R}^2_+$, satisfying the equations of the isoclines

$$\begin{aligned}(1-u)\,u-Qu^\alpha v^\beta &= 0\\ u+C-v &= 0\end{aligned}\tag{3}$$

Since $(1-u)\,u=Qu^\alpha v^\beta>0$ then $0<u<1$. Thus, of the second isocline, we obtain $C<v<1+C$. The abscissa u is a solution of the equation

$$f(u)=Q$$

where the function $f:[0,1]\to\mathbb{R}_{+,0}$ is given by

$$f(u)=\tfrac{(1-u)u}{u^\alpha(u+C)^\beta},\qquad (C,\alpha,\beta)\in\mathbb{R}_+\times\,]0,1]^2.$$

We consider two cases: $\alpha<1$ and $\alpha=1$.

If $\alpha<1$, $f(0)=f(1)=0$ and we obtain

$$\tfrac{df}{du}(u)=-\tfrac{q(u)}{u^\alpha(u+C)^{\beta+1}},\qquad q(u)=au^2+bu-C(1-\alpha),$$

with $a=2-\beta-\alpha>0$ and $b=\alpha+\beta-1+(2-\alpha)C$. q is a parabola that opens upward with only positive root $\bar{u}$, then

$$\tfrac{df}{du}(\bar{u})=0\Leftrightarrow q(\bar{u})=0\Leftrightarrow \bar{u}=\tfrac{-b+\sqrt{b^2+4aC(1-\alpha)}}{2a}$$

Moreover, since $q(\bar{u})=0<1+C=q(1)$, $\bar{u}<1$. Then $\bar{u}\in\,]0,1[$. Deriving again and evaluating in $\bar{u}$ we have

$$\tfrac{d^2f}{du^2}(u)=\tfrac{q(u)((1+\alpha+\beta)u+\alpha C)}{u^{\alpha+1}(u+C)^{\beta+2}}-\tfrac{b+2au}{u^\alpha(u+C)^{\beta+1}},\qquad \tfrac{d^2f}{du^2}(\bar{u})=-\tfrac{\sqrt{b^2+4aC(1-\alpha)}}{\bar{u}^\alpha(\bar{u}+C)^{\beta+1}}<0.$$

Therefore, f is increasing in $[0,\bar{u}]$, decreasing in $[\bar{u},1]$ and with maximun value in $\bar{u}$.

For $\alpha=1$ we have

$$f(u)=\tfrac{(1-u)}{(u+C)^\beta},\qquad f(0)=\tfrac{1}{C^\beta},\qquad f(1)=0,\qquad \tfrac{df}{du}(u)=-\tfrac{\beta+(1-\beta)u}{(u+C)^{\beta+1}}<0.$$

then f is decreasing.

3 Main Results

For the system (2) or vector field Y_η, we have the following results.

Lemma 1 *The set* $\Gamma=\left\{(u,v)\in\mathbb{R}^2\mid 0<u<1, C<v<1+C\right\}$ *is an invariant region.*

 ISBN: 978-84-617-8694-7

Proof. On the upper boundary of Γ,

$$\frac{dv}{d\tau}(u, 1+C) = S(u-1)(1+C) \leq 0, \qquad u \in [0,1].$$

On the lower boundary of Γ,

$$\frac{dv}{d\tau}(u, C) = SuC \geq 0, \qquad u \in [0,1].$$

On the right boundary of Γ,

$$\frac{du}{d\tau}(1, v) = -Qv^{\beta}(1+C) \leq 0, \qquad v \in [0, 1+C].$$

Therefore, all orbits starting from the interior of Γ cannot cross the boundary. ■

We define the functions $F : [0,1] \times \mathbb{R}_+ \to \mathbb{R}_{+,0}$ and $g : [0,1] \to \mathbb{R}_{+,0}$ such as

$$F(u, C) = \frac{(1-u)u}{u^{\alpha}(u+C)^{\beta}}, \qquad g(u) = (1-u)u^{1-\alpha-\beta}, \ with\,(\alpha, \beta) \in]0,1[\times]0,1].$$

Also, we define $\bar{u}$ as function of C, this is, $\bar{u} : \mathbb{R}_+ \to [0,1]$ such that

$$\bar{u}(C) = \frac{-(\alpha+\beta-1+(2-\alpha)C)+\sqrt{(\alpha+\beta-1+(2-\alpha)C)^2+4(2-\beta-\alpha)C(1-\alpha)}}{2(2-\beta-\alpha)},$$

with $(\alpha, \beta) \in]0,1[\times]0,1]$.

For $(\alpha, \beta) \in]0,1[\times]0,1]$, the following statements are true:

i) For $u \in]0,1]$ fixed, $lim_{C\to 0} F(u, C) = g(u)$.

ii) $\bar{u}(0) = 0$ if $1-\alpha-\beta \leq 0$ and $\bar{u}(0) = \frac{(1-\alpha-\beta)}{(2-\alpha-\beta)}$ if $1-\alpha-\beta > 0$.

iii) $lim_{C\to\infty} F(u, C) = 0$ uniformly in u.

iv) $\frac{dF(\bar{u}(C),C)}{dC} = \frac{\partial F}{\partial u}(\bar{u}(C), C)\frac{d\bar{u}}{dC}(C) + \frac{\partial F}{\partial C}(\bar{u}(C), C) = (0)\frac{d\bar{u}}{dC}(C) - \beta\frac{(1-u)u}{u^{\alpha}(u+C)^{\beta+1}} < 0$, namely, $F(\bar{u}(C), C)$ is decreasing in C.

Ultimately, we defined the following sets of parameters

$$\Delta^{sg(\varepsilon)} = \left\{\eta \in \mathbb{R}^5_+ \mid 1-\alpha = sg(\varepsilon), \beta \leq 1\right\},$$
$$\Upsilon^{sg(\varepsilon)} = \left\{\eta \in \Delta^+ \mid 1-\alpha-\beta = sg(e)\right\},$$
$$\Lambda^{sg(\varepsilon)} = \left\{\eta \in \Delta^+ \mid Q - (1-\alpha-\beta)^{1-\alpha-\beta}(2-\alpha-\beta)^{\alpha+\beta-2} = sg(\varepsilon)\right\},$$

where $\eta = (Q, C, S, \alpha, \beta)$.

Lemma 2 *For $\eta = (Q, C, S, \alpha, \beta) \in \Delta^+$:*

1. *If $\eta \in \Upsilon^-$, $\exists!$ $C_1 > 0$ such that $F(\bar{u}(C_1), C_1) = Q$.*

 ISBN: 978-84-617-8694-7

2. *If* $\eta \in \Upsilon^0 \cap \Lambda^-$, $\exists!\ C_2 > 0$ *such that* $F\left(\bar{u}\left(C_2\right), C_2\right) = Q$;

3. *If* $\eta \in \Upsilon^+ \cap \Lambda^-$, $\exists!\ C_3 > 0$ *such that* $F\left(\bar{u}\left(C_3\right), C_3\right) = Q$.

Proof. Proof of 1. Let $K > 0$. If $\eta \in \Upsilon^-$, for the function g we have

$$g\left(1\right) = 0, \qquad lim_{u \to 0} g\left(u\right) = \infty, \qquad \frac{dg}{du} = \frac{(1-\alpha-\beta)-(2-\alpha-\beta)u}{u^{\alpha+\beta}} < 0,$$

then, there is $u_1 < 1$ such that $K = g\left(u_1\right)$. Let $\varepsilon < u_1 = g^{-1}\left(K\right)$. As g is decreasing, we can choose some $\delta > 0$ such that $\delta < g\left(\varepsilon\right) - K$. Since i), for u fixed, there is $\tilde{C}$ such that

$$g\left(u\right) - F\left(u, C\right) < \delta < g\left(\varepsilon\right) - K, \qquad C < \tilde{C}.$$

We choose $u = \varepsilon$, then $K < F\left(\varepsilon, C\right)$ for $C < \tilde{C}$. By ii), there is $\bar{C}$ such that

$$\bar{u}\left(C\right) < \varepsilon, \qquad C < \bar{C},$$

and since $\bar{u}$ is a maximun, $F\left(\bar{u}\left(C\right), C\right) > F\left(\varepsilon, C\right)$ for all $C < \bar{C}$. Then, we choose $\check{C} = min\left\{\tilde{C}, \bar{C}\right\}$. Thus

$$F\left(\bar{u}\left(C\right), C\right) > F\left(\varepsilon, C\right) > K, \qquad C < \check{C}.$$

Therefore, $lim_{C \to 0} F\left(\bar{u}\left(C\right), C\right) = \infty$. By iii), there is $\hat{C}$ such that $F\left(\bar{u}\left(\hat{C}\right), \hat{C}\right) < Q$. Then, by intermediate value theorem, there is $C_1 \in \left]0, \hat{C}\right[$ such that $F\left(\bar{u}\left(C_1\right), C_1\right) = Q$. By vi), $F\left(\bar{u}\left(C\right), C\right)$ is decreasing, then C_1 is unique.

Proof of 2. Let $\delta > 0$. If $\eta \in \Upsilon^0$, $g\left(u\right) = 1 - u$. We choose $\varepsilon < min\left\{1, \delta\right\}$ and $\theta = \delta - \varepsilon = \delta - 1 + g\left(\varepsilon\right) > 0$. Since i), for u fixed, there is $\tilde{C}$ such that

$$g\left(u\right) - F\left(u, C\right) < \theta = \delta - 1 + g\left(\varepsilon\right) \qquad C < \tilde{C}.$$

We choose $u = \varepsilon$, then $1 - F\left(\varepsilon, C\right) < \delta$ for all $C < \tilde{C}$. By ii), there is $\bar{C}$ such that

$$\bar{u}\left(C\right) < \varepsilon, \qquad C < \bar{C},$$

and since $\bar{u}$ is a maximun, $F\left(\bar{u}\left(C\right), C\right) > F\left(\varepsilon, C\right)$ for all $C < \bar{C}$. Then we choose $\check{C} = min\left\{\tilde{C}, \bar{C}\right\}$. Thus

$$1 - F\left(\bar{u}\left(C\right), C\right) < 1 - F\left(\varepsilon, C\right) < \delta, \qquad C < \check{C}.$$

Therefore, $lim_{C \to 0} F\left(\bar{u}\left(C\right), C\right) = 1$. By iii) there is $\hat{C}$ such that $F\left(\bar{u}\left(\hat{C}\right), \hat{C}\right) < Q$. If $\eta \in \Lambda^-$, $Q < 1$ and by intermediate value theorem, there is $C_2 \in \left]0, \hat{C}\right[$ such that $F\left(\bar{u}\left(C_2\right), C_2\right) = Q$. By vi) $F\left(\bar{u}\left(C\right), C\right)$ is decreasing, then C_2 is unique.

 ISBN: 978-84-617-8694-7

Proof of 3. Let $\delta > 0$. If $\eta \in \Upsilon^+$, for the function g we have

$$g(0) = g(1) = 0, \qquad \frac{dg}{du} = \frac{(1-\alpha-\beta)-(2-\alpha-\beta)u}{u^{\alpha+\beta}}, \qquad \frac{dg}{du}(\hat{u}) = 0 \Leftrightarrow \hat{u} = \frac{(1-\alpha-\beta)}{(2-\alpha-\beta)}, \qquad \frac{d^2g}{du^2} < 0,$$

then g has a maximun at $\hat{u}$ and $g(\hat{u}) = \frac{(1-\alpha-\beta)^{1-\alpha-\beta}}{(2-\alpha-\beta)^{2-\alpha-\beta}}$. $F(\bar{u}(C), C)$ is $C^0([0,\infty[)$ and by ii), $F(\bar{u}(0), 0) = g(\hat{u})$. Since iii), there is $\hat{C}$ such that $F\left(\bar{u}\left(\hat{C}\right), \hat{C}\right) < Q$. Thus, if $\eta \in \Lambda^-$, $Q < g(\hat{u})$ by intermediate value theorem, there is $C_3 \in \left]0, \hat{C}\right[$ such that $F(\bar{u}(C_3), C_3) = Q$. By vi), $F(\bar{u}(C), C)$ is decreasing, then C_3 is unique. ■

Theorem 3 *The existence of singularities in* Γ *is given by:*

1. *For* $\eta = (Q, C, S, \alpha, \beta) \in \Delta^0$,
   (a) *if* $QC^\beta \geq 1$, *there are not singularities;*
   (b) *if* $QC^\beta < 1$, $Sing(Y_\eta(\Gamma)) = \{(u_0, u_0 + C)\}$.
2. *For* $\eta = (Q, C, S, \alpha, \beta) \in \Delta^+$,
   (a) *either if* $\eta \in \Upsilon^-$ *with* $C > C_1$ *or if* $\eta \in \Upsilon^0 \cap \Lambda^-$ *with* $C > C_2$ *or if* $\eta \in \Upsilon^+ \cap \Lambda^-$ *with* $C > C_3$ *or if* $\eta \in \Upsilon^{0,+} \cap \Lambda^{0,+}$, *there are not singularities;*
   (b) *either if* $\eta \in \Upsilon^-$ *with* $C = C_1$ *or if* $\eta \in \Upsilon^0 \cap \Lambda^-$ *with* $C = C_2$ *or if* $\eta \in \Upsilon^+ \cap \Lambda^-$ *with* $C = C_3$, $Sing(Y_\eta(\Gamma)) = \{(u_1, u_1 + C)\}$;
   (c) *either if* $\eta \in \Upsilon^-$ *with* $C < C_1$ *or if* $\eta \in \Upsilon^0 \cap \Lambda^-$ *with* $C < C_2$ *or if* $\eta \in \Upsilon^+ \cap \Lambda^-$ *with* $C < C_3$, $Sing(Y_\eta(\Gamma)) = \{(u_2, u_2 + C), (u_3, u_3 + C)\}$.

Proof.

Proof of 1. Since the function f is decreasing if $\alpha = 1$, there is u_0 satisfying $f(u) = Q$ iff $f(0) = \frac{1}{C^\beta} > Q$. Moreover, u_0 is unique. This proves a) and b).

Proof of 2. (u_e, v_e) is solution of (3) iff is solution of

$$f(u) = Q, \qquad v = u + C. \tag{4}$$

and by Lemma 2, if $\eta \in \Upsilon^- \cup \left(\Upsilon^0 \cap \Lambda^-\right) \cup (\Upsilon^+ \cap \Lambda^-)$ there is C_i, with $i \in \{1, 2, 3\}$ depending on the case, such that $F(\bar{u}(C_i), C_i) = Q$. Moreover, f has a maximum value in $\bar{u}$.

a. If $C > C_i$ and as by the vi) property, $F(\bar{u}(C), C)$ is decreasing, we obtain

$$f(u) \leq f(\bar{u}) = F(\bar{u}(C), C) < F(\bar{u}(C_i), C_i) = Q, \qquad u \in [0, 1].$$

Thus, any u can verify (4). If $\eta \in \Upsilon^0 \cap \Lambda^{0,+}$, then $g(u) = 1 - u$ and $Q \geq 1$. Then

$$f(u) < g(u) \leq Q, \qquad u \in]0, 1[,$$

 ISBN: 978-84-617-8694-7

y thus, any u can verify (4). If $\eta \in \Upsilon^{+} \cap \Lambda^{0,+}$, then

$$f(u) < g(u) \leq g(\hat{u}) = \frac{(1-\alpha-\beta)^{1-\alpha-\beta}}{(2-\alpha-\beta)^{2-\alpha-\beta}} \leq Q, \qquad u \in]0,1[,$$

Thus, any u can verify (4).

b. If $C = C_i$ then

$$f(u) \leq f(\bar{u}) = F(\bar{u}(C), C) = Q, \qquad u \in [0,1].$$

Thus, only $u_1 = \bar{u}$ can verify (4).

c. If $C < C_i$ and as by vi), $F(\bar{u}(C), C)$ is decreasing, then

$$Q = F(\bar{u}(C_i), C_i) < F(\bar{u}(C), C) = f(\bar{u}).$$

As $f(0) = f(1) = 0$ and f has a maximun value in $\bar{u}$, there are $u_2, u_3 \in]0,1[$ such that $u_2 < \bar{u} < u_3$ and $f(u_2) = f(u_3) = Q$. ■

Proposition 4 *The singularity* $(0,0)$ *is an unstable node.*

Proof. The Jacobian matrix at $(0,0)$ is

$$DY_{\eta}(0,0) = \begin{pmatrix} C & 0 \\ 0 & SC \end{pmatrix}$$

with $detDY_{\eta}(0,0) = SC^2 > 0$ and $traDY_{\eta}(0,0) = C(1+S) > 0$, then the point is an unstable node. ■

Proposition 5 *The singularity* $(1,0)$ *is a saddle point.*

Proof. The Jacobian matrix at $(1,0)$ is

$$DZ_{\eta}(1,0) = \begin{pmatrix} -1-C & -Q(1+C) \\ 0 & \beta S(1+C) \end{pmatrix}$$

with $detDZ_{\eta}(1,0) = -(1+C)\beta S(1+C) < 0$ and therefore, $(1,0)$ is a saddle point. ■

Proposition 6 *If* $\eta = (Q, C, S, \alpha, \beta) \in \Delta^{0}$, *i. e.* $\alpha = 1$ *for* $(0,C)$ *we have:*

1. *if* $QC^{\beta} < 1$, $(0,C)$ *is a saddle point.*
2. *if* $QC^{\beta} > 1$, $(0,C)$ *is stable.*

 ISBN: 978-84-617-8694-7

Proof. The Jacobian matrix at $(0,C)$ is

$$DY_\eta(0,C)=\begin{pmatrix}\left(1-QC^\beta\right)C & 0\\ SC & -SC\end{pmatrix}$$

with $detDY_\eta(0,C)=\left(QC^\beta-1\right)SC^2$ and $traDY_\eta(0,C)=C\left(1-QC^\beta-S\right)$.

(1) If $QC^\beta<1$, $detDY_\eta(0,C)<0$ and $(0,C)$ is a saddle point.

(2) If $QC^\beta>1$, $traDY_\eta(0,C)<0<detDY_\eta(0,C)$ and $(0,C)$ is stable. ■

Lemma 7 *If $\eta\in\Delta^+$, there is not uniqueness of solutions at points in the positive v-axis, different from the singularity $(0,C)$.*

Proof. If $\eta\in\Delta^+$, $\alpha<1$. We consider the change of variables and the time rescaling given by

$$\phi:\mathbb{R}^2_+\times\mathbb{R}\to\mathbb{R}^2_+\times\mathbb{R},\qquad \phi(z,w,\kappa)=\left(z^{\frac{2}{1-\alpha}},w,z\kappa\right)=(u,v,\tau),$$

with

$$detD\phi(z,w,\kappa)=\left|\begin{pmatrix}\frac{2}{1-\alpha}z^{\frac{2}{1-\alpha}-1} & 0 & 0\\ 0 & 1 & 0\\ \kappa & 0 & z\end{pmatrix}\right|=\frac{2}{1-\alpha}z^{\frac{2}{1-\alpha}}>0\ .$$

and $\phi(0,C)=(0,C)$. By the rule chain $\frac{dz}{d\kappa}=\frac{1-\alpha}{2}z^{1-\frac{1-\alpha}{2}}\frac{du}{d\tau}\frac{d\tau}{d\kappa}$ and $\frac{dw}{d\kappa}=\frac{dv}{d\tau}\frac{d\tau}{d\kappa}$, in the new coordinates, the new vector field is

$$Z_\eta:\begin{cases}\frac{dz}{d\kappa} &= \frac{1-\alpha}{2}\left(\left(1-z^{\frac{2}{1-\alpha}}\right)z^2-Qw^\beta\right)\left(z^{\frac{2}{1-\alpha}}+C\right)\\ \frac{dw}{d\kappa} &= S\left(z^{\frac{2}{1-\alpha}}+C-w\right)wz\end{cases}. \tag{5}$$

Clearly $Z_\eta(0,w)=-\frac{1-\alpha}{2}QCw^\beta\frac{\partial}{\partial z}$. Then, for $w>0$, the vector field Z_η is orthogonal to the w-axis. If $0<w_0\neq C$ and γ is the orbit of vector field (5) with initial condition in the point $(0,w_0)$, then $\gamma^*=\gamma-\{(0,w_0)\}$ is also an orbit to the vector field (5).

As ϕ is a homeomorphism, systems (2) and (5) are C^0-equivalent in the first quadrant $\mathbb{R}^2_+$; hence if $\phi(\gamma^*)$ is an orbit of (2), by continuity $\phi(\gamma)$ is an orbit of (2) that is tangent to the vector field Y_η a the point $(0,w_0)$. But the v-axis, $u=0$ is clearly an invariant set and $Y_\eta(0,w_0)=S(C-w_0)w_0\frac{\partial}{\partial v}\neq 0$. Thus, for the point $(0,w_0)$, at least two orbits exist. ■

Evaluating the Jacobian matrix of vector field Y_η at the equilibrium point (u_e,v_e), we have

$$DY_\eta(u_e,v_e)=\begin{pmatrix}\left(1-2u_e-\alpha(1-u_e)\right)(u_e+C) & -\beta(1-u_e)u_e\\ S(u_e+C) & -S(u_e+C)\end{pmatrix},$$

with trace and determinant given by

$$\begin{aligned} detDY_\eta(u_e,v_e) &= \left((2-\alpha-\beta)u_e^2+(\alpha+\beta-1+(2-\alpha)C)u_e-C(1-\alpha)\right)S(u_e+C)\\ &= q(u_e)S(u_e+C),\\ traDY_\eta(u_e,v_e) &= (1-\alpha+(\alpha-2)u_e-S)(u_e+C).\end{aligned}$$

 ISBN: 978-84-617-8694-7

In the parameters space, in order to obtain a simpler description of the bifurcation diagram of (2), for $\eta = (Q, C, S, \alpha, \beta)$, we define the sets

$$\Theta^{sg(\varepsilon)} = \{\eta \in \Delta^+ \mid S - 1 + \alpha + (2-\alpha)\,\bar{u} = sg(\varepsilon), \bar{u} = \bar{u}(C, \alpha, \beta)\},$$
$$\Pi^{sg(\varepsilon)} = \left\{\eta \in \Delta^+ \mid Q - (1+S)(1-\alpha-S)^{1-\alpha}(2-\alpha)^{\alpha+\beta-2}(C(2-\alpha)+1-\alpha-S)^{-\beta} = sg(\varepsilon)\right\}.$$

Theorem 8 *The nature of singularities in* Γ *is given by:*

1. *The singularity* $p_0 = (u_0, u_0 + C)$ *is stable.*
2. *For the singularity* $p_1 = (u_1, u_1 + C)$ *we have*
   (a) *if* $\eta \in \Theta^-$, p_1 *is a unstable saddle-node;*
   (b) *if* $\eta \in \Theta^0$, p_1 *is a cusp point;*
   (c) *if* $\eta \in \Theta^+$, p_1 *is a stable saddle-node.*
3. *The singularity* $p_2 = (u_2, u_2 + C)$ *is a saddle-point*
4. *For the singularity* $p_3 = (u_3, u_3 + C)$ *we have*
   (a) *either if* $\eta \in \Theta^- \cap \Pi^-$ *or if* $\eta \in \Theta^0 \cup \Theta^+$, p_3 *is stable;*
   (b) *if* $\eta \in \Theta^- \cap \Pi^0$, *a Hopf bifurcation occurs at* p_3*;*
   (c) *if* $\eta \in \Theta^- \cap \Pi^+$, p_3 *is unstable.*

Proof. Proof of 1. The trace and the determinat of the Jacobian matrix $DY_\eta(p_0)$ are

$$detDY_\eta(p_0) = \left((1-\beta)u_0^2 + (\beta + C)u_0\right) S(u_0 + C) > 0,$$
$$traDY_\eta(p_0) = -(u_0 + S)(u_0 + C) < 0,$$

thus, p_1 is stable.

Proof of 2. Since $u_1 = \bar{u}$ y $q(\bar{u}) = 0$, the trace and the determinant of $DY_\eta(p_1)$ are

$$detDY_\eta(p_1) = p(\bar{u})\, S(\bar{u} + C) = 0,$$
$$traDY_\eta(p_1) = (1 - \alpha + (\alpha - 2)\,\bar{u} - S)(\bar{u} + C),$$

then, the sign of $traDY_\eta(p_1)$ depends of the factor $\bar{S} = 1 - \alpha + (\alpha - 2)\,\bar{u} - S$. If $\eta \in \Theta^-$ or Θ^+, $\bar{S}$ is positive o negative, respectively, therefore, we obtain (a) and (c). In the particular case $\eta \in \Theta^0$, $\bar{S} = 0$, and the Jacobian matrix at p_1 is

$$DY_\eta(p_1) = S(\bar{u} + C)\begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix}.$$

 ISBN: 978-84-617-8694-7

The Jordan form matrix corresponding to this Jacobian matrix is

$$\begin{pmatrix} 0 & S(\bar{u}+C) \\ 0 & 0 \end{pmatrix}.$$

and we have the Bogdanov–Takens bifurcation [16], that is, the point p_1 is a cusp point.

Proof of 3. Since $q(u_2) < 0$, $detDY_\eta(p_2) = q(u_2)S(u_2+C) < 0$ and p_2 is a saddle point.

Proof of 4. Since $q(u_3) > 0$, $detDY_\eta(p_3) = q(u_3)S(u_3+C) > 0$ and the nature of p_3 depends on the trace, given by

$$traDY_\eta(p_3) = (1-\alpha+(\alpha-2)u_3 - S)(u_3+C),$$

i.e., depends on the factor $\bar{S} = 1-\alpha+(\alpha-2)u_3 - S$. If $\eta \in \Theta^0 \cup \Theta^+$ and since $\bar{u} < u_3$, is true that

$$1-\alpha-(2-\alpha)u_3 < 1-\alpha-(2-\alpha)\bar{u} \leq S,$$

hence, $\bar{S} < 0$ and then p_3 is stable. If $\eta \in \Theta^-$, $\bar{u} < \frac{1-\alpha-S}{2-\alpha}$ and since f is decreasing in $]\bar{u}, 1[$, we have that

$$\eta \in \Pi^- \Rightarrow f(u_3) = Q < \frac{(1+S)(1-\alpha-S)^{1-\alpha}(2-\alpha)^{\alpha+\beta-2}}{(C(2-\alpha)+1-\alpha-S)^\beta} = f\left(\frac{1-\alpha-S}{2-\alpha}\right) \Rightarrow \frac{1-\alpha-S}{2-\alpha} < u_3 \Rightarrow \bar{S} < 0,$$

$$\eta \in \Pi^0 \Rightarrow f(u_3) = Q = \frac{(1+S)(1-\alpha-S)^{1-\alpha}(2-\alpha)^{\alpha+\beta-2}}{(C(2-\alpha)+1-\alpha-S)^\beta} = f\left(\frac{1-\alpha-S}{2-\alpha}\right) \Rightarrow \frac{1-\alpha-S}{2-\alpha} = u_3 \Rightarrow \bar{S} = 0,$$

$$\eta \in \Pi^+ \Rightarrow f(u_3) = Q > \frac{(1+S)(1-\alpha-S)^{1-\alpha}(2-\alpha)^{\alpha+\beta-2}}{(C(2-\alpha)+1-\alpha-S)^\beta} = f\left(\frac{1-\alpha-S}{2-\alpha}\right) \Rightarrow \frac{1-\alpha-S}{2-\alpha} > u_3 \Rightarrow \bar{S} > 0.$$

Thus, we obtain (a) and (c). The proof of (b) follows from that $traDY_\eta(p_3)$ changes sign and the $detDY_\eta(p_3)$ is always positive. Moreover, verifying the transversality condition [12], we have

$$\frac{\partial(traDY_\eta(p_3))}{\partial S} = -(u_2+C) < 0. \ .$$

Therefore, at the point $p_3 = \left(\frac{1-\alpha-S}{2-\alpha}, \frac{1-\alpha-S}{2-\alpha}+C\right)$ occurs a Hopf bifurcation [16] for the bifurcation value $Q = \frac{(1+S)(1-\alpha-S)^{1-\alpha}(2-\alpha)^{\alpha+\beta-2}}{(C(2-\alpha)+1-\alpha-S)^\beta}$. ■

Remark. The existence of homoclinic curve can be proved, which is generated by the intersection of the stable and unstable manifold of the saddle point p_2.

Proposition 9 *If $\eta \in \Delta^0$, there are not limit cycle in $\mathbb{R}^2_+$.*

Proof. Let $g(u,v) = \frac{1}{u(u+C)v}$. Clearly $g \in C^1\left(\mathbb{R}^2_+\right)$. Then

$$\begin{aligned} div(g(u,v)Y_\eta(u,v)) &= \frac{d}{du}\left(\frac{\left((1-u)u - Qu^\alpha v^\beta\right)(u+C)}{u(u+C)v}\right) + \frac{d}{dv}\left(\frac{S(u+C-v)v}{u(u+C)v}\right), \qquad \forall\,(u,v) \in \mathbb{R}^2_+. \\ &= -\frac{1}{v} - \frac{Q(\alpha-1)}{u^{2-\alpha}v^{1-\beta}} - \frac{S}{u(u+C)} \end{aligned}$$

 ISBN: 978-84-617-8694-7

If $\alpha = 1$, $div\left(g\left(u,v\right)Y_{\eta}\left(u,v\right)\right) = -\frac{1}{v} - \frac{S}{u(u+C)} < 0$. Therefore, by the Dulac criteria [16], there are not limit cycles in $\mathbb{R}^2_+$. ■

If $\beta < 1$, the vector fied Y_{η} is non-lipchitzian in the u-axis. However, we have the following property:

Proposition 10 *If $\beta < 1$, Y_{η} is topologically equivalent to a vector field of Kolmogorov type and lipchitzian in the u-axis.*

Proof. Making a change in variables $\varphi : \mathbb{R}^2_+ \times \mathbb{R} \to \mathbb{R}^2_+ \times \mathbb{R}$, such as

$\varphi\left(z,w\right) = \left(z, w^{\frac{1}{\beta}}\right) = (u,v)$ with

$\mathrm{detD}\varphi\left(z,w\right) = \left|\begin{pmatrix} 1 & 0 \\ 0 & \frac{1}{\beta}w^{\frac{1-\beta}{\beta}} \end{pmatrix}\right| = \frac{1}{\beta}w^{\frac{1-\beta}{\beta}} > 0.$

Then, φ is a diffeomorphism preserving time orientation; hence, in the new coordinates, the topologically equivalent vector field to Y_{η} is

$$Z_{\eta} : \begin{cases} \frac{dz}{d\tau} &= \left(\left(1-z\right)z - Qz^{\alpha}w\right)\left(z+C\right) \\ \frac{dw}{d\tau} &= \beta S\left(z + C - w^{\frac{1}{\beta}}\right)w \end{cases},$$

which it is of Kolmogorov type and lipchitzian on the z-axis (u-axis). ■

Abstract

We consider the multipoint nonlocal boundary value problem for the two-dimensional Laplace equation in a rectangular domainThe solution of this problem is defined as a 9-point finite difference solution, with the fourth order gluing operator of the local Dirichlet boundary value problem, by constructing a special method to find a function as the boundary value on the side of the rectangle, where the nonlocal condition is given. Numerical experiments are illustrated to support the analysis made.

1 Introduction

The paper of A.V. Bitsadze and A.A. Samarskii [1] stated a nonlocal boundary value problem for finding a function on the rectangle, for the given continuous boundary values on three sides of the rectangle. This function has the following properties: it is a solution of Poisson's equation on the open rectangle, it is continuous on the closed rectangle, also on the fourth side of the rectangle and on the midline of the rectangle, which is parallel to this side the function takes coinciding values.

Different generalizations of the nonlocal conditions and their approximate solutions were investigated by numerous authors (see [2], [3], [4], and references therein). As follows from the existing papers, difficulties arise in the analysis of both the exact and numerical solutions due to the existence of the nonlocal conditions.

In [5]-[7] a new constructive method for the solution of the Poisson equation with nonlocal boundary condition have been proposed and justified.

In this paper by the 9-point approximation of the Laplace equation with the fourth order interpolation operator, the approximate method used in [5]-[7] is developed. The 9-point solution of the multilevel nonlocal problem is defined as the 9-point solution of the Dirichlet problem by finding a function given as the boundary value on the side of the rectangle where the nonlocal condition was given. Finally, the numerical experiments are illustrated to support the obtained theoretical results.

2 Multipoint Nonlocal Boundary Value Problem

Let

$$R = \{(x, y) : 0 < x < 1, 0 < y < 2\} \tag{1}$$

be an open rectangle, γ^p, $p = 1, 2, 3, 4$ be its sides including the ends, numerated in the clockwise direction, starting with the side which lies on the y-axis, and let $\gamma = \cup_{p=1}^{4}\gamma^p$ be the boundary of R, $\overline{R} = R \cup \gamma$.

Let $\eta_1, \eta_2, ..., \eta_m$, and $\alpha_1, \alpha_2, ..., \alpha_m$ be given numbers satisfying for some fixed number $\delta > 0$ the inequalities

$$0 < \delta \le \eta_1 < \eta_2 < ... < \eta_m \le 2 - \delta < 2, \tag{2}$$

$$\Big(1 - \frac{\eta_1}{2}\Big) \sum_{k=1}^{m} |\alpha_k| < 1. \tag{3}$$

We consider the following nonlocal boundary value problem on R :

$$\Delta u = 0 \ \text{ on } \ R, \ u = 0 \ \text{ on } \gamma^1 \cup \gamma^3, \ u = \tau(x) \ \text{ on } \gamma^2, \tag{4}$$

$$\sum_{k=1}^{m} \alpha_k u(x, \eta_k) = u(x, 0), \quad 0 \le x \le 1, \tag{5}$$

where $\Delta \equiv \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplace operator, $\tau(x)$ is the given continuous function on $[0, 1]$ and $\tau(0) = \tau(1) = 0$.

The existence and uniqueness of the classical solution $u \in C(\overline{R}) \cap C^2(R)$ of the problem (4), (5) is given in [8], [3].

3 Approximate solution of the nonlocal problem by the finite difference method

We say that $\phi \in C^{k,\lambda}(D)$, if ϕ has k-th derivatives on D satisfying the Hölder condition with exponent λ. Let $\tau(x) \in C^{4,\lambda}(\gamma^2)$, $0 < \lambda < 1$, and $\tau^{(2q)}(0) = \tau^{(2q)}(1)$, $q = 0, 1, 2$.

 ISBN: 978-84-617-8694-7

We assign a square mesh D_h obtained with the lines $x, y = 0, h, 2h, \ldots$, where $h = \frac{1}{N}$ is the step size, $N > 2$ is an integer, such that h is less than half of the minimum length of the intervals $[0, \eta_1]$, $[\eta_1, \eta_2], ..., [\eta_m, 2]$, and we denote by j_l the number for which

$$j_l h \le \eta_l < (j_l + 1)h.$$

We denote by $R_h = D_h \cap R$, γ_h^p is the set of grids on γ^p, $p = 1, ..., 4$, $\gamma_h = \cup_{p=1}^4 \gamma_h^p$, $\overline{R}_h = R_h \cup \gamma_h$, and for each integer l, $1 \le l \le m$, the set of intersection points of the line $y = \eta_l$ with the grid lines $x = ih$, $i = 1, ..., N-1$, is denoted by Y_l^h; $\widetilde{R}_h = \overline{R}_h \cup (\cup_l^m Y_l^h)$.

On the set $Y^h = \cup_{l=1}^m Y_l^h$, we introduce the fourth order liear matching operator S^4 from the condition that the expression $S^4(F_3)$ gives the exact value of any third order harmonic polynomial $F_3(x, y)$ at each point $P \in Y^h$. Let P_0 be the grid node closest to P. We place the origin of the rectangular system of coordinates at the node P_0 and direct the positive axis of x along the grid line so that $P = P(\sigma h, 0)$, $0 \le \sigma < 1$. In the neighborhood $|z| < 2h$, where $z = x + iy$ in the new coordinate system, for the harmonic function $u \in C^{4,0}$ on the basis of Taylor's formula, we have

$$u(x, y) = F_3(x, y) + O(h^4), \tag{6}$$

where

$$F_3(x, y) = \sum_{k=0}^{3} a_k \,\mathrm{Re}\ z^k + \sum_{k=1}^{3} b_k \,\mathrm{Im}\ z^k \tag{7}$$

$$a_0 = u(0,0), a_1 = \frac{\partial u(0,0)}{\partial x}, a_2 = \frac{1}{2}\frac{\partial^2 u(0,0)}{\partial x^2}, a_3 = \frac{1}{3!}\frac{\partial^3 u(0,0)}{\partial x^3};$$
$$b_1 = \frac{\partial u(0,0)}{\partial y}, b_2 = \frac{1}{2}\frac{\partial^2 u(0,0)}{\partial x \partial y}, b_3 = \frac{1}{3!}\frac{\partial^3 u(0,0)}{\partial x^2 \partial y}.$$

We take the points $P_1(h, 0)$, $P_2(h, h)$, and $P_3(0, h)$ to find numerical coefficients μ_0', μ_1', μ_2' and μ_3' such that the representation

$$u_0 = \mu_0' u + \mu_1' u_1 + \mu_2' u_2 + \mu_3' u_3 \tag{8}$$

is satisfied for the harmonic polynomials $\mathrm{Re}\, z^n$, $z = x + iy$, $n = 0, 1, 2, 3$, where $u = u(P)$, $u_k = u(P_k)$, $k = 0, 1, 2, 3$. We then have

$$\mu_0' + \mu_1' + \mu_2' + \mu_3' = 1, \quad \sigma\mu_0' + \mu_1' + \mu_2' = 0, \tag{9}$$
$$\sigma^2\mu_0' + \mu_1' - \mu_3' = 0, \quad \sigma^3\mu_0' + \mu_1' - 2\mu_2' = 0. \tag{10}$$

Solving system (9), (10), we obtain $\mu_0' = 3\lambda_0$, $\mu_1' = -\sigma(2 + \sigma^2)\lambda_0$, $\mu_2' = -\sigma(1 - \sigma^2)\lambda_0$, $\mu_3' = -\sigma(2 - \sigma)(1 - \sigma)\lambda_0$, where $\lambda_0 = 1/(3 - 5\sigma + 3\sigma^2 - \sigma^3)$.

Now, we take the nodal points $P_4(h,-h)$ and $P_5(0,-h)$ respectively symmetric to the points P_2 and P_3 with respect to the x axis. Since Im $z^k = 0$, $k = 1,2,3$ for $y = 0$ and is odd with respect to y, and Re z^k, $k = 0,1,2,3$ is even with respect to y, from (7) and (8) we obtain the expression

$$S^4 u \equiv \sum_{k=0}^{5} \mu_k u_k, \tag{11}$$

which, on the basis of $(6)-(7)$, gives the exact value of the harmonic polynomial $F_3(x,y)$ at the point P, where

$$\mu_0 = 1/\mu_0',\ \mu_1 = -\mu_1'/\mu_0',\ \mu_q = \mu_{q+2} = -\mu_q'/2\mu_0',\ q = 2,3. \tag{12}$$

It is easy to check that

$$\mu_0 > 0,\ \mu_q \geq 0, q \neq 0;\quad \sum_{k=0}^{5} \mu_k = 1. \tag{13}$$

More general construction of the fourth order matchinh operator S^4 see [9].

Let $[0,1]_h = \left\{x = x_i,\ x_i = ih,\ i = 0,1,...,N;\ h = \frac{1}{N}\right\}$, be the set of nodes on the interval $[0,1]$ with the step size h. Let C_h^0 be the set of grid functions f_h on $[0,1]_h$ for which $f_h(0) = f_h(1) = 0$. We define the norm $\|f_h\|_{C_h^0} = \max_{x\in[0,1]_h} |f_h|$. It is obvious that the space C_h^0 is complete equipped with this norm.

Let $\widetilde{v}_h$ be a solution of the following system of equations defined on $\widetilde{R}_h$:

$$\widetilde{v}_h = B\widetilde{v}_h \ \text{ on } R_h, \tag{14}$$

$$\widetilde{v}_h = S^4\widetilde{v}_h \ \text{ on } Y_l^h,\ l = 1,2,...,m, \tag{15}$$

$$\widetilde{v}_h = \tau_h \ \text{ on } \gamma_h^2,\ \ \widetilde{v}_h = 0 \ \text{ on } \gamma_h \setminus \gamma_h^2, \tag{16}$$

where τ_h is the trace of τ on γ_h^2, S^4 be the operator defined by (11), and

$$\begin{aligned} Bu(x,y) = {} & (u(x+h,y) + u(x-h,y) + u(x,y+h) + u(x,y-h))/5 \\ & + (u(x+h,y+h) + u(x+h,y-h) + u(x-h,y+h) + u(x-h,y-h))/20. \end{aligned}$$

On the basis of maximum principle, the problem (14)-(16) has a unique solution.

We define

$$\widetilde{\varphi}_h = \widetilde{\varphi}_h(x) = \sum_{l=1}^{m} \alpha_l \widetilde{v}_h(x,\eta_l) \in C_h^0,\ \ x \in [0,1]_h\,, \tag{17}$$

where $\widetilde{v}_h(x,\eta_l)$ are the solution values of the system $(14)-(16)$ on Y_l^h, $l = 1,2,...,m$.

We consider the following problem on $\widetilde{R}_h$

$$w_h = Aw_h \ \text{ on } R_h, \tag{18}$$

$$w_h = S^4 w_h \ \text{ on } Y_l^h,\ l = 1,2,...,m, \tag{19}$$

$$w_h = 0 \ \text{ on } \gamma_h^m,\ m = 1,2,3,\ \ w_h = f_h \ \text{ on } \gamma_h^4, \tag{20}$$

 ISBN: 978-84-617-8694-7

where $f_h \in C_h^0$, is an arbitrary function. On the basis of (13) and the maximum principle, for any f_h problem $(18)-(20)$ has a unique solution.

We introduce a linear operator $B_l^h : C_h^0 \to C_h^0$, and let for any grid function $f_h = f_h(x) \in C_h^0$

$$B_l^h f_h \equiv w_h(x, \eta_l) \in C_h^0,\ l = 1, 2, ..., m, \tag{21}$$

where w_h is the solution of the problem (18)-(20).

On the basis of properties (13) of the matching operator S^4 and maximum principle, we obtain

$$\begin{aligned}\left\|B_l^h f_h\right\|_{C_h^0} &\le \frac{1}{2}\left\|f_h\right\|_{C_h^0}(\mu_1+\mu_2+\mu_4)(2-(j_l+1)h)\\ &+\frac{1}{2}\left\|f_h\right\|_{C_h^0}(\mu_0+\mu_3+\mu_5)(2-j_l h)\\ &=\frac{1}{2}\left\|f_h\right\|(2-\eta_l),\ l=1,2,...,m,\end{aligned} \tag{22}$$

i.e., the norm of operator B_l^h does not exceed $q_l = 1 - \frac{\eta_l}{2}$, $l = 1, 2, ..., m$.

Let $\widetilde{\psi}_{l,h}$, $l = 1, 2, ..., m$ be the solution of the system of equations

$$\widetilde{\psi}_{l,h} = B_l^h\left(\widetilde{\varphi}_h + \sum_{k=1}^{m}\alpha_k\widetilde{\psi}_{k,h}\right),\ l = 1, 2, ..., m, \tag{23}$$

where $\widetilde{\varphi}_h$ is defined by (17).

We seek the solution of system (23) by the following fixed-point iteration´

$$\widetilde{\psi}_{l,h}^0 = 0,\quad \widetilde{\psi}_{l,h}^n = B_l^h\left(\widetilde{\varphi}_h + \sum_{k=1}^{m}\alpha_k\widetilde{\psi}_{k,h}^{n-1}\right),\ l = 1, 2, ..., m;\ n = 1, 2, ... \tag{24}$$

On the basis of inequality (22) follows that the iteration converges to the unique solution of the equation (23).

We define the function

$$\widetilde{f}_h^n = \widetilde{\varphi}_h + \sum_{l=1}^{m}\alpha_l\widetilde{\psi}_{l,h}^n,\quad \text{on } \gamma_h^4, \tag{25}$$

where $\widetilde{\varphi}_h$ is defined by (17), $\widetilde{\psi}_{l,h}^n$ is the n-th element of the sequence (24)

For the approximate solution of problem (4), (5), we take the solution of the following finite difference problem

$$\widetilde{u}_h^n = A\widetilde{u}_h^n \ \text{ on } R_h,\quad \widetilde{u}_h^n = 0 \ \text{ on } \gamma_h^m,\ m = 1, 3\ \ \widetilde{u}_h = \tau_h \ \text{ on } \gamma_h^2, \tag{26}$$

$$\widetilde{u}_h^n = \widetilde{f}_h^n \ \text{ on } \gamma_h^4, \tag{27}$$

where $\widetilde{f}_h^n$ is defined by (25).

The following Theorem is proved:

 ISBN: 978-84-617-8694-7

Theorem 1 *Let the boundary function $\tau(x)$ in the problem (4), (5) be from the Hölder classes $C^{4,\lambda}(\gamma^2)$ and $\tau^{(2q)}(0) = \tau^{(2q)}(1) = 0$, $q = 0, 1, 2$. The next estimation holds*

$$\max_{(x,y)\in\overline{R}_h} |\widetilde{u}_h^n - u_h| \le ch^4 + c_1 \frac{q^{n+1}}{1-q}, \ n \ge 2, \tag{28}$$

where $\widetilde{u}_h^n$ is a solution of the problem (26), (27), u_h is the trace of the exact solution of the nonlocal problem (4), (5), c and c_1 are constants independent of n and h,
$q = \max\left\{1 - \frac{\eta_1}{2}, \left(1 - \frac{\eta_1}{2}\right)\sum_{k=1}^{m} |\alpha_k|\right\} < 1.$

4 Numerical results

Let

$$R = \{(x, y) : 0 < x < 1, 0 < y < 2\}.$$

Problem 1:

$$\begin{aligned} \Delta u = 0 \ \text{ on } R, \ u(0, y) = u(1, y) = 0, \ 0 \le y \le 2, \\ u(x, 2) = 100e^{-\pi} \sin \pi x, \ 0 \le x \le 1, \\ u(x, 0) = \frac{1}{2}u\left(x, \frac{3}{5}\right) + \frac{1}{4}u\left(x, \frac{6}{5}\right) + \frac{1}{4}u\left(x, \frac{9}{5}\right), \ 0 \le x \le 1. \end{aligned}$$

Problem 2:

$$\begin{aligned} \Delta u = 0 \ \text{ on } R, \ u(0, y) = u(1, y) = 0, \ 0 \le y \le 2, \\ u(x, 2) = 100e^{-\pi} \sin \pi x, \ 0 \le x \le 1, \\ u(x, 0) = \frac{1}{4}u\left(x, \frac{3}{2}\right) + \frac{1}{4}u\left(x, \frac{9}{5}\right), \ 0 \le x \le 1. \end{aligned}$$

The exact solutions of this problems are unknown. The approximate solutions obtained by the proposed method are demonstrated on line $y = 0$ (Table 1 and Table 2). According to the repeated digits, for the decreasing mesh steps $h = \frac{1}{16}, \frac{1}{32}, \frac{1}{64}, \frac{1}{128}$ it follows that the maximum error on these line decreases as $O(h^4)$. To achieve this accuracy just 11 iterations in (25) are needed. These problems were solved in [7] with the $O(h^2)$ order of accuracy.

Abstract

Numerical simulations of the flow control using a synthetic jet are presented. The flow considered is around a NACA 0012 airfoil at $Re = 5000$ and the actuator is located at 6% of the chord from the leading edge. This work will be focused on the study of the effect of the frequency of the actuator on the flow parameters in order to find in which range of frequencies the actuation is more efficient.

Key words: flow control, synthetic jets, numerical simulations

1 Introduction

The field of active flow control (AFC) has experimented a dramatic growth in the recent years, specially in the aeronautic field (despite being a multidisciplinary field). AFC consists on techniques in which energy is actively expended to modify the flow around a specific surface. Periodic excitation introduced at the surface has shown as an efficient and practical means of flow control [1]. It has, among other advantages, the potential to significantly change the lift and drag of an airfoil and the separation of the boundary layer [2].

Regarding periodic actuation, it has been reported two different ranges of frequency in which actuation has been considered optimal i.e. at $F^+O(1)$ and at $F^+O(10)$, where $F^+ = f_{act}L/U_{ref}$ is defined in terms of the position of the actuator from the trailing edge

ISBN: 978-84-617-8694-7

L [3]. Another parameter that should also be considered when it comes to synthetic jets actuators (SJA) is the location and number of jets. This work is a preliminary study regarding the influence of the frequency of the actuation on the flow past a NACA 0012. Most of the studies conducted so far have been performed on thick airfoils with a trailing edge stall and at relatively large Reynolds numbers $Re > 1e5$ (see for instance [3, 4, 5] and citations therein). However, in spite of the studies done so far, there is no consensus on whether the optimum frequency should be on the order of the vortex shedding frequency or an order of magnitude larger, nor if these frequencies have the same effects on thinner airfoils at lower Reynolds numbers (typical of UAVs) where a combination of leading-edge/trailing-edge stall might occur [6]. In order to analyse the influence of the frequency of the actuator, several numerical simulations of a NACA 0012 at $Re = 5000$ and $AoA = 6°$ and $10°$ are performed.

2 Mathematical and numerical model

The incompressible Navier-Stokes equations can be written as

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial u_i}{\partial t} + \frac{\partial u_i u_j}{\partial x_j} = -\rho^{-1}\frac{\partial p}{\partial x_i} + \nu\frac{\partial^2 u_i}{\partial x_j \partial x_j} \tag{2}$$

where x_i are the spatial coordinates (or x, y, and z) in the stream-wise, cross-stream and span-wise directions. u_i (or u, v, and w) stand for the velocity components and p is the pressure. ν is the kinematic viscosity and ρ the density of the fluid.

The discretisation of the governing equations has been performed using a low dissipation finite element (FE) scheme, which is based on the same principles followed by Verstappen and Veldman [7], generalised for unstructured finite volumes by Jofre et al. [8] and Trias et al. [9] and extended to finite element (FE) schemes by Lehmkuhl et al. [10]. The basic idea behind this approach remains the same: to mimic the fundamental symmetry properties of the underlying differential operators, i.e., the convective operator is approximated by a skew-symmetric matrix and the diffusive operator by a symmetric, positive-definite matrix. The final set of equations is time integrated using an explicit third order conservative Runge-Kutta method. The pressure stabilisation is achieved by means of a non-incremental fractional step. The chosen low dissipation FE scheme presents good accuracy compared to other low dissipation finite volume and finite difference methods with the advantage of being able to increase the order of accuracy at will without breaking the fundamental symmetry properties of the discrete operators. This methodology is implemented into Alya code, which is a multi-physics parallel code organized in a modular way: kernel, services and modules, which can be separately compiled and linked. Each module represents a single

 ISBN: 978-84-617-8694-7

set of Partial Differential Equations (PDE) for a given physical model. To solve a coupled multi-physics problem, all the required modules must be active and interacting following a well-defined workflow. For more details, the reader is referred to [11].

2.1 Definition of the cases and boundary conditions

All computed flows around a NACA 0012 airfoil extended to include a sharp trailing edge are at Reynolds number $Re = U_{ref}C/\nu = 5000$. The Reynolds number is defined in terms of the free-stream velocity U_{ref} and the airfoil chord C. Two different angles of attack, $AoA = 6^\circ$ and 10° have been considered. As separation at $AoA = 10^\circ$ occurs close to the leading edge of the airfoil, a synthetic jet actuator has been placed at a distance from the leading edge of $x/C = 0.057$. The width of the actuator is $h/C = 0.00748$, similar to that used in the experimental work of Gilarranz [1]. The actuator results in a periodic injection and suction of mass flow with a constant frequency. The velocity at the neck of the actuator is given by,

$$(u, v) = (cos(AoA), -sin(AoA))A_p \sin(2\pi f_{act} t)U_{ref} \tag{3}$$

Considering that there is no consensus regarding the most effective frequency of the sinusoidal oscillation f_{act}, in this work different frequencies are varied from $F^+ = f_{act}U_{ref}/C = 0.85$ to 10 [3]. A_p is the amplitude of the oscillation and is characterised by the momentum coefficient C_μ,

$$C_\mu = \frac{h(\rho U_{max}^2)sin\theta_j}{C(\rho U_{ref}^2)} \tag{4}$$

being θ_j the jet angle with respect to the airfoil surface. In this work it has been set to $\theta_j = 30^\circ$ as in [1].

Due to the large computational resources that might be required to perform a thorough study on three-dimensional meshes, in this work and as a first step in order to analyse the influence of the frequency on the performance of the actuator, two-dimensional simulations are here considered. It is of course known that a final study with a three-dimensional domain will be necessary, but in order to find the range and order of magnitude of the most effective frequencies, it is expected that the results will be acceptable without loss of generality. Thus, the domain to be computed has dimensions of $25C \times 30C$ with the airfoil leading edge placed at $(0, 0)$, see figure 1. In all cases, the meshes used are unstructured and have been constructed clustering the points around the airfoil surface and in the near wake behind the airfoil. In the regions far from the airfoil and the wake, the flow complexity diminishes as the distance increases and so does the computational mesh. Moreover, at the outlet of the actuator, the mesh has been refined so as to carefully capture the actuation of the jet on the boundary layer.

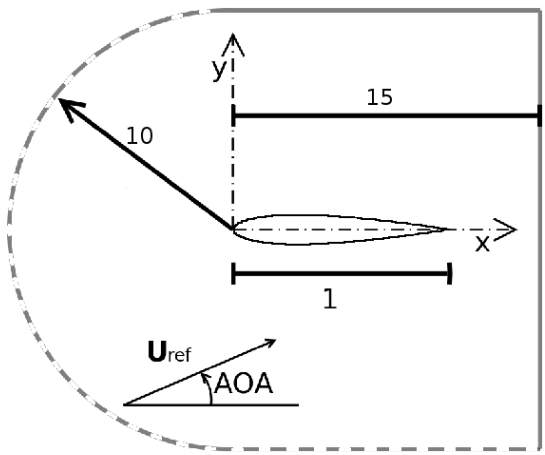

Figure 1: Computational domain (not to scale)

3 Preliminary results

Preliminary results are obtained for $AoA = 10°$ and actuation frequency $F^+ = 1$. In figure 2 the streamlines for both the baseline flow and the actuated one are plotted. As can be seen from the figure, at this AoA a large recirculation bubble can be observed (figure 2a) and the flow reattaches to the airfoil surface close to the trailing edge. For the actuated case, separation occurs at a position downstream of the baseline case and even though a large recirculation bubble is formed, the height of this bubble is smaller than for the baseline case. Indeed, if the streamwise velocity profiles at different streamwise locations are inspected (see figure 3) it can be seen that the size of the separated boundary layer is smaller for the actuated case than for the baseline flow. However, in the case of the baseline case, reattachment occurs earlier than for the actuated case.

At the time this work is being written, several actuation frequencies are being simulated. It is expected to present in the conference a complete set of results with the optimal range of frequencies for which the efficiency of the airfoil is higher.

Abstract

We consider the Richards equation for the fluid flow in variably saturated porous media, which is a crucial problem in several application fields like water resource management, assessment of water-related disaster and agriculture. So, efficient methods for the numerical solution of the Richards equation can provide great benefits for society. We define four numerical procedures for the solution of such an equation. The computational performances of these procedures are tested and compared in two experiments: a water infiltration problem for three types of soil, a landslide hazard evaluation on a geographical area.

Key words: soil moisture, Richards equation, hydrological modelling, landslide hazard.

MSC 2000: 76S05

1 Introduction

The prediction of fluid movement in porous media is an important problem in many branches of sciences and engineering [6]. The most important application field is probably the soil moisture dynamics, which is a fundamental component of the hydrological cycle. In fact, it is a relevant phenomenon in several natural man-induced processes, such as the soil pollution, which consists of altering the chemical and geological balance caused by the transmission and transport of pollutants into groundwater, compromising quality of freshwater [1]. The soil moisture dynamics can give also important inputs to the efficient use of water resources for agriculture and silviculture activities, avoiding unnecessary irrigations and providing

information for the optimal management operations [2]. It is also strictly connected to the water-related risk analysis: heavy rains combined with the particular conditions characterizing a region, can cause natural disasters such as landslides or floods. An efficient landslide warning system should combine the dynamics of soil moisture, with a model for a quantitative evaluation of the slope stability [3].
The dynamics of the soil moisture can be formally described by the Darcy's law and mass continuity law, in fact the combination of these two principles gives the Richards equation [4], that is a non linear partial differential equation, defining the water flow both in the saturated and unsaturated porous media.
Richards equation cannot be solved analytically under realistic situations, such as three-dimensional heterogeneous media, therefore a numerical solution of this equation has to be computed by discretization methods. The most usual numerical approaches, i.e. the finite difference method [11] and the finite element method [12], can also be applied to Richards equation producing in this way non-linear systems of algebraic equations. However, these general approaches are usually coupled with special linearization techniques to deal with the strong non-linearity of the soil hydraulic functions. In particular, the main objective of these techniques is the achievement of the accurate numerical solutions of the Richards equation, also providing a good approximation of the mass-conservation property [5].
In this paper, four numerical procedures are considered for the solution of Richards equation: such procedures differ for the discretization scheme and/or for the linearization approach as well as for the solution of the linearized equations. These procedures are tested in two numerical experiments concerning the water infiltration on three homogeneous types of soil, and the landslide hazard evaluation on a geographical area having a heterogeneous soil.

The remaining part of the paper is organized as follows. Section 2 defines the Richards equation. In Section 3, we describe two numerical methods for the discretization of the space domain, i.e. the finite difference method and the finite element method, then we define four different implementation procedures. Section 4 provides the first numerical experiment comparing the performance of the procedures on a water infiltration problem in a three types of soil. In Section 5, an application of the Richards equation relative to the landslide hazard problem is studied and the corresponding results are provided for a test area in the Italian territory. In section 6 we give some conclusions and future development of this work.

2 The dynamics of soil humidity

The water movement into the soil can be formally described by Darcy's law and mass continuity law; in fact, these two principles can be combined to obtain the so called Richards

equation [4], that is

$$\Big(C(\psi) + S_s \frac{\theta(\psi)}{n_\epsilon}\Big)\frac{\partial h}{\partial t} = div(K\nabla h) + W - ET, \tag{1}$$

where $div(\cdot) = \frac{\partial(\cdot)}{\partial x}\hat{i} + \frac{\partial(\cdot)}{\partial y}\hat{j} + \frac{\partial(\cdot)}{\partial z}\hat{k}$, $\nabla h = \Big(\frac{\partial h}{\partial x}, \frac{\partial h}{\partial y}, \frac{\partial h}{\partial z}\Big)$, $C(\psi) = \frac{d\theta}{d\psi}$ is the specific capillary capacity, ψ is the pressure head, S_s is the storage coefficient, $\theta(\psi)$ is the water content, n_ϵ is the porosity, $h = \psi + z$ is the hydraulic head, $K(\psi)$ is the hydraulic conductivity, W is the recharge and it is related to the rate of precipitation, ET is the evapotranspiration rate (usually estimated by $Penman - Montieth\ equation$ [9]).
It is worth noticing that equation (1) defines the water flow both in the saturated and in the unsaturated porous media.
The Van Genuchten model is probably the most used formulation of functions $\theta(\psi)$ and $K(\psi)$, see [10] for a detailed definition of these relations. We note that this model depends on various hydraulic parameters, e.g., α that is the inverse of the value of ψ at the air entry point, the residual water content θ_r, the saturated water content θ_s, n that is an empirical parameter, K_s that is the value of the hydraulic conductivity when the soil is saturated. These parameters are all related to the pore size distribution and geometry and so they ultimately depend on the soil type.
The solution of equation (1) requires knowledge of the initial distribution of the hydraulic head h inside the space domain Ω. Moreover, it requires knowledge of appropriate boundary conditions to describe the interactions along the domain boundary $\partial\Omega$: specified hydraulic head (Dirichlet type) and specified flux (Neumann type) are the most commonly used for Richards equation [6].

3 The discretization schemes and their implementation

We describe two numerical methods for the discretization of the Richards equation in the space domain: the finite difference method and the finite element method. Both methods yield to a first order non-linear initial-value problem in the time variable whose solution can be found by applying an iterative procedure. Moreover, linearization strategy is taken into account to deal with such a non linear problem. On the base of these numerical approximations, we define four different procedures for the solution of the problem.

3.1 The Finite difference approximation

The finite difference scheme is obtained from the equation (1) by using central difference quotients for the space derivatives:

$$\Big(C(\psi_{i,j,k}) + S_s \frac{\theta(\psi_{i,j,k})}{n_\epsilon}\Big)\frac{\partial h}{\partial t}(x_i, y_j, z_k) =$$

 ISBN: 978-84-617-8694-7

$$= \frac{1}{(\Delta x)^2}\Big[K(\psi_{i+1/2,j,k})(h_{i+1,j,k} - h_{i,j,k}) - K(\psi_{i-1/2,j,k})(h_{i,j,k} - h_{i-1,j,k})\Big] +$$

$$+\frac{1}{(\Delta y)^2}\Big[K(\psi_{i,j+1/2,k})(h_{i,j+1,k} - h_{i,j,k}) - K(\psi_{i,j-1/2,k})(h_{i,j,k} - h_{i,j-1,k})\Big] +$$

$$+\frac{1}{(\Delta z)^2}\Big[K(\psi_{i,j,k+1/2})(h_{i,j,k+1} - h_{i,j,k}) - K(\psi_{i,j,k-1/2})(h_{i,j,k} - h_{i,j,k-1})\Big] + W_{i,j,k} - ET_{i,j,k}, \quad (2)$$

where Δx, Δy, Δz are the discretization steps in the x, y and z direction, respectively, $h_{i,j,k}$ and $\psi_{i,j,k}$ denote the approximate value of h and ψ at in the generic grid point (x_i, y_j, z_k); for brevity, in equation (2) the time-dependence of these functions is not explicitly denoted.

3.2 Finite element approximation

In the following we suppose $\partial\Omega = \partial\Omega^D \cup \partial\Omega^N$, where we impose a Dirichlet boundary condition in $\partial\Omega^D$ and a Neumann boundary condition in $\partial\Omega^N$. We consider the Galerkin method [12], that is based on the weak formulation of the Richards equation (1):

$$\int_\Omega w\Big(C(\psi) + S_s\frac{\theta(\psi)}{n_\epsilon}\Big)\frac{\partial h}{\partial t}\; d\underline{x} + \int_\Omega \nabla w \cdot [K(\psi)\cdot\nabla h]\; d\underline{x}$$

$$-\int_\Omega w(W - ET)\; d\underline{x} + \int_{\partial\Omega^N} wq_h\; ds(\underline{x}) = 0; \quad \forall w \in {H^1}_0(\Omega) \quad (3)$$

where $q_h = [K(\psi)\cdot\nabla h]\cdot n$, and $H_0^1(\Omega)$ is the space of square integrable functions w having square integrable derivative defined almost everywhere, an such that $w(x) = 0$, $x \in \partial\Omega^D$. Solution h is approximated by a function $\tilde{h}(x,t) \approx \sum_{j=1}^{N_p} N_j(x)h_j(t)$ where N_j, $j = 1, 2, \ldots, N_p$ are basis functions and $h_j(t)$ are unknown coefficients to be determined; for semplicity we suppose that an homogeneous Dirichilet boundary condition is prescribed on $\partial\Omega^D$. In particular, this basis is usually defined by piece-wise polynomial functions N_i having a small support Ω_i with respect to the domain. The Galerkin method considers the weighting function w equal to the representation functions, i.e. N_i, so formula (3) becomes

$$\sum_e \int_{\Omega_e} N_i\Big(C(\psi^e) + S_s^e\frac{\theta(\psi^e)}{n_\epsilon^e}\Big)\frac{\partial}{\partial t}\Big(\sum_j N_j h_j\Big)\; d\underline{x} + \sum_e \int_{\Omega_e} \nabla N_i \cdot [K(\psi^e)\cdot\nabla(\sum_j N_j h_j)]\; d\underline{x}$$

$$-\sum_e \int_{\Omega_e} N_i(W^e - ET^e)d\underline{x} + \sum_e \int_{\partial\Omega_e{}^N} N_i {q_h}^e ds(d\underline{x}) = 0$$

$$1 \le i \le N_p. \quad (4)$$

 ISBN: 978-84-617-8694-7

3.3 Time discretization

Both equation (2) and equation (4) represent a first-order initial-value problem in the time variable. This problem is numerically solved by an iterative process. Let $\Delta t > 0$ be a time step which defines a partion of the time domain $[0, T_0]$ such that $t_n = n\Delta t$, $n = 0, \dots N$. On the base of this discretization, both (2) and (4) can be formally rewritten as

$$\frac{\partial \underline{h}^n}{\partial t} = F(\underline{h}^n, t_n), \tag{5}$$

where $\underline{h}^n$ is the vector of the unknowns at time $t = t_n$, $F(\underline{h}^n, t_n)$ is a non linear vectorial function. We replace the time derivative by the finite difference approximation

$$\frac{\partial \underline{h}^n}{\partial t} = \frac{\underline{h}^{n+1} - \underline{h}^n}{\Delta t}. \tag{6}$$

So, in order to define the iterative process for the numerical solution of (5), we take into account the single step methods which are expressed in their generalized form as

$$\underline{h}^{n+1} = \underline{h}^n + \Delta t[(1-\lambda)F(\underline{h}^n, t_n) + \lambda F(\underline{h}^{n+1}, t_{n+1})], \tag{7}$$

where λ is a time-weighting factor, $0 \leq \lambda \leq 1$.
In particular, the case $\lambda = 0$ is called explicit Euler method, the case $\lambda = \frac{1}{2}$ is called Crank Nicolson method while the case $\lambda = 1$ is called implicit Euler method.

3.4 Linearization tecniques

At each time t_n, the numerical solution of nonlinear system (7) requires an iterative procedure, where, roughly speaking, several local linearized models are subsequently solved. We consider the following iterative procedure: we define $\underline{h}^{n+1,r}$ as the vector solution at time level $n+1$ at the r-th refinement iterate and for $r = 1, \cdots R$ we compute

$$\underline{h}^{n+1,r} = \underline{h}^n + \Delta t[(1-\lambda)F(\underline{h}^n, t_n) + \lambda F(\underline{h}^{n+1,r-1}, t_{n+1})], \tag{8}$$

where R is the first iterate that, given an appropriate tolerance *toll*, satisfies

$$\left|\left|\underline{h}^{n+1,r} - \underline{h}^{n+1,r-1}\right|\right|_\infty < toll. \tag{9}$$

At the end of the cycle we define

$$h^{n+1} = h^{n+1,R}. \tag{10}$$

Other linearization methods used to solve (7) are *Picard linearization scheme* and *Newton scheme* [7].

 ISBN: 978-84-617-8694-7

3.5 The procedures

We consider four numerical procedures for the solution of Richards equation. These procedures are obtained by combining the previously described approximation approaches in order to compare their efficiency.

Procedure 1 *The finite difference method is used for space discretization; the solution of the system (7) is carried out by Crank-Nicolson method togheter with the linearization scheme (8) and the solution at the iterate* $r = 1$ *is given by the explicit Euler method.*

Procedure 2 *The finite difference method is used for space discretization; the solution of the system (7) is carried out by implicit Euler method togheter with the Picard linearization scheme and the solution of the linearized system is obtainded by means of a direct method based on a sparse variant of Gaussian elimination, that is called multifrontal method [13].*

Procedure 3 *The finite difference method is used for space discretization; the solution of the system (7) is carried out by implicit Euler method togheter with the Picard linearization scheme and the solution of the linearized system is obtainded by means of the preconditioned conjugate gradient method.*

Procedure 4 *The finite element method is used for space discretization; the solution of the system (7) is carried out by implicit Euler method togheter with the Picard linearization scheme and the solution of the linearized system is obtainded by means of the preconditioned conjugate gradient method.*

4 Numerical experiments

We tested the four numerical procedures presented in the previous section with three examples. All these examples consider the same spatial domain $\Omega_1 = [0, L_x] \times [0, L_y] \times [0, L_z]$, where $L_x = 90$ m, $L_y = 50$ m and $L_z = 4$ m and the same time period of 30 days, but with three different soil types. Table 1 shows the values of α, θ_r, θ_s, n, K_s of these considered soil types in the Van Genucthen model (see [8] for details). In particular, the first example considers a clay soil, at time $t = 0$ the simulation starts from a saturation equal to 50% and the time period is characterized by a precipitation rate of 100 mm/day. The second and third examples consider sand and coarse sand soils, respectively, at time $t = 0$ the saturation is equal to 30% and the precipitation rate considered is 50 mm/day. At the boundary of Ω_1 we impose the zero normal flow condition as we supposed that these boundaries do not interact with the outside. Procedure 1 is implemented inside a program written in Fortran language, while, in order to implement the multifrontal method in Procedure 2, we used the package MA57 [14], taken from the HSL software library. Procedure 3 is implemented inside the computer model MODFLOW-2005 [11] which numerically solves the three-dimensional

 ISBN: 978-84-617-8694-7

ground-water flow equation by using a finite-difference method. Procedure 4 is implemented inside the demo version of FEFLOW software [12], that is an advanced Finite-Element subsurface flow and transport modeling system.

Grainsize	Description	θ_r	θ_s	$\alpha[1/m]$	n	$K_s[m/s]$
Clay	Cl> 75%	0.11	0.48	1.33	1.31	1.00E-08
Sand	Sa> 75%	0.05	0.39	3.36	2.11	5.83E-05
Coarse Sand	CSa> 75%	0.02	0.36	15.85	2.91	1.00E-03

Table 1: Different types of grain sizes and the corresponding parameters θ_r, θ_s, α, n, K_{sat} in Van Genucthen model.

Table 2 shows a comparison between the results obtained by the four numerical procedures on the basis of the time step Δt, the elapsed CPU time of the computation and the $RE(i,j)$, i.e. the relative error in the 2-norm between the solution computed by the procedure i and the one computed by procedure j at the end of the simulation period. We observe that, despite its simple structure, Procedure 1 performs quite well with the exception of the coarse sand type where, in order to achieve the convergence of the method, we had to decrease the time step by a factor 100, compromising the efficiency of the procedure. Figure 1 shows the saturation in the domain Ω_1 at the end of the simulation period relative to the clay case: from this figure, we observe a similar behaviour in the solutions computed by the four procedures.
We tested our simulations using Window PCs with 128 GB of RAM and 8 Core of CPU.

5 A landslide hazard application

We consider the application of the dynamics of the soil moisture for a quantitative evaluation of landslide hazard.
The landslide hazard problem is usually formulated in terms of the $Safety\ Factor$, which is given by the ratio between the forces that prevent the slope from failing and those that bring the slope to collapse; in particular, *the last forces depend on the soil saturation, given by the solution of Richards equation* (1). Therefore, the safety factor is a hazard index: a value larger than 1 indicates stable conditions, a value smaller than 1 indicates unstable conditions.
The $Infinite\ Slope\ Model$ [15] is probably the easiest evaluation method for the safety factor F, that is given by

$$F = \frac{C + (z\gamma - z_w\gamma_w)\cos^2\beta\tan\phi}{z\gamma\sin\beta\cos\beta}, \tag{11}$$

Table 2: Comparison between the solution computed by the four different procedures relative to the three soil types described in Table 1.

where C is the effective cohesion; γ is the unit weight of the soil; γ_w is the unit weight of water; z is the depth of the failure surface; z_w is the height of the watertable above failure surface; β is the slope of the inclined surface; ϕ is the angle of internal friction.
The Infinite Slope Model has been used to analyse a geographical area of 11,69 km^2 located in the hydrographic basin of the Esino River in the province of Ancona (Italy), where a landslide occurred on March 2015. This area is representative due to its landslide susceptibility, moreover several meteorological stations are located in it. Previous geological and geotechnical studies provided the geomorphological information: in particular, we know that the soil is mostly characterized by clay and sand.
The proposed experiment considers the test area during the three months before the landslide event: Figure 2 shows the millimeters of rain fell every days during the observation period (12/6/2014 to 3/6/2015). The four procedures described in section 3, are combined with the infinite slope model (11): in particular, the solution of Richards equation (1) is used in order to obtained information about z_w in formula (11).
Figure 2 shows the trend of the minimum value of F computed during the observation period: this diagram shows that during the three months before the landslide initiation, the safety factor values gradually decreased, passing from values larger than 1 (indicating stable region) to values smaller than 1 (indicating unstable region).
Figure 3 shows a graphical representation of the safety factor values concerning the last day of the simulation: a nearly black zone is an unstable region ($F < 1$); a nearly white zone

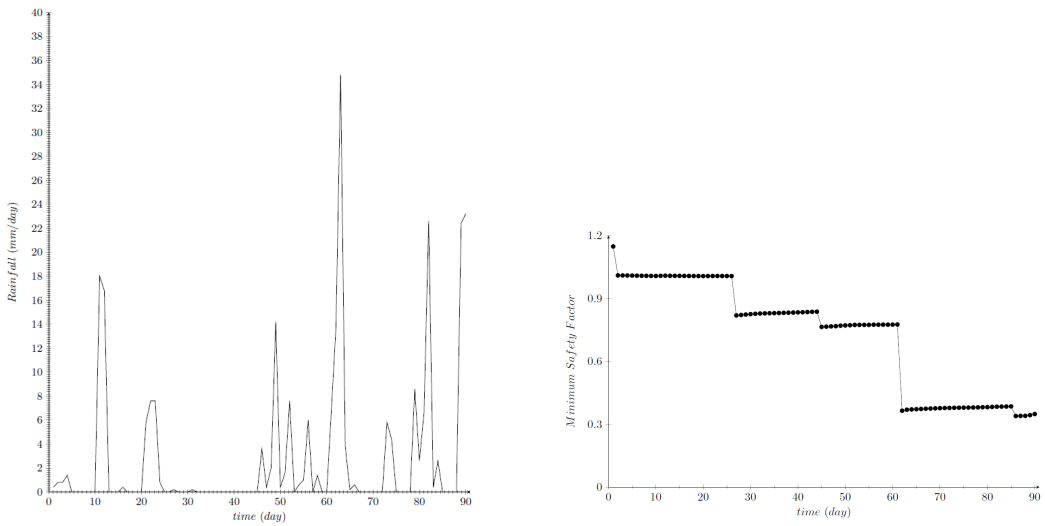
Figure 1: The saturation in Ω_1 at the time $t = 30$ dayes related to clay.

is a stable region ($F > 1$). The four images in this figure are relative to the four numerical procedures for the soil moisture dynamics. So these results show that the four procedures give the same solution for the computation of the safety factor.

6 Conclusions

The water movement in the unsaturated porous media is described by Richards equation that is a non-linear partial differential equation. Four numerical procedures are considered for the solution of this equation: such procedures differ for the discretization scheme and/or for the linearization approach as well as for the solution of the linearized equations.
We tested and compared the four procedures in two numerical experiments: the soil moisture dynamics in three soil types (clay, sand, coarse sand) and the landslide hazard evaluation on a geographical area with mixed soil (clay, sand). Results show that, Procedure 1 performs quite well, even if it breaks down when we consider the coarse sand type with a discretization time of 15 minutes, however the convergence can be achieved if we decrease the time step. In the other cases, Procedure 1 seems to provide acceptable results in a very efficient way.
This preliminary study should be extended by comparing the four procedures on the basis of a larger range of soil types. This would allow a more detailed evaluation of the efficiency of Procedure 1 and the possible remedies to overcome its inefficiencies. The results of such



(a) (b)

Figure 2: (a) the millimeters of rain fell every dayes during the three months before the landslide event; (b) trend of the minimum safety factor during the observation period.

an analysis will be useful in several application fields like natural hazard evaluation, water resource analysis and weather forecast.
Another further difficulty in Richards equation is the efficient acquisition of model parameters. Actually, this is a quite common situation to all mathematical models for complex phenomena; however, in this particular case, it is a very crucial issue since it depends on the weather data and on the geotechnical features of the soil. Weather is usually acquired by proper stations on the territory or by satellite measurements. Soil features are mainly characterized by the granulometry, which can be used to identify the textural class of the soil studied among a number of possible classes and it can be obtained by direct measurements and/or general geomorphological features of the territory. So, both sets of these data are difficult to get with high spatial resolution and accuracy. Unfortunately the lack of information can limit the successfull application of Richards equation to real-world problems, so a precise sensitivity analysis for such a model should be provided in order to obtain reliable results.

Abstract

Present research concerns the physical background of a wild-fire propagation model based on the split of the front motion into two parts - drifting and fluctuating. The drifting part is solved by the level set method and the fluctuating part describes turbulence and fire-spotting. These phenomena have a random nature and can be modeled as a stochastic process with the appropriate probability density function. Thus, wildland fire propagation results to be described by a nonlinear partial differential equation (PDE) of the reaction-diffusion type. A numerical study of the effects of the atmospheric stability on wildfire propagation is performed through its effects on fire-spotting. Moreover, it is shown that the solution of the PDE as an indicator function allows to construct the energy balance equation in terms of the temperature.

Key words: fire propagation, fire-spotting, level set method, energy balance
MSC 2000: 00A59, 35K57, 65C20, 70H20

1 Introduction

In wildland fire propagation, fire-spotting phenomena cause isolated fire from the main fire. It is an important aspect because it affects the rate of spread of the fire and may cause

dangerous effects. The present study deals with fire propagation modelling and its physical background.

In the proposed model, the front motion is splitted into two parts - drifting and fluctuating. Each of them can be solved by using an appropriate method. In the present study, the Eulerian Level Set Method (LSM) is chosen for the drifting part while the fluctuating part is the result of a comprehensive statistical description of the physics of the system and takes into account the randomness of the hot air turbulent transport and fire-spotting. Thus, in order to treat the fluctuating part, specific probability density function has to be taken into account [1].

Fire-spotting is a complicated physical process due to many factors, such as wind, fire intensity, fuel characteristics, atmospheric conditions, etc. The statistical formulation of fire-spotting has been proposed in [1] and completed by the physical parametrisation in [2]. This formulation does not depend on the method used for fire propagation. In the present study we extend this approach and include into account the change of wind direction and possibility of the several secondary fires appearance.

The main aim of the present study is to explain the physical background of the proposed model. The solution of the underlying PDE is connected to a temperature field. The transfer of the temperature due to the turbulent flows is then described by the energy balance equation. The rest of the paper is organized as follows. The wildland fire propagation model is proposed in the next section, including a brief description of the level-set method and physical parametrisation of the fire-spotting. Section 3 deals with the energy balance equation for the proposed model. Numerical examples for several test cases, such as different wind conditions, and merging of the secondary fires, are provided in Section 4.

2 Fire propagation model

2.1 Level-set method

LSM is widely used as effective method for the front-tracking. For some computational domain S the fire front contour is represented by a closed curve Γ. The region bounded by Γ is denoted by Ω and represents the burnt area. Let us introduce an indicator function $\phi(\mathbf{x}, t)$:

$$\phi(\mathbf{x}, t) = \begin{cases} 1, & \mathbf{x} \in \Omega(t), \\ 0, & \text{othervise.} \end{cases} \tag{1}$$

Let $\gamma : S \times [0, \infty) \to \mathbb{R}$ be a level-set function, such that for some fixed γ^* at the moment t the fire front can be described by $\Gamma(t) = \{\mathbf{x} \in S | \gamma(\mathbf{x}, t) = \gamma^*\}$. If $\gamma(\mathbf{x}, t) > \gamma^*$, then the ignition is observed at the point $\mathbf{x}$. The level-set function $\gamma(\mathbf{x}, t)$ evolves according to the following ordinary level-set equation

 ISBN: 978-84-617-8694-7

$$\frac{\partial \gamma}{\partial t} = V(\mathbf{x}, t)||\nabla \gamma||, \tag{2}$$

where $V(\mathbf{x}, t)$ is a rate of spread (ROS) of the fire front. The ROS value depends on many elements, such as the intensity and direction of the wind, fuel conditions, etc.

2.2 Turbulence and fire-spotting modelling

Together with other factors, turbulence and fire-spotting cause the random motion of the fire-front. Thus, the random front contour can be defined by the effective indicator function [1]:

$$\phi_e(\mathbf{x}, t) = \int_{\Omega(t)} f(\mathbf{x}; t|\bar{\mathbf{x}}) d\bar{\mathbf{x}}, \tag{3}$$

where $f(\mathbf{x}; t|\bar{\mathbf{x}})$ is the probability density function (PDF) that accounts for turbulence and fire-spotting effects. Note that the point is labelled as burnt, if $\phi_e(\mathbf{x}, t)$ exceeds some threshold value ϕ_e^{th}.

In accordance with the Reynold transport theorem, the evolution of the effective indicator function $\phi_e(\mathbf{x}, t)$ takes the form

$$\frac{\partial \phi_e}{\partial t} = \int_{\Omega(t)} \frac{\partial f}{\partial t} d\bar{\mathbf{x}} + \int_{\Omega(t)} \nabla_{\bar{\mathbf{x}}} \left[V(\bar{\mathbf{x}}, t) f(\mathbf{x}; t|\bar{\mathbf{x}}) \right] d\bar{\mathbf{x}}. \tag{4}$$

Evolution equation for the PDF $f(\mathbf{x}; t|\bar{\mathbf{x}})$ takes the form

$$\frac{\partial f}{\partial t} = \epsilon f, \tag{5}$$

where $\epsilon = \epsilon(\mathbf{x})$ is a generic evolution operator. Hence, (4) can be rewritten in the following form

$$\frac{\partial \phi_e}{\partial t} = \epsilon \phi_e + \int_{\Omega(t)} \nabla_{\bar{\mathbf{x}}} \left[V(\bar{\mathbf{x}}, t) f(\mathbf{x}; t|\bar{\mathbf{x}}) \right] d\bar{\mathbf{x}}. \tag{6}$$

In (6) the front-line velocity is controlled by the ROS, while random process, such as turbulence and fire-spotting, are modelled by modifying PDF. Thus, if $f(\mathbf{x}; t|\bar{\mathbf{x}}) = \delta(\mathbf{x} - \bar{\mathbf{x}})$, equation (6) reduces to the deterministic case described by (2).

Assuming that the downwind phenomenon of fire-spotting is independent of turbulence, the random process handled by $f(\mathbf{x}; t|\bar{\mathbf{x}})$ in (6) can be defined as follows

$$f(\mathbf{x}; t|\bar{\mathbf{x}}) = \begin{cases} \int_0^\infty G(\mathbf{x} - \bar{\mathbf{x}} - l\hat{\mathbf{n}}; t) q(l) dl, & \text{if downwind,} \\ G(\mathbf{x} - \bar{\mathbf{x}}; t), & \text{otherwise.} \end{cases} \tag{7}$$

 ISBN: 978-84-617-8694-7

The shape of the PDF is defined by the isotropic bi-variate Gaussian function (considering turbulence effects) $G(\mathbf{x}-\bar{\mathbf{x}};t)$ and the firebrand landing distribution $q(l)$ is defined by a lognormal distribution as follows

$$q(l)=\frac{1}{\sqrt{2\pi}\sigma l}\exp\frac{-(\ln l/\mu)^2}{2\sigma^2}, \tag{8}$$

where μ is the ratio between the square of the mean of landing distance l and its standard deviation, σ is the standard deviation of $\ln l/\mu$.

In [3] authors complete the study of the fire-spotting proposed in [1] by describing this phenomenon in terms of the fire intensity, wind velocity and fuel characteristics. It includes only the vital ingredients, each firebrand is assumed to be spherical of the constant size. Then lognormal parameters μ and σ in (8) take the following form

$$\mu=H\left(\frac{3\rho_a C_d}{2\rho_f r g}\right)^{1/2},\quad \sigma=\frac{1}{2z_p}\ln\left(\frac{U^2}{rg}\right), \tag{9}$$

where U is the wind velocity and H is the maximum loftable height, that is according to [4],

$$H=\alpha H_{ABL}+\beta\left(\frac{I}{dP_{f_0}}\right)^{\gamma}\exp\left(-\frac{\delta N_{FT}^2}{N_0^2}\right), \tag{10}$$

where all the parameters are defined in Table 1.

3 Energy balance equation

Wildfire model can be formulated based on balance equations for energy and fuel, as it is proposed in [5,6]. In the present study we follow the level-set formulation with the stochastic process. However, there is a connection between these two formulations. In order to derive the energy balance equation, the physical laws are used, mainly, conservation of energy and fuel reaction. In present study we focus on the solution in the form of indicator function. Thus, it is important to show, that the found solution is connected to the temperature and the energy balance equation can be derived by using the indicator function.

An important part of study deals with the temperature field. Temperature is transferred due to the turbulent flows, and it can be modelled by the diffusion process. The heating-before-burning mechanism, that is accumulation in time of potential fire, can be associated with an amount of heat:

$$\psi(\mathbf{x},t)=\int_0^t \phi_e(\mathbf{x},\eta)\frac{d\eta}{\tau}, \tag{11}$$

where τ is the ignition delay, that can be understood as a resistance to the hot-air heating and firebrand landing in parallel.

 ISBN: 978-84-617-8694-7

Notation	Description	
α	Part of ABL passed freely, $\alpha < 1$	0.24 [4]
β	$[m]$ Contribution of the fire intensity, $\beta > 0$	170 [4]
γ	Power-law dependence on FRP, $\gamma < 0.5$	0.35 [4]
δ	Dependence on stability of the FT, $\delta \geq 0$	0 [4]
H_{abl}	$[m]$ Height of the atmospheric boundary layer (ABL)	1200
d	$[m\ ]$ Unit depth of the combustion zone	1
P_{f_0}	$[MWm^{-2}]$ Ratio of reference fire power	1 [4]
N^2_{FT}	$[s^{-2}]$ Brunt-Väisälä frequency in the FT	$2.789 \cdot 1e-4$
N^2_0	$[s^{-2}]$ Brunt-Väisälä frequency	$2.5 \cdot 1e-4$
H	$[m]$ The maximum loftable height	
ρ_a	$[kg/m^3]$ Density of the ambient air	1.1
ρ_f	$[kg/m^3]$ Density of the wild-land fuels	542
C_d	Drag coefficient	0.45
z_p	p-th percentile	0.45
r	$[m]$ Brand radius	0.015
g	$[ms^{-2}]$ Acceleration due to gravity	9.81

Table 1: Physical parameters of the atmospheric boundary layer and fire-spotting.

The amount of heat is proportional to the increasing of the temperature $T(\mathbf{x}, t)$. For the sake of simplicity, we can assume that

$$\psi(\mathbf{x}, t) = \frac{T(\mathbf{x}, t) - T_a(\mathbf{x})}{T_{ign} - T_a(\mathbf{x})}, \quad T < T_{ign}, \tag{12}$$

where ambient temperature is denoted by T_a, and T_{ign} stands for the ignition temperature. From (12) one can see, that $\psi(\mathbf{x}, t) = 1$ entails that $T(\mathbf{x}, t) = T_{ign}$ and the spacial point $\mathbf{x}$ at the moment t belongs to the burning area.

Temperature $T(\mathbf{x}, t)$ can be found from (12) as follows

$$T(\mathbf{x}, t) = T_a(\mathbf{x}) + \psi(\mathbf{x}, t)\left(T_{ign} - T_a(\mathbf{x})\right), \tag{13}$$

that by the differentiation leads to

$$\frac{\partial T}{\partial t} = \frac{(T_{ign} - T_a(\mathbf{x}))}{\tau}\phi(\mathbf{x}, t). \tag{14}$$

According to the heat-before-burning mechanism, the temperature field is described by the following reaction-diffusion type equation [1]

$$\frac{\partial T}{\partial t} = \epsilon T + \frac{T_{ign} - T_a}{\tau}\left(I_{\Omega_0}(\mathbf{x}) + W(\mathbf{x}, t)\right), \tag{15}$$

 ISBN: 978-84-617-8694-7

where T_{ign} is the ignition temperature, $T_a(\mathbf{x})$ is the ambient temperature, $I_{\Omega_0}(\mathbf{x}) = \phi_e(\mathbf{x}, 0)$ and

$$W(\mathbf{x}, t) = \int_0^t \left(\int_{\Omega(\theta)} \nabla_{\bar{x}} \cdot [\mathbf{V}(\bar{\mathbf{x}}, \theta) f(\mathbf{x}; \theta | \bar{\mathbf{x}})] \, d\bar{\mathbf{x}} \right) d\theta. \tag{16}$$

Equation (15) can be understood as the energy balance equation associated to the model. In (15) $\epsilon = \epsilon(\mathbf{x})$ is a generic evolution operator, associated to the evolution of $f(\mathbf{x}; t|\bar{\mathbf{x}})$, and it models the turbulent heat transfer due to radiation. Moreover, the second term on the RHS corresponds to the convective heat lost to the atmosphere and the third to the rate of fuel consumed by the fire with Rate of Spread $\mathbf{V}(\bar{\mathbf{x}}, t)$ in the outward direction.

4 Numerical results

In this section some numerical examples are considered in order to study effects of the wind and the choice of underlying PDF on the rate of spread. It is natural that if there is no wind, for the homogeneous moisture the fire front would grow slower and in all directions, as it is shown in Figure 1. If there is wind (we consider $U = 6.7ms^{-1}$, the fire intensity $I = 20MW$), then the fire propagates in the downwind direction (see Figure 2).

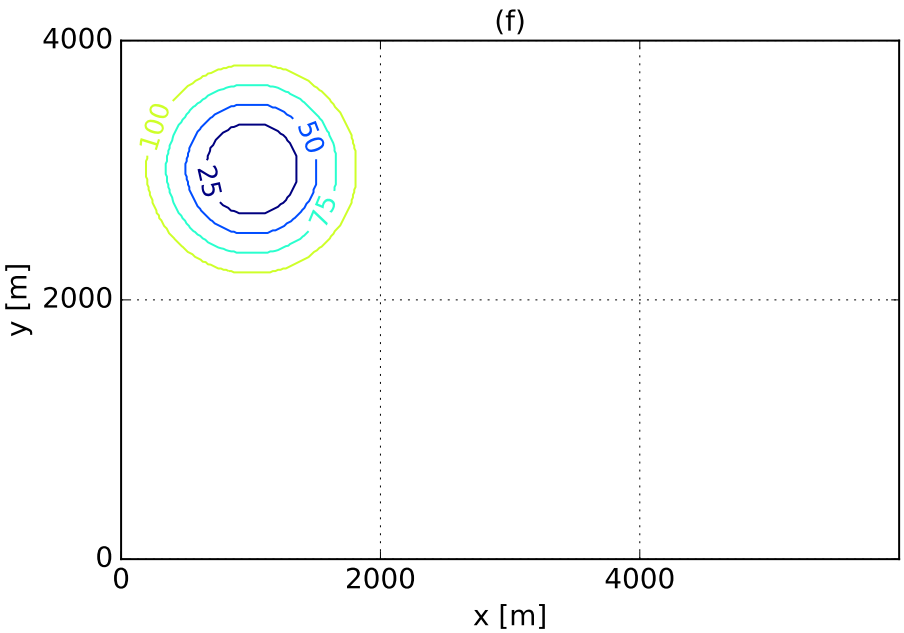

Figure 1: Fire propagation with zero wind.

 ISBN: 978-84-617-8694-7

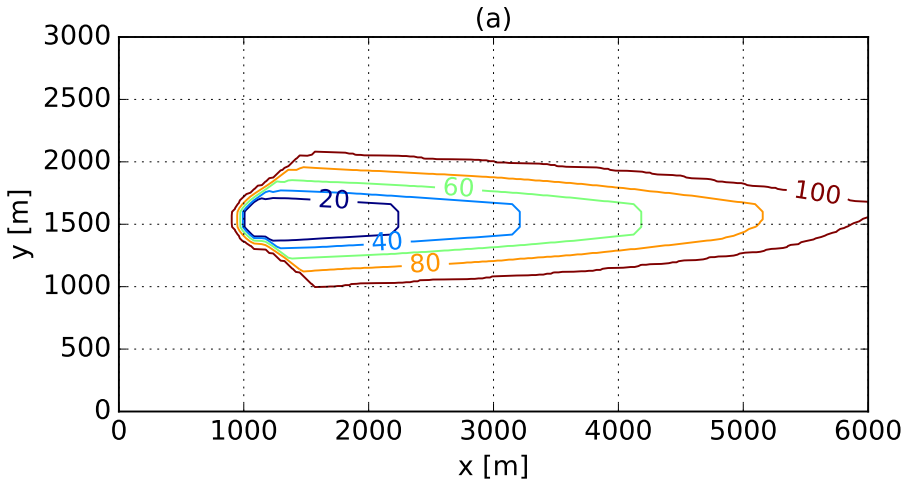

Figure 2: Fire propagation with mean wind $U = 6.7ms^{-1}$.

The model treats the fire-spotting. In order to model this phenomenon the lognormal PDF (8), as it is shown in Figure 3. The point of ignition of the secondary fire also depends on the wind direction. If at some moment $t = t^*$ the wind changes the direction, then new secondary fires appear in new direction, as it is shown in Figure 4. For the sake of simplicity, the initial conditions for new ignitions are chosen the same as for the main fire zone, that causes the same form of the secondary fires.

However, not for any set of the parameters the sire-spotting can be observable. In some cases the fire intensity is not high enough to let the firebrands jump from the main column and produce new independent fire. Moreover, it can occur the situation when the firebrand jumps not that far, so it merges to the main fire changing the curvature of the fire front (see Figure 5).

Improved bisection eigenvalue method for band symmetric Teoplitz matrices

Yuli Eidelman[1] **and Iulian Haimovici**[1]

[1] *Department of Mathematics, Tel-Aviv University*

emails: eideyu@post.tau.ac.il, iulianh@zahav.net.il

Abstract

We specify a new bisection eigenstructure algorithm developed for symmetric quasiseparable of any order matrices to band Toeplitz matrices. It is shown that there is a small perturbation of a band symmetric Toeplitz matrix with the eigendata obtained explicitly and with interlacing property between eigenvalues of the original matrix and of the perturbed one. This allows to improve the performance of the eigenvalue algorithm essentially.

Key words: Toeplitz, quasiseparable, band, eigenstructure, bisection
MSC 2000: 15A18, 15A42, 65N25

Given an $N \times N$ Toeplitz symmetric $2q+1$-band matrix T_q with the only nonzero entries $T_q(i,j) = t_{|i-j|},\ |i-j| \le q,\ i,j = 1,\dots,N$. We perform on the corner of its first entries a small perturbation, such that

$$T_q(i,j) = t_{|i-j|} - t_{i+j}, \quad 2 \le i+j \le q$$

and a centrosymmetric perturbation on the corner of its last entries, no matter how large N is. We prove that if $t_q > 0$, which we can presume without loss of generality, the eigenvalues of the such obtained matrix A_q are

$$\lambda_k^A = t_0 + 2\sum_{j=1}^{q} t_j \cos\left(\frac{jk\pi}{N+1}\right), \quad k = 1,\dots,N, \tag{1}$$

which in the sequel will be sorted in ascending order to almost interlace with the eigenvalues of T_q. More precisely, if the corner matrix $T_q(1:q-1,1:q-1) - A_q(1:q-1,1:q-1)$

 ISBN: 978-84-617-8694-7

is strongly regular and we denote by n the number of its negative eigenvalues and by $p = q - 1 - n$ the number of its positive eigenvalues (including multiplicities), then

$$\lambda^A_{k-2n} \leq \lambda^T_k \leq \lambda^A_{k+2p}, \quad k = 2n+1, \ldots, N-2p.$$

For $q = 2$, if $t_q > 0$, we show that the eigenvalues of A_2 and T_2 almost interlace, more exactly

$$\lambda^A_k \leq \lambda^T_k \leq \lambda^A_{k+2}, \quad k = 1, \ldots, N-2.$$

For 7-band matrices, i.e. $q = 3$, we show that the eigenvalues of A_3 and T_3 satisfy

$$\lambda^A_{k-2} \leq \lambda^T_k \leq \lambda^A_{k+2}, \quad k = 3, \ldots, N-2.$$

As the perturbing matrix is null on $N-2q+2$ rows, i.e. except of two diagonal blocks of size $(q-1)\times(q-1)$, which are a Hankel matrix, we use known results about small symmetric matrix perturbations of a symmetric matrix in order to approximate the eigenvalues of T_q. For instance, we show that if $m_k,\ k = 1, \ldots, N$ are the unwanted differences between the eigenvalues of T_q and A_q, then $\sum_{k=1}^N m_k^2 \leq 2\sum_{j=1}^{q-1} j t_{j+1}^2$ independently on how large is the size N of the matrices T_q and A_q. The approximation is better for larger matrices and/or tridiagonally dominated matrices. For instance for 11-band $10,000 \times 10,000$ matrices with $t_j = t_0/2^j,\ j = 1, \ldots, 5$ we obtain five exact digits. This permits us to find lower and upper bounds when we look only for selected eigenvalues of T_q.

We then specify the bisection algorithm developed for quasiseparable Hermitian matrices to the particular case of symmetric band Toeplitz matrices. We obtain a fast and accurate complete algorithm to solve the eigenproblem in this case. To this end, we use interlacing properties between the eigenvalues of T_q and A_q.

The basic part of the bisection algorithm is the computation of the number of sign changes in the Sturm sequence

$$D_k(\lambda) = \frac{\gamma_k(\lambda)}{\gamma_{k-1}(\lambda)}, \quad k = 1, 2, \ldots, N, \tag{2}$$

where

$$\gamma_0(\lambda) \equiv 1, \gamma_1(\lambda), \gamma_2(\lambda), \ldots, \gamma_N(\lambda)$$

are characteristic polynomials of the principal leading submatrices of a matrix. In our case this number is obtained as follows.

Algorithm. *The number ν of sign changes in the Sturm sequence (2) for a given real value λ and for an $N \times N$ Toeplitz symmetric $2m+1$-band matrix T_m with the given diagonal entry $d \equiv t_0$ and the given row vector $q = (t_1, \cdots, t_m)^T$ of Toeplitz coefficients is computed by the following steps.*

1. Compute $r = m-1, \delta = d - \lambda, v = q^T/\delta; f = vq$. Set $v(m) = q(m)$ and set $\nu = 1$ if $\delta < 0$ and $\nu = 0$ otherwise.

 ISBN: 978-84-617-8694-7

2. Compute $N-2$ *times* $D=\delta-f(1,1)$, $v(1:r)=q(1:r)^T-f(2:m,1)$ *and*

$$\phi=vv^T/D,\quad \phi(1:r,1:r)=\phi(1:r,1:r)+f(2:m,2:m),\quad f=\phi.$$

Set $\nu=\nu+1$ *if* $D<0$.

3. Set $\nu=\nu+1$ *if* $\delta-f(1,1)<0$.

For a given simple eigenvalue λ the normalized eigenvector is obtained as follows.

Algorithm. *The normalized eigenvector for a given simple eigenvalue* λ *and for an* $N\times N$ *Toeplitz symmetric* $2m+1$*-band matrix* T_m *with the given diagonal entry* $d\equiv t_0$ *and the given row vector* $q=(t_1,\cdots,t_m)^T$ *of Toeplitz coefficients is computed by the following steps.*

1.1. Setr $=m-1$, $h_m=(N-\rho)/2$ *where* ρ *is the remainder of the integer division of* N *to* 2 *and* $h_p=h_m+1$, $u(m,N-1)=1$. *Set also* $\delta=d-\lambda$, $u(:,1)=q(:)^T/\delta$, $f=u(:,1)q(:)$, *where* f *is a* $m\times m$ *auxiliary matrix.*

1.2. For $k=2,\ldots,N-1$ *perform:*

$$D=\delta-f(1,1),\quad u(m,k)=q(m)/D,\quad u(1:r,k)=(q(1:r))^T-f(2:m,1:1))/D,$$

$$F=u(:,k)(u(:,k))^TD,\quad F(1:r,1:r)=F(1:r,1:r)+f(2:m,2:m),\quad f=F.$$

2.1. Set $x(N)=1$, $s(2:m)=0$, $s(1)=1$.

2.2. For $k=N-1,N-2,\ldots,h_m$ *set* $n=1$ *and perform:*

$$x(k)=-u(:,k)'s(:),\quad s(2:m)=s(1:r),\quad s(1)=x(k),\quad n=n+(x(k))^2.$$

2.3. Compute $n=\sqrt{2(n-(x(h_m))^2)-\rho(x(h_p))^2}$.

3.1. Set $\sigma=1$ *if* $x(h_m)x(h_p+\rho)>0$ *else* $\sigma=-1$.

3.2. For $j=h_p+1,\ldots,N$ *set* $x(N+1-j)=\sigma x(j)$.

3.3. Normalize $x(1:N)=x(1:N)/n$.

The results of numerical tests demonstrate a good behavior of presented algorithms.

Positive solutions for second order boundary value problems with sign changing Green's functions

Ricardo Enguiça[1]

[1] *Área Departamental de Matemática, Instituto Superior de Engenharia de Lisboa*

emails: rroque@adm.isel.pt

Abstract

Key words: second order differential equations; Dirichlet boundary conditions, periodic boundary conditions, change sign Green's function.
MSC 2000: 34B15, 34A40

In the literature it has been widely studied the existence of positive solutions for boundary value problems (BVP), namely second order BVP with Periodic and Dirichlet boundary conditions. A standard technique consists on obtaining the existence of positive solutions through Krasnoselskii's fixed point theorem on cones, or to use fixed point index theory. In these cases, the positivity of the associated Green's functions is usually fundamental to prove such results. In this paper we are able to prove existence of solutions for several problems where the associated Green's function changes sign.

Hill's operator properties have been described in several papers, where existence and multiplicity results, comparison principles, Green's functions and spectral analysis were studied.

Positivity results for BVP where the Green's function can vanish are treated for example in [4, 8]. In [4], Graef, Kong and Wang studied the periodic BVP (with $T = 1$ in the paper)

$$u''(t) + a(t)\,u(t) = g(t)\,f(u(t)), \quad u(0) = u(T),\ u'(0) = u'(T), \tag{1}$$

with f and g nonnegative continuous functions and g satisfying $\min_{t\in[0,1]} g(t) > 0$. They assumed the Green's function to be nonnegative and to satisfy the following condition

$$\min_{0\le s\le T} \int_0^T G(t,s)\,dt > 0. \tag{2}$$

Webb ([8]) considered weaker assumptions to prove the existence of positive solutions of the previous problem, but he still assumed the Green's function to be nonnegative.

 ISBN: 978-84-617-8694-7

Despite our results do not require the Green's function to be nonnegative, they could be applied to this particular case, obtaining positive solutions assuming an integral condition weaker than the one above.

On the other hand, some existence results for BVP with sign-changing Green's function have been considered in [3, 6], where the authors asked for the existence of a subinterval $[c,d] \subset [0,T]$, a function $\phi \in L^1([0,T])$ and a constant $c \in (0,1]$ such that the Green's function G satisfies the following condition:

$$|G(t,s)| \leq \phi(s),\ t \in [0,T],\ \ pps \in [0,T], \tag{3}$$

$$G(t,s) \geq c\,\phi(s)\ t \in [c,d],\ \ pps \in [0,T]. \tag{4}$$

It must be pointed out that, if we consider a periodic problem with constant potential $a(t) = \rho^2$ for which the related Green's function changes it's sign (i.e. $\rho > \pi/T$, $\rho \neq 2k\pi/T$, $k = 1,2,...$), the condition above is never fulfilled for any strictly positive function ϕ. This is due to the fact that in such situation the Green's function is constant along the straight lines of slope equals to one (see [2] for details). Meanwhile, our results can be applied without further complications for this case.

Moreover, for Dirichlet BVP with constant potential $a(t) = \rho^2$ with sign change Green's function (i.e. $\rho > \pi/T$, $\rho \neq k\pi/T$, $k = 1,2,...$) it is easy to verify that the condition above holds if and only if ρ^2 lies between the first and the second eigenvalues of the problem ($\frac{\pi}{T} < \rho < \frac{2\,\pi}{T}$) but it is never satisfied for $\rho > \frac{2\,\pi}{T}$. However, our results can be applied for any nonresonant value of $\rho > \pi/T$. Despite this, we must note that the imposed restrictions increase with ρ.

Furthermore, in [3, 6] the authors proved the existence of solutions in the cone

$$K_0 = \left\{ u \in \mathcal{C}[0,T],\ \min_{t\in[c,d]} u(t) \geq c\|u\| \right\},$$

that is, they ensured the positivity of the solutions on the subinterval $[c,d]$ but such solutions were allowed to change sign when considering the whole interval $[0,T]$.

As far as we know, positive solutions for BVP with sign-changing Green's function can be tracked only as back as 2011 in the papers [7, 10]. In the first of these papers, R. Ma considers the following one parameter family of problems,

$$u''(t) + a(t)\,u(t) = \lambda\, g(t)\, f(u(t)),\ t \in (0,T), \quad u(0) = u(T),\ u'(0) = u'(T). \tag{5}$$

By using the Schauder's fixed point Theorem, the author obtains the existence of a positive solution for sufficiently small values of λ. These existence results are not comparable with the ones we will obtain in this paper. On the second paper [10], S. Zhong and Y. An study the following autonomous periodic BVP, with constant potential $\rho \in (0, \frac{3\,\pi}{2\,T}]$.

$$u'' + \rho^2 u = f(u),\ t \in (0,T), \quad u(0) = u(T),\ u'(0) = u'(T). \tag{6}$$

In this case, it is very well known that the related Green's function $G_P(t,s) \geq 0$ for all $\rho \in (0, \frac{\pi}{T}]$ and it changes sign for $\rho \in (\frac{\pi}{T}, \frac{3\,\pi}{2\,T}]$ (see [2]). With this, it can be defined the constant

$$\delta = \begin{cases} \infty & \text{if} \quad \rho \in (0, \frac{\pi}{T}], \\ \inf_{t\in I} \frac{\int_0^T G_P^+(t,s)\,ds}{\int_0^T G_P^-(t,s)\,ds} & \text{if} \quad \rho \in (\frac{\pi}{T}, \frac{3\,\pi}{2\,T}] \end{cases} \tag{7}$$

 ISBN: 978-84-617-8694-7

and using the Krasnoselskii's fixed point Theorem, the authors prove the following existence result:

Theorem. *[10, Theorem 3] Suppose that the following assumptions are fulfilled:*

$(J1)$ $f : [0, \infty) \to [0, \infty)$ *is continuous.*

$(J2)$ $0 \leq m = \inf_{u \geq 0} \{f(u)\}$ *and* $M = \sup_{u \geq 0} \{f(u)\} \leq M \leq \infty$.

$(J3)$ $M/m \leq \delta$, *with* $M/m = \infty$ *when* $m = 0$.

Moreover, if $\delta = \infty$ *assume that*

$$\lim_{x \to \infty} \frac{f(x)}{x} < \rho^2 < \lim_{x \to 0^+} \frac{f(x)}{x}.$$

Then problem stated above has a positive solution on $[0, T]$.

Concerning this specific case, along this work we improve the range of the values ρ *for which the result is still valid. Furthermore, we apply our study to nonconstant potentials and nonautonomous nonlinear parts.*

Some of the positivity conditions imposed in the periodic BVP cannot be adapted for the Dirichlet BVP, so the approach that must be used needs to be considerably modified, by using, in this case, a different type of cones.

Abstract

In this paper, we propose, analyze and test a post-processing implementation of a projection-based variational multiscale (VMS) method with proper orthogonal decomposition (POD) for the incompressible Navier-Stokes equations. The projection-based VMS stabilization is added as a separate post-processing step to the standard POD approximation, and since the stabilization step is completely decoupled, the method can easily be incorporated into existing codes, and stabilization parameters can be tuned independent from the time evolution step. We present a theoretical analysis of the method, and give results for several numerical tests on benchmark problems which both illustrate the theory and show the proposed method's effectiveness.

Key words: proper orthogonal decomposition, projection-based variational multiscale, reduced order models, post-processing

1 Introduction

We consider the incompressible Navier-Stokes equations (NSE) on a polyhedral domain $\Omega \subset \mathbb{R}^d, d \in \{2,3\}$ with boundary $\partial\Omega$:

$$\begin{aligned} \mathbf{u}_t - \nu\Delta\mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \nabla p &= \mathbf{f} \quad \text{in } (0,T]\times\Omega, \\ \nabla\cdot\mathbf{u} &= 0 \quad \text{in } [0,T]\times\Omega, \\ \mathbf{u} &= \mathbf{0} \quad \text{in } [0,T]\times\partial\Omega, \\ \mathbf{u}(0,\mathbf{x}) &= \mathbf{u}_0 \quad \text{in } \Omega, \\ \int_\Omega p\, d\mathbf{x} &= 0, \quad \text{in } (0,T]. \end{aligned} \tag{1}$$

 ISBN: 978-84-617-8694-7

Here, $\mathbf{u}(t,\mathbf{x})$ is the fluid velocity and $p(t,\mathbf{x})$ the fluid pressure. The parameters in (1) are the kinematic viscosity $\nu > 0$, the prescribed body forces $\mathbf{f}(t,\mathbf{x})$ and the initial velocity field $\mathbf{u}_0(\mathbf{x})$. Simulating complex flows by a direct numerical simulation (DNS) can be very expensive. In this case reduced order models are needed to decrease computational cost. The proper orthogonal decomposition (POD) approach is most widely used reduced order model. POD only uses the most energetic base functions. However, POD causes numerical instability in turbulent flows. Using VMS in POD was pioneered in [1, 2], and their studies showed this could increased numerical accuracy for convection-dominated convection-diffusion equations [2] and for NSE [1].

2 Post-Processed VMS-POD Schemes

We proposes fully discrete VMS-POD methods. We analyze the backward Euler temporal discretization. We consider the extension to BDF2 time stepping. In our analysis, we assume that the eddy viscosity coefficient ν_T is known bounded, positive and element-wise constant. In that analysis that follows, we denote variables at time $t^n = n\Delta t, n = 0, 1, 2, \ldots, M, T := M\Delta t$ using superscripts, e.g. $\mathbf{f}^n := \mathbf{f}(t^n)$. The two step VMS-POD scheme equipped with backward Euler time stepping reads as follows:

Algorithm 2.1 *Let $\mathbf{f} \in L^2(0,T;\mathbf{H}^{-1}(\Omega))$ and $\mathbf{u}_r^0 = \mathbf{w}_r^0$ be given with L^2 projection of $\mathbf{u}_0$ in $\mathbf{X}^r$. Given $\mathbf{u}_r^n \in \mathbf{X}_r$ compute $\mathbf{u}_r^{n+1}$ by applying the following two steps:*
Step 1. *Calculate $\mathbf{w}_r^{n+1} \in \mathbf{X}^r$ satisfying $\forall \psi \in \mathbf{X}^r$,*

$$\left(\frac{\mathbf{w}_r^{n+1} - \mathbf{u}_r^n}{\Delta t}, \psi\right) + b(\mathbf{w}_r^{n+1}, \mathbf{w}_r^{n+1}, \psi) + \nu(\nabla \mathbf{w}_r^{n+1}, \nabla\psi) = (\mathbf{f}^{n+1}, \psi). \tag{2}$$

Step 2. *Post-process $\mathbf{w}_r^{n+1}$ by applying projection P_R to obtain $\mathbf{u}_r^{n+1} \in \mathbf{X}_r$, $\forall \psi \in \mathbf{X}^r$:*

$$\left(\frac{\mathbf{w}_r^{n+1} - \mathbf{u}_r^{n+1}}{\Delta t}, \psi\right) = (\nu_T(I - P_R)\nabla\frac{(\mathbf{w}_r^{n+1} + \mathbf{u}_r^{n+1})}{2}, (I - P_R)\nabla\psi), \tag{3}$$

We note that Step 1 is the standard Galerkin POD method, and Step 2 is completely decoupled VMS stabilization step. The projection in Step 2 is not a filter but constructed to recover VMS eddy viscosity term.

Lemma 2.1 *(Stability of Algorithm 2.1) The post-processed-VMS-POD approximation (2)-(3) is unconditionally stable in the following sense: for any $\Delta t > 0$,*

$$\|\mathbf{u}_r^M\|^2 + \sum_{n=0}^{M-1}\Big[2\nu_T\Delta t\|(I - P_R)\nabla\frac{(\mathbf{w}_r^{n+1} + \mathbf{u}_r^{n+1})}{2}\|^2 + \|\mathbf{w}_r^{n+1} - \mathbf{u}_r^n\|^2 + \nu\Delta t\|\nabla\mathbf{w}_r^{n+1}\|^2\Big] \le \|\mathbf{u}_r^0\|^2 + \nu^{-1}|||\mathbf{f}|||_{2,-1}^2.$$

 ISBN: 978-84-617-8694-7

We present the error analysis of the true solution of Navier Stokes equations and VMS-POD approximation (2)-(3). The optimal asymptotic error estimation requires the following regularity assumptions for the true solution:

$$\mathbf{u} \in L^\infty(0,T;H^{m+1}(\Omega)) \quad p \in L^\infty(0,T;H^m(\Omega)) \quad \mathbf{u}_{tt} \in L^2(0,T;H^1(\Omega))$$
$$\mathbf{f} \in L^2(0,T;H^{-1}(\Omega)) \tag{4}$$

Theorem 2.1 *Suppose (4) holds and $\mathbf{u}_r^n$ and $\mathbf{w}_r^n$ given by Algorithm 2.1. For sufficiently small Δt, i.e. $\Delta t \le [C\nu^{-3}\|\nabla \mathbf{u}\|_{\infty,0}^4]^{-1}$ we have the following asymptotic error estimation:*

$$\|\mathbf{u}^M - \mathbf{u}_r^M\|^2 + \sum_{n=0}^{M-1}\left[\frac{1}{4}\Delta t\nu_T\|(I-P_R)\nabla(\mathbf{u}^{n+1} - (\mathbf{u}_r^{n+1}+\mathbf{w}_r^{n+1})/2)\|^2\right.$$
$$\left.+\nu\Delta t\|\nabla(\mathbf{u}^{n+1}-\mathbf{w}_r^{n+1})\|^2\right] \le C\Big(h^{2m} + (\Delta t)^2 + (1+\|S_R\|_2+\|S_r\|_2)h^{2m+2}$$
$$+\sum_{j=R+1}^{d}\|\psi_j\|_1^2\lambda_j + \sum_{j=r+1}^{d}(1+\|\psi_j\|_1^2)\lambda_j\Big)$$

We consider now an extension of Algorithm 2.1 to BDF2 time stepping.

Algorithm 2.2 *Let $\mathbf{f} \in L^2(0,T;\mathbf{H}^{-1}(\Omega))$ and initial conditions $\mathbf{u}_r^0$ and $\mathbf{u}_r^{-1}$ be given in $\mathbf{X}^r$. Then for n=0,1,2,...*

Step 1. *Calculate $\mathbf{w}_r^{n+1} \in \mathbf{X}^r$ satisfying $\forall \psi \in \mathbf{X}^r$,*

$$\left(\frac{3\mathbf{w}_r^{n+1} - 4\mathbf{u}_r^n + \mathbf{u}_r^{n-1}}{2\Delta t}, \psi\right) + b(\mathbf{w}_r^{n+1}, \mathbf{w}_r^{n+1}, \psi) + \nu(\nabla \mathbf{w}_r^{n+1}, \nabla\psi) = (\mathbf{f}^{n+1}, \psi) \tag{5}$$

Step 2. *Post-process $\mathbf{w}_r^{n+1}$ to obtain $\mathbf{u}_r^{n+1} \in \mathbf{X}^r$ satisfying $\forall \psi \in \mathbf{X}^r$,*

$$\left(\frac{\mathbf{w}_r^{n+1} - \mathbf{u}_r^{n+1}}{\Delta t}, \psi\right) = (\nu_T(I-P_R)\nabla\frac{(\mathbf{w}_r^{n+1}+\mathbf{u}_r^{n+1})}{2}, (I-P_R)\nabla\psi). \tag{6}$$

We note the post-processing step is exactly the same as in the backward Euler case. Also as in the case of the backward Euler method above, without Step 2, Algorithm 2.2 reduces to the classical Galerkin POD formulation for the NSE, although now using BDF2 time stepping.

Lemma 2.2 *(Stability of Algorithm 2.2) The post-processed VMS-POD approximation (5)-(6) is stable for the eddy viscosity term $\nu_T < 4\nu$ in the following sense:*

$$\|\mathbf{u}_r^{M+1}\|^2 + \|2\mathbf{u}_r^{M+1} - \mathbf{u}_r^M\|^2 + 2\nu_T\Delta t\left\|(I-P_R)\nabla\frac{(\mathbf{w}_r^{M+1}+\mathbf{u}_r^{M+1})}{2}\right\|^2$$
$$+2\nu\Delta t\|\nabla\mathbf{w}_r^{M+1}\|^2 + \sum_{n=1}^{M}\|\mathbf{w}_r^{n+1} - 2\mathbf{u}_r^n + \mathbf{u}_r^{n-1}\|^2 + (4\nu-\nu_T)\frac{\Delta t}{2}\sum_{n=1}^{M-1}\|\nabla\mathbf{w}_r^{n+1}\|^2$$
$$\le \|\mathbf{u}_r^1\|^2 + \|2\mathbf{u}_r^1 + \mathbf{u}_r^0\|^2 + \frac{\nu_T\Delta t}{2}\|\nabla\mathbf{u}_r^1\|^2 + 2\nu^{-1}|||\mathbf{f}|||_{2,-1}^2.$$

 ISBN: 978-84-617-8694-7

3 Numerical Experiments

We test the VMS-POD approximate solution with three numerical experiments. In all cases we use Algorithm 2.2, i.e. the scheme with second order time stepping. Our first test considers the predicted convergence rates of the previous section, with respect to varying R and Δt. For the second test, we compare accuracy of the proposed VMS-POD scheme compared with the usual Galerkin POD method (i.e. unstabilized POD, computed by eliminating the post-processing step of the VMS-POD) in 2D channel flow past a cylinder. Finally we consider the VMS-POD for a 3D turbulent channel flow simulation.

4 Conclusion

We proposed, analyzed and tested a VMS-POD method for incompressible NSE simulation, where the stabilization is completely decoupled into the second step of a two step implementation at each time step. Decoupling of the stabilization has the advantage of easily being incorporated into existing POD-G codes, and also that stabilization parameters can be adjusted only in the stabilization step (and not as part of the evolution equation). We rigorously prove an error estimate for the model, in terms of the number of POD modes r, the stabilization parameters R (number of modes not to add stabilization to) and ν_T, as well as the time step size Δt and the mesh width h of the underlying FEM simulation that produced the POD modes. Results from several numerical experiments are provided that show how effective the method can be. In particular, we show for 2D channel flow past a step, POD-G has an energy growth that causes poor lift and drag prediction, especially for longer times. The proposed VMS-POD is able to fix this by stabilizing so that the energy matches the DNS energy, which in turn leads to excellent lift and drag prediction, even up to $t = 10$ (and from the plots, it appear the accurate predictions can continue for even longer time).

Abstract

The study of contractions of Lie algebras is profusely extended in the last decades. In this paper we study the graded contractions of some lower-dimensional filiform Lie algebras which have not been studied earlier. Particularly, we deal with graded contractions of model filiform Lie algebras of dimension less than or equal to 6 and with the ones of a non-model 6-dimensional filiform Lie algebra.

Key words: Graded contractions; filiform Lie algebras.
MSC 2000: 17B30; 17B40; 17B51.

1 Introduction

One of the most relevant and useful results in Physics is the so called *Correspondence principle*, which sets that a new theory should coincide with the old one in predictions for phenomena where these conditions are satisfied.

The mathematical formulation of this principle for relativistic mechanics was given by In*ö*n*ü* and Wigner [3] when introducing the In*ö*n*ü*-Wigner contractions (IW-contractions).

In this paper we concentrate on the algebraical approach to contractions, so called *graded contractions*, which were originally introduced in [4] as a generalization of IW-contractions.

There are two types of graded contractions: continuous graded contractions, which correspond to IW-contractions and discrete graded contractions, which possess no equivalent in continuous contractions. The general solution of the graded contractions, considering

only so called generic case, was achieved in [7, 8]. Since this solution depends solely on the grading group (the structure of the Lie algebra does not matter at all), it is obtained simultaneously for all Lie algebras which allow the given grading. However, this approach is in a certain sense too general. It motivates our study.

Indeed, graded contraction of several types of Lie algebras have been already dealt in previous papers. For instance, Novotny studied in deep graded contractions of the simple Lie algebra $sl(3,\mathbb{C})$ [5]. He showed 4 gradings for this algebra. Later, Novotny himself obtained the contractions for each grading. Bahturin, Goze y Remm [1] classified, up to isomorphism, gradings by abelian groups on nilpotent Lie algebras of nonzero rank and, in the case of rank 0, they described conditions to obtain non trivial Z_k-gradings.

So, by continuing with this study, which we began to deal with in [2], we show in the paper the graded contractions of the model filiform Lie algebras of dimension 3 and 4. These ones, together with those of dimensions 5 and 6, which have been also obtained by us, but are not included in the paper for reasons of length, have allowed us to study the general case of the contractions of n-dimensional model filiform Lie algebras, which is dealt with in Section 5. Moreover, with the objective of comparing the model case with the non-model one, the graded contractions of a non-model 6-dimensional filiform Lie algebra has been also obtained. It is convenient to say that our motivation for dealing with this type of algebras is due to the fact of that these algebras, which were introduced by Vergne in 1966, in her Ph. D. Thesis, later published in 1979 [6], constitute the most structured subset of nilpotent Lie algebras.

Let us now recall brief preliminaries on this subject.

2 Preliminaries

Let $\mathfrak{g}$ be a finite dimensional complex Lie algebra over $\mathbb{C}$. A decomposition $\Gamma : \mathfrak{g} = \oplus_{i\in I}\mathfrak{g}_i$ of the vector space $\mathfrak{g}$ into a direct sum of vector subspaces $\mathfrak{g}_i \neq 0$, $i \in I$, is called a *grading* of $\mathfrak{g}$ if for any pair of indices $i, j \in I$, there exists $k \in I$, such that $[\mathfrak{g}_i, \mathfrak{g}_j] \subset \mathfrak{g}_k$. Vector subspaces $\mathfrak{g}_i$ are called *grading subspaces*. The number of grading subspaces is equal to the cardinality $|I|$ of the index set I.

A grading $\Gamma : \mathfrak{g} = \oplus_{i\in I}\mathfrak{g}_i$ is called *group grading* (respectively, *semigroup grading*) if there exist an abelian group (resp. semigroup) G and an injective mapping $f : I \to G$ such that for any pair of indices $i, j \in I$, the equality $f(i \circ j) = f(i) + f(j)$ holds, where $+$ denotes the binary operation in G. The group (resp. semigroup) G is called *grading group (resp. semigroup)*.

The *universal group* is the Abelian finitely generated group U which contains the set of indices J of a grading group $J \subset U$.

Let $\Gamma : \mathfrak{g} = \oplus_{i\in I}\mathfrak{g}_i$ be a grading of the Lie algebra $\mathfrak{g}$, with $|I| = m \in \mathbb{N}$ grading subspaces. A complex Lie algebra $\mathfrak{g}^{\varepsilon}$ endowed with a Lie bracket $[,]_{\varepsilon}$ and satisfying the

 ISBN: 978-84-617-8694-7

two conditions: *i)* the underlying vector space of $\mathfrak{g}^\epsilon$ is the underlying vector space of $\mathfrak{g}$, i.e. $\mathfrak{g}^\epsilon = \oplus_{i\in I}\mathfrak{g}_i$, and *ii)* for all $i, j \in I$, there exists $\varepsilon_{ij} \in \mathbb{C}$ such that $[x, y]_\varepsilon = \varepsilon_{ij}[x, y]$, for all $x \in \mathfrak{g}_i$ and $y \in \mathfrak{g}_j$, is called Γ-*graded contraction* of the Lie algebra $\mathfrak{g}$.

We define the *contraction matrix* ε of the Lie algebra $\mathfrak{g}^\varepsilon$ as a matrix whose elements are ε_{ij}. This matrix determines the Lie algebra $\mathfrak{g}^\varepsilon$.

The elements ε_{ij} associated with Lie brackets verifying $[\mathfrak{g}_i, \mathfrak{g}_j] \neq 0$ will be called *relevant* elements. On the contrary, those elements verifying $[\mathfrak{g}_i, \mathfrak{g}_j] = 0$ will be called *non-relevant* elements and they will be considered null. The null relevant elements will be called *singular* elements. The set of the pairs (i, j) such that ε_{ij} is a relevant element of the contraction matrix ε will be denoted by $\mathcal{I}$.

Let P_n denote the symmetric group of the set $\{1, 2, ..., n\}$. We define an equivalence relation on I^n as follows: two n-tuples $(x_1, ..., x_n), (y_1, ..., y_n) \in I^n$ are equivalent if and only if there exists $\sigma \in \Pi_n$ such that $x_i = y_{\sigma(i)}$, for all $i = 1, ..., n$. The classes $(x_1\, x_2 \ldots x_n) = \{(x_{\sigma 1}, ..., x_{\sigma n}) | \sigma \in \Pi_n\}$ defined by this relation are called *unordered n-tuples* and the set of all unordered n-tuples with entries in I is denoted by I_u^n.

The *lower central series* of a Lie algebra $\mathfrak{g}$ is defined as $\mathfrak{g}^1 = \mathfrak{g},\ \mathfrak{g}^2 = [\mathfrak{g}^1, \mathfrak{g}],\ \ldots,\ \mathfrak{g}^k = [\mathfrak{g}^{k-1}, \mathfrak{g}],\ \ldots$.

If there exists $m \in \mathbb{N}$ such that $\mathfrak{g}^m \equiv 0$, then $\mathfrak{g}$ is called *nilpotent*. An n-dimensional nilpotent Lie algebra $\mathfrak{g}$ is said to be *filiform* if it is verified that $dim\, \mathfrak{g}^k = n - k$, for all $k \in \{2, \ldots, n\}$. A n-dimensional filiform Lie algebra is called *model* if the only nonzero brackets are $[e_1, e_k] = e_{k+1}$, for $2 \leq k \leq n - 1$, where $\{e_1, \ldots, e_n\}$ is an adapted basis.

3 Graded contractions of the model filiform Lie algebra of dimension 3

All the computations needed to obtain the graded contractions of model filiform Lie algebras will be only detailed in this dimension 3. For the next dimensions, these computations will be only indicated.

Let $\mathfrak{f}_3 : [e_1, e_2] = e_3$ be the model filiform Lie algebra of dimension 3. A grading of $\mathfrak{f}_3$ is given by (see [1])

$$\Gamma : \mathfrak{f}_3 = \mathfrak{f}^3_{(1,0)} \oplus \mathfrak{f}^3_{(0,1)} \oplus \mathfrak{f}^3_{(1,1)}$$

The universal group U of $\mathfrak{f}_3$ is $\mathbb{Z}_2 \otimes \mathbb{Z}_2$ and $\mathfrak{f}^3_{(1,0)} = \langle e_1 \rangle$, $\mathfrak{f}^3_{(0,1)} = \langle e_2 \rangle$ and $\mathfrak{f}^3_{(1,1)} = \langle e_3 \rangle$.

Let us now denote

$$I = \{(1, 0), (0, 1), (1, 1)\}$$

and let us consider a order relation on I

 ISBN: 978-84-617-8694-7

$$O : \begin{cases} 1 & \to & (1,0) \\ 2 & \to & (0,1) \\ 3 & \to & (1,1) \end{cases}$$

Let us consider

$$\Pi_3 = \begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix}, \text{ with } a \in \mathbb{Z}_2,$$

and the set $G_{\Pi_3} = \{g \in Aut(\mathfrak{f}^3) \mid \exists \pi \in \Pi_3 \mid g(\mathfrak{f}_i^3) = \mathfrak{f}_{\pi(i)}^3, \text{ for all } i \in I\}$.

We define π as the mapping $I \mapsto I$, which maps an element $i \in I$ into the matrix product in I. Then, it is easy to see that G_{Π_3} is a subgroup of $Aut(\mathfrak{f}^3)$. Indeed, if $g_1, g_2 \in G_{\Pi_3}$, then there exist $\pi_1, \pi_2 \in \Pi_3$, such that $g_1(f_i^3) = f_{\pi_1(i)}^3$ and $g_2(f_i^3) = f_{\pi_2(i)}^3$, for all $i \in I$. Therefore, $(g_1 g_2^{-1}) f_i^3 = g_1(g_2^{-1}(f_{\pi_2(\pi_2^{-1}(i))}^3)) = g_1(f_{\pi_2^{-1}(i)}^3) = f_{\pi_1(\pi_2^{-1}(i))}^3$. Therefore, $g_1 g_2^{-1} \in G_{\Pi_3}$, and thus G_{Π_3} is a subgroup of de $Aut(\mathfrak{f}^3)$.

1. Orbits of I.

Let us recall that the concept of *orbit* is the following: If G is a group acting on a set I, the *orbit* of an element x in I is the set of elements in I to which x can be moved by the elements of G, that is, $G \cdot x = \{g \cdot x \mid g \in G\}$.

Now, let us see how we can obtain the orbits of I.

Let

$$\pi_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \pi_2 = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

be the generators of Π_3. Then

$$\pi_1((1,0)) = (1,0)\pi_1 = (1,0) \in I, \quad \pi_2((1,0)) = (1,0)\pi_2 = (1,0) \in I.$$

Therefore, $(1,0)$ represents a orbit which contains itself. Similarly, as

$$\pi_1((0,1)) = (0,1)\pi_1 = (0,1) \in I, \pi_2((0,1)) = (0,1)\pi_2 = (1,1) \in I,$$

$(0,1)$ represents a orbit containing itself and the index $(1,1)$. So, we have

Represented by the points	Orbits
$(1,0)$	$(1,0)$
$(0,1)$	$(0,1)$ and $(1,1)$

Similarly, we obtain and show in the following tables the rest of orbits.

2. Orbits of the 3 points of I_u^2

These orbits are obtained by the following definition $\pi_i((p,q)(r,s)) = (\pi_i(p,q)\pi_i(r,s))$, for all $i \in \{1,2,3\}$. We obtain that

 ISBN: 978-84-617-8694-7

Orbits	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1))$ and $((1,0)(1,1))$
$((0,1)(1,1))$	$((0,1)(1,1))$

3. Orbit of the unique point of I_u^3

Similarly, these orbits are obtained by the following definition $\pi_i((m,n)(p,q)(r,s)) = (\pi_i(m,n)\pi_i(p,q)\pi_i(r,s))$, for all $i \in \{1,2,3\}$. We have

Orbits	Represented by the points
$((1,0)(0,1)(1,1))$	$((1,0)(0,1)(1,1))$

Let us observe that this orbit contains an unique triple, which is the one of indices of the vectors which satisfy Jacobi Identity.

4. Orbit of the 3 points of $\mathcal{I}$:

The non-relevant elements of the contraction matrix ε which might be different from zero are $\varepsilon_{(1,0)(0,1)}$ and $\varepsilon_{(1,0)(1,1)}$. We obtain

Orbits	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1))$ and $((1,0)(1,1))$

However, $\varepsilon_{(1,0)(1,1)} = 0$, because $0 = [\mathfrak{f}^3_{(1,0)}, \mathfrak{f}^3_{(1,1)}]_\varepsilon = \varepsilon_{(1,0)(1,1)}\,[\mathfrak{f}^3_{(1,0)}, \mathfrak{f}^3_{(1,1)}] = \varepsilon_{(1,0)(1,1)}$ $[\mathfrak{f}^3_{\pi_2(1,0)}, \mathfrak{f}^3_{\pi_2(1,1)}] = \varepsilon_{(1,0)(1,1)} g_2\,[\mathfrak{f}^3_{(1,0)}, \mathfrak{f}^3_{(0,1)}]$, but the bracket $[\mathfrak{f}^3_{(1,0)}, \mathfrak{f}^3_{(0,1)}] \neq 0$. So, the element $\varepsilon_{(1,0)(1,1)}$ of the contraction matrix is singular.

The explicit form of the contraction matrix ε with respect to the chosen order O is

$$\begin{pmatrix} 0 & \varepsilon_{(1,0)(0,1)} & 0 \\ \varepsilon_{(1,0)(0,1)} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Now, we are trying to find if the relevant elements of the contraction matrix verify some particular conditions. To do this, the elements of this matrix have to satisfy the following conditions

By imposing the Jacobi identity

$$[X,[Y,Z]_\varepsilon]_\varepsilon + [Y,[Z,X]_\varepsilon]_\varepsilon + [Z,[X,Y]_\varepsilon]_\varepsilon = 0 \qquad (1)$$

for all $X \in \mathfrak{f}^3_{(i,j)}$, $Y \in \mathfrak{f}^3_{kl}$, $Z \in \mathfrak{f}^3_{(m,n)}$ and for all $(i,j)(k,l)(m,n) \in I_u^3$, we obtain that

$$\varepsilon_{(i,j)(k+m,l+n)}\varepsilon_{(k,l)(m,n)}[X_{i,j},[X_{k,l},X_{m,n}]] + \varepsilon_{(k,l)(m+i,n+j)}\varepsilon_{(m,n)(i,j)}[X_{k,l},[X_{m,n},X_{i,j}]]$$

$$+\varepsilon_{(m,n)(i+k,j+l)}\varepsilon_{(i,j)(k,l)}[X_{m,n},[X_{i,j},X_{k,l}]] = 0, \qquad (2)$$

 ISBN: 978-84-617-8694-7

for all $((i,j)(k,l)(m,n)) \in I_u^3$.

From this expression and for all $\pi \in \Pi_3$, it is deduced that

$\varepsilon_{\pi(i,j)\pi(k+m,l+n)}\varepsilon_{\pi(k,l)\pi(m,n)}[X_{\pi(i,j)},[X_{\pi(k,l)},X_{\pi(m,n)}]] + \varepsilon_{\pi(k,l)\pi(m+i,n+j)}\varepsilon_{\pi(m,n)\pi(i,j)}$ $[X_{\pi(k,l)},[X_{\pi(m,n)},X_{\pi(i,j)}]] + \varepsilon_{\pi(m,n)\pi(i+k,j+l)}\varepsilon_{\pi(i,j)\pi(k,l)}[X_{\pi(m,n)},[X_{\pi(i,j)},X_{\pi(k,l)}]] = 0$, for all $((i,j)(k,l)(m,n)) \in I_u^3$.

Let now $g \in G_{\Pi_3}$ be such that $g(X_{(k,l)}) = X_{\pi(k,l)}$, for all $(k,l) \in I$. We have the three following restrictions for the elements of the contraction matrix

$\varepsilon_{\pi(i,j)\pi(k+m,l+n)}\varepsilon_{\pi(k,l)\pi(m,n)}\ g[X_{(i,j)},[X_{(k,l)},X_{(m,n)}]] + \varepsilon_{\pi(k,l)\pi(m+i,n+j)}\varepsilon_{\pi(m,n)\pi(i,j)}\ g[X_{(k,l)},$ $[X_{(m,n)},X_{(i,j)}]]+\varepsilon_{\pi(m,n)\pi(i+k,j+l)}\varepsilon_{(i,j)(k,l)}g[X_{(m,n)},[X_{(i,j)},X_{(k,l)}]] = 0$, for all $((i,j)(k,l)(m,n))$ $\in I_u^3$.

$g(\varepsilon_{\pi(i,j)\pi(k+m,l+n)}\varepsilon_{\pi(k,l)\pi(m,n)}\ [X_{(i,j)},[X_{(k,l)},X_{(m,n)}]] + \varepsilon_{\pi(k,l)\pi(m+i,n+j)}\varepsilon_{\pi(m,n)\pi(i,j)}\ [X_{(k,l)},$ $[X_{(m,n)},X_{(i,j)}]]\varepsilon_{\pi(m,n)\pi(i+k,j+l)}\varepsilon_{(i,j)(k,l)}[X_{(m,n)},[X_{(i,j)},X_{(k,l)}]]) = 0$, for all $((i,j)(k,l)(m,n))$ $\in I_u^3$.

$\varepsilon_{\pi(i,j)\pi(k+m,l+n)}\varepsilon_{\pi(k,l)\pi(m,n)}\ [X_{(i,j)},[X_{(k,l)},X_{(m,n)}]] + \varepsilon_{\pi(k,l)\pi(m+i,n+j)}\varepsilon_{\pi(m,n)\pi(i,j)}[X_{(k,l)},$ $[X_{(m,n)},X_{(i,j)}]]+\varepsilon_{\pi(m,n)\pi(i+k,j+l)}\varepsilon_{(i,j)(k,l)}[X_{(m,n)},[X_{(i,j)},X_{(k,l)}]] = 0$, for all $((i,j)(k,l)(m,n)) \in$ I_u^3.

These expressions allow us to obtain the restrictions which verify the rest of elements of the contraction matrix. It implies that the relevant elements $\varepsilon_{\pi(i,j)}$ are also elements of that matrix and satisfy the same conditions as $\varepsilon_{(i,j)}$.

Moreover, $[X_{i,j},[X_{k,l},X_{m,n}]]$, $[X_{m,n},[X_{i,j},X_{k,l}]]$ and $[X_{k,l},[X_{m,n},X_{i,j}]]$ are null for $\mathfrak{f}_3$. This implies that the element $\varepsilon_{(1,0)(0,1)}$ can take any complex value.

On the other hand, if $\varepsilon = (\varepsilon_{ij})$ is a contraction matrix, then we define $\tau = (\tau_{ij})$ such that $\tau_{ij} = \frac{1}{\varepsilon_{ij}}$, if $\varepsilon_{ij} \neq 0$ or $\tau_{ij} = 0$, otherwise. Besides, $\varepsilon \diamond \tau$ ($\diamond$ means the Hadamard product, that is the binary operation that takes two matrices of the same dimensions, and produces another matrix where each element pq is the product of elements pq of the original two matrices) is a contraction matrix in which all non-null elements are 1. We call *normalized contraction matrix* of ε to the matrix $\varepsilon \diamond \tau$, and we denote by $N(\mathfrak{f}_3)$ to the set of all normalized contraction matrices of $\mathfrak{f}_3$. This set has 2 elements, which are the 3×3 null matrix and the matrix $\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$.

 ISBN: 978-84-617-8694-7

4 Graded contractions of the model filiform Lie algebra of dimension 4

Let $\mathfrak{f}_4 : [e_1, e_k] = e_{k+1}$, for $2 \leq k \leq 3$ be the model filiform Lie algebra of dimension 4. A grading of $\mathfrak{f}_4$ is given by

$$\Gamma : \mathfrak{f}^4 = \mathfrak{f}^4_{(1,0)} \oplus \mathfrak{f}^4_{(0,1)} \oplus \mathfrak{f}^4_{(1,1)} \oplus \mathfrak{f}^4_{(2,1)}$$

The universal group of $\mathfrak{f}_4$ is $\mathbb{Z}_3 \otimes \mathbb{Z}_2$ and $\mathfrak{f}^4_{(1,0)} = \langle e_1 \rangle$, $\mathfrak{f}^4_{(0,1)} = \langle e_2 \rangle$, $\mathfrak{f}^4_{(1,1)} = \langle e_3 \rangle$ and $\mathfrak{f}^4_{(2,1)} = \langle e_4 \rangle$.

Let us consider

$$\Pi_4 = \begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix}, \text{ with } a \in \mathbb{Z}_3 \text{ and } \mathrm{I} = \{(1,0),(0,1),(1,1),(2,1)\}.$$

We now consider the following order O on $I : 1 \to (1,0), 2 \to (0,1), 3 \to (1,1)$ and $4 \to (2,1)$. By straightforward computations, we obtain that the elements of I constitute the following orbits

Represented by the points	Orbits
$(1,0)$	$(1,0)$
$(0,1)$	$(0,1),(1,1)$ and $(2,1)$

Similarly, we show in the following tables the following orbits

2. Orbits of the 6 points of I^2_u

Orbits	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1)),((1,0)(1,1))$ and $((1,0)(2,1))$
$((0,1)(1,1))$	$((0,1)(1,1)),((1,1)(2,1))$ and $((2,1)(0,1))$

3. Orbits of the 4 point of I^3_u

Orbits	Represented by the points
$((1,0)(0,1)(1,1))$	$((1,0)(0,1)(1,1)),((1,0)(1,1)(2,1))$ and $((1,0)(2,1)(0,1))$
$((0,1)(1,1)(2,1))$	$((0,1)(1,1)(2,1))$

Let us observe that these two orbits contain $\binom{4}{3} = 4$ triples, which correspond with the indices of the triples of vectors which must satisfy the Jacobi Identity.

4. Orbits of the 3 points of $\mathcal{I}$:

Orbits	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1)),((1,0)(1,1))$ and $((1,0)(2,1))$

 ISBN: 978-84-617-8694-7

The non-relevant elements of the contraction matrix ε that might be different from zero are $\varepsilon_{(1,0)(0,1)}$, $\varepsilon_{(1,0)(1,1)}$ and $\varepsilon_{(1,0)(2,1)}$. However, a similar reasoning as in the previous case shows that the element $\varepsilon_{(1,0)(2,1)}$ is singular. So, the explicit form of the contraction matrix ε with respect to the chosen order O is

$$\begin{pmatrix} 0 & \varepsilon_{(1,0)(0,1)} & \varepsilon_{(1,0)(1,1)} & 0 \\ \varepsilon_{(1,0)(0,1)} & 0 & 0 & 0 \\ \varepsilon_{(1,0)(1,1)} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

where the non-null elements of this matrix have to satisfy Equation (2).

Moreover, from Equation (1) is deduced that the elements $\varepsilon_{(1,0)(0,1)}$ and $\varepsilon_{(1,0)(1,1)}$ can take any complex value.

By reasoning as we did in the previous dimension, we deduce that the set $N(\mathfrak{f}_4)$ of all normalized contraction matrices of $\mathfrak{f}_4$ has 4 elements, which are the following matrices

$$\begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \text{ and the } 3 \times 3 \text{ null matrix.}$$

5 Graded contractions of the n-dimensional filiform Lie algebra

Let $\mathfrak{f}_n : [e_1, e_k] = e_{k+1}$, for $2 \leq k \leq n-1$ be the model filiform Lie algebra of dimension n. A grading of $\mathfrak{f}_n$ is given by

$$\Gamma : \mathfrak{f}_n = \mathfrak{f}^n_{(1,0)} \oplus \mathfrak{f}^n_{(0,1)} \oplus \mathfrak{f}^n_{(1,1)} \oplus \mathfrak{f}^n_{(2,1)} \oplus \mathfrak{f}^n_{(3,1)} \oplus \mathfrak{f}^n_{(4,1)} \oplus \ldots \oplus \mathfrak{f}^n_{(n-2,1)}.$$

The universal group of $\mathfrak{f}_n$ is $\mathbb{Z}_{n-1} \otimes \mathbb{Z}_2$ and $\mathfrak{f}^n_{(1,0)} = \langle e_1 \rangle$, $\mathfrak{f}^n_{(0,1)} = \langle e_2 \rangle$, $\mathfrak{f}^n_{(1,1)} = \langle e_3 \rangle$, $\mathfrak{f}^n_{(2,1)} = \langle e_4 \rangle$, $\mathfrak{f}^n_{(3,1)} = \langle e_5 \rangle$, $\mathfrak{f}^n_{(4,1)} = \langle e_6 \rangle, \ldots, \mathfrak{f}^n_{(n-2,1)} = \langle e_n \rangle$.

Let us consider

$$\Pi_n = \begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix}, \text{ with } a \in \mathbb{Z}_{n-1} \text{ and } \mathrm{I} = \{(1,0), (0,1), (1,1), (2,1), (3,1), \ldots, (n-2,1\}.$$

We now consider the following order O on $I : 1 \to (1,0)$, $2 \to (0,1)$, $3 \to (1,1)$, $4 \to (2,1)$, $\ldots$, and $n \to (n-2,1)$ and starting from this point and by using any symbolic computation package for computations we proceed in the same way as the indicated in the previous particular cases. Indeed, we obtain the orbits of the points of I, I^2_u and I^3_u and consider the elements of the $n \times n$ contraction matrix ε that might be different from zero.

 ISBN: 978-84-617-8694-7

These elements are $\varepsilon_{(1,0)(0,1)}$, $\varepsilon_{(1,0)(1,1)}$, $\varepsilon_{(1,0)(2,1)}$, $\varepsilon_{(1,0)(3,1)}, \ldots$ and $\varepsilon_{(1,0)(n-2\ 1)}$. The resting elements are null. Moreover, we find that $\varepsilon_{(1,0)(n-2\ 1)} = 0$. It allows us to obtain the explicit form of the contraction matrix ε with respect to the chosen order O.

Let us recall that for any n-dimensional filiform Lie algebra, the elements, the non-null ones have to verify the following conditions (Equation (2))

$$\varepsilon_{(i,j)(k+m,l+n)}\varepsilon_{(k,l)(m,n)}[X_{i,j},[X_{k,l},X_{m,n}]] + \varepsilon_{(k,l)(m+i,n+j)}\varepsilon_{(m,n)(i,j)}[X_{k,l},[X_{m,n},X_{i,j}]]$$
$$+\varepsilon_{(m,n)(i+k,j+l)}\varepsilon_{(i,j)(k,l)}[X_{m,n},[X_{i,j},X_{k,l}]] = 0, \forall((i,j)(k,l)(m,n)) \in I_u^3.$$

Moreover, $[X_{i,j},[X_{k,l},X_{m,n}]]$, $[X_{m,n},[X_{i,j},X_{k,l}]]$ and $[X_{k,l},[X_{m,n},X_{i,j}]]$ are null for $\mathfrak{f}_n$. This implies that the elements $\varepsilon_{(1,0)(0,1)}$, $\varepsilon_{(1,0)(0,1)}$, $\varepsilon_{(1,0)(1,1)}$, $\varepsilon_{(1,0)(2,1)}$, $\ldots$, $\varepsilon_{(1,0)(n-3\,1)}$ can take any complex value, which allow us to obtain the conclusions in each dimension.

In any case, $\varepsilon \diamond \tau$ is the contraction matrix in which all the non-null elements are 1 and we find that the set $N(\mathfrak{g}^n)$ of all normalized contraction matrices of $\mathfrak{f}^n$ has 2^{n-2} elements.

Now, we are going to study, as a particular example, the case of a non-model filiform Lie algebra.

6 Graded contractions of the 6-dimensional filiform Lie algebra Q_6

Let $\mathcal{Q}_6$, defined by the law $[e_1,e_k] = e_{k+1}$, for $2 \leq k \leq 5$, $[e_2,e_5] = -e_6$ and $[e_3,e_4] = e_6$ be the filiform Lie algebra of dimension 6. A grading of $\mathcal{Q}_6$ is given by

$$\Gamma : \mathcal{Q}_6 = Q^6_{(1,0)} \oplus Q^6_{(0,1)} \oplus Q^6_{(1,1)} \oplus Q^6_{(2,1)} \oplus Q^6_{(3,1)} \oplus Q^6_{(3,2)}$$

By proceeding in a similar way as in previous sections, we have that the universal group of $\mathcal{Q}_6$ is $\mathbb{Z}_4 \otimes \mathbb{Z}_3$. Besides, $\mathcal{Q}^6_{(1,0)} = \langle e_1 + e_2 \rangle$, $Q_{(0,1)} = \langle e_2 \rangle$, $\mathcal{Q}^6_{(1,1)} = \langle e_3 \rangle$, $\mathcal{Q}^6_{(2,1)} = \langle e_4 \rangle$, $\mathcal{Q}^6_{(3,1)} = \langle e_5 \rangle$ and $\mathcal{Q}^6_{(3,2)} = \langle e_6 \rangle$.

Let now consider

$$H_{\Pi_6} = \begin{pmatrix} 1 & 0 \\ 2\,a & 1 \end{pmatrix}, \text{ with } a \in \mathbb{Z}_4 \text{ and } \mathrm{I} = \{(1,0),(0,1),(1,1),(2,1),(3,1),(3,2)\}.$$

The considered order O on I is $\{1 \to (1,0); 2 \to (0,1); 3 \to (1,1); 4 \to (2,1); 5 \to (3,1); 6 \to (3,2)\}$. The tables now obtained for the elements of I and the orbits of the points of I_u^2 and I_u^3 are the following

Represented by the points	Orbits
$(1,0)$	$(1,0)$
$(0,1)$	$(0,1),(2,1)$
$(1,1)$	$(1,1),(3,1)$
$(3,2)$	$(3,2)$

 ISBN: 978-84-617-8694-7

Orbits of the 15 points of I_u^2

Orbit	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1)),((1,0)(2,1))$
$((1,0)(1,1))$	$((1,0)(1,1)),((1,0)(3,1))$
$((1,0)(3,2))$	$((1,0)(3,2))$
$((0,1)(1,1))$	$((0,1)(1,1)),((2,1)(3,1))$
$((0,1)(2,1))$	$((0,1)(2,1))$
$((0,1)(3,1))$	$((0,1)(3,1)),((2,1)(1,1))$
$((0,1)(3,2))$	$((0,1)(3,2)),((2,1)(3,1))$
$((1,1)(3,2))$	$((1,1)(3,2)),((3,1)(3,2))$
$((1,1)(3,1))$	$((1,1)(3,1))$

Orbits of the 20 points of I_u^3

$((1,0)(0,1)(2,1))$	$((1,0)(0,1)(2,1))$
$((1,0)(0,1)(3,1))$	$((1,0)(0,1)(3,1)),((1,0)(2,1)(1,1))$
$((1,0)(1,1)(3,1))$	$((1,0)(1,1)(3,1))$
$((1,0)(1,1)(3,2))$	$((1,0)(1,1)(3,2)),((1,0)(3,1)(3,2))$
$((1,0)(0,1)(3,2))$	$((1,0)(0,1)(3,2)),((1,0)(2,1)(3,2))$
$((0,1)(1,1)(2,1))$	$((0,1)(1,1)(2,1)),((2,1)(3,1)(0,1))$
$((0,1)(1,1)(3,1))$	$((0,1)(1,1)(3,1)),((2,1)(3,1)(1,1))$
$((0,1)(1,1)(3,2))$	$((0,1)(1,1)(3,2)),((2,1)(3,1)(3,2))$
$((0,1)(3,1)(3,2))$	$((0,1)(3,1)(3,2)),((2,1)(1,1)(3,2))$
$((1,1)(3,1)(3,2))$	$((1,1)(3,1)(3,2))$
$((0,1)(2,1)(3,2))$	$((0,1)(2,1)(3,2))$

Orbits of the 6 points of $\mathcal{I}$:

Orbit	Represented by the points
$((1,0)(0,1))$	$((1,0)(0,1)),((1,0)(1,1)),((1,0)(2,1)),((1,0)(3,1))$ and $((2,1)(1,1))$

The explicit form of the contraction matrix ε with respect to chosen order O is

$$\begin{pmatrix} 0 & \varepsilon_{(1,0)(0,1)} & \varepsilon_{(1,0)(1,1)} & \varepsilon_{(1,0)(2,1)} & 0 & 0 \\ \varepsilon_{(1,0)(0,1)} & 0 & 0 & 0 & 0 & 0 \\ \varepsilon_{(1,0)(1,1)} & 0 & 0 & \varepsilon_{(1,1)(2,1)} & 0 & 0 \\ \varepsilon_{(1,0)(2,1)} & 0 & \varepsilon_{(1,1)(2,1)} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

The conditions for the non-null elements of the contraction matrix are

$$\varepsilon_{(i,j)(k+m,l+n)}\varepsilon_{(k,l)(m,n)}[X_{ij},[X_{kl},X_{mn}]]+\varepsilon_{(k,l)(m+i,n+j)}\varepsilon_{(m,n)(i,j)}[X_{kl},[X_{mn},X_{ij}]]$$

$$+\varepsilon_{(m,n)(i+k,j+l)}\varepsilon_{(i,j)(k,l)}[X_{mn},[X_{ij},X_{kl}]]=0,\forall((i,j)(k,l)(m,n))\in I_u^3.$$

In this case, the following restriction $\varepsilon_{(1,0)(0,1)}\varepsilon_{(1,1)(2,1)}=0$ is obtained.

Moreover, the elements of any contraction matrix verify the following conditions

- If $\varepsilon_{(1,0)(0,1)}\neq 0$, then $\varepsilon_{(1,1)(2,1)}=0$ and the parameters $\varepsilon_{(1,0)(1,1)}$ and $\varepsilon_{(1,0)(2,1)}$ could be null. So, there are 2^2 different types of contraction matrices with $\varepsilon_{(1,0)(0,1)}\neq 0$.

 ISBN: 978-84-617-8694-7

- If $\varepsilon_{(1,0)(0,1)} = 0$, then the parameters $\varepsilon_{(1,0)(1,1)}$, $\varepsilon_{(1,0)(2,1)}$ y $\varepsilon_{(1,1)(2,1)}$ could be null. So, there are 2^3 different types of contraction matrices with $\varepsilon_{(1,0)(0,1)} = 0$.

If $\varepsilon = (\varepsilon_{ij})$ is a contraction matrix, then $\tau = (\tau_{ij})$, such that $\tau_{ij} = \frac{1}{\varepsilon_{ij}}$ if $\varepsilon_{ij} \neq 0$ or $\tau_{ij} = 0$, if $\varepsilon_{ij} = 0$ is also a contraction matrix. Moreover, $\varepsilon \diamond \tau$ is the contraction matrix in which all the non-null elements are 1. That matrix is the normalized contraction matrix of ε. If we denote by $N(\mathcal{Q}_6)$ to the set of all normalized contraction matrices of $\mathcal{Q}_6$, we find that this set has 12 elements.

7 Certain conclusions

In our research we have obtained the graded contractions of some lower-dimensional filiform Lie algebra, concretely, of the model filiform Lie algebras of dimensions $3, 4, 5$ and 6, although in this paper only the two first cases are shown, due to reasons of length. Then, as a consequence of the results obtained, we have dealt with the general case n-dimensional for this type of algebras. Moreover, we have repeated this study for the dimension 6 with a non-model filiform Lie algebra.

Two have been the reasons for the authors to deal with this subject. The first of them is to complete previous papers by different authors, like Inönü and Wigner [3] in 1953, Weimar-Woods [7] in 2006 or Bahturin, Goze and Remm [1] in 2013, for instance.

The second one is the possibility of setting new theoretical results on it. Indeed, as consequences of this study, we find some question which could make us think of giving an answer to the following facts, thereby determining some conjectures. For instance: a) will have the orbits of I_u^2, for the filiform Lie algebras $\mathfrak{f}_5$ and $\mathfrak{f}_6$, the same representatives? Have these orbits 4 points at most? b) have the contraction matrices of the filiform Lie algebras $\mathfrak{f}_n$ and Q_n an unique null relevant contraction parameter? and c) which is the form of the symmetry groups of filiform Lie algebras $\mathfrak{f}_n$ and Q_n?

We hope to give responses to these questions in future work.

Abstract

We use an auxiliary point in the analysis of the semilocal convergence of Newton's method under center conditions on high order derivatives of the operator involved and use the majorant principle of Kantorovich to do it.

Key words: Newton's method, semilocal convergence, majorant principle
MSC 2000: 47H99, 65H10, 65J15

1 Introduction

The application of Newton's method to solve nonlinear equations has a long history and different types of conditions has been used over the past years to analyse the semilocal convergence of the method. Remember that semilocal convergence results for iterative methods, in general, and, for Newton's method, in particular, require conditions on the starting points and conditions on the operator involved. Different types of conditions on the operator can be required as we can see in the mathematical literature, but, if we pay attention to center conditions on the operator, we see that the starting points are used to center the conditions on the first or second derivative of the operator. In this work, we propose to require conditions on higher order derivatives of the operator and on an auxiliary point different from the starting point of Newton's method.

For the last, we consider a nonlinear operator $F : \Omega \subseteq X \to Y$ defined on a nonempty open convex domain Ω of a Banach space X with values in a Banach space Y in order to give sufficient generality to our study, so that problems from computational sciences, physics and other disciplines can be brought into the equation $F(x) = 0$ by using mathematical modelling, so that the unknowns of this equation can be functions (difference, differential, and integral equations), vectors (systems of linear or nonlinear algebraic equations), or real/complex numbers (single algebraic equations with single unknowns).

 ISBN: 978-84-617-8694-7

2 Preliminaries

The algorithm of Newton's method for solving equation $F(x) = 0$ is:

$$x_0 \in \Omega, \quad x_{n+1} = x_n - [F'(x_n)]^{-1} F(x_n), \quad n \geq 0,$$

and the first semilocal convergence result given for Newton's method in Banach spaces is due to the Russian mathematician L. V. Kantorovich, who proves, at the beginning of the 50s of the last century, the semilocal convergence of Newton's method using "the majorant principle" and under the following conditions [3]:

(K1) There exists $\Gamma_0 = [F'(x_0)]^{-1} \in \mathcal{L}(Y, X)$, for some $x_0 \in \Omega$, with $\|\Gamma_0\| \leq \beta$ and $\|\Gamma_0 F(x_0)\| \leq \eta$, where $\mathcal{L}(Y, X)$ is the set of bounded linear operators from Y to X,

(K2) $\|F''(x)\| \leq M$ for $x \in \Omega$,

(K3) $M\beta\eta \leq \frac{1}{2}$.

From that moment, a plethora of studies on the weakness and/or extension of conditions (K1)–(K3) have been made.

Focusing on center conditions on F, we underline the papers of Gutiérrez [1] and Gutiérrez and Hernández [2], where semilocal convergence results under conditions of type

$$\|F''(x) - F''(x_0)\| \leq L_0 \|x - x_0\|, \quad L_0 \geq 0, \quad x \in \Omega,$$

or

$$\|F'(x) - F'(x_0)\| \leq K_0 \|x - x_0\|, \quad K_0 \geq 0, \quad x \in \Omega,$$

are respectively given. In this work, we propose to study the semilocal convergence of Newton's method under conditions of the last two types, but with two significant variants: derivatives of higher order than two and center conditions on an auxiliary point $\widetilde{x}$ instead of on the starting point x_0; in particular, under a condition of type

$$\|F^{(k)}(x) - F^{(k)}(\widetilde{x})\| \leq \omega(\|x - \widetilde{x}\|), \quad x \in \Omega,$$

where $k \geq 3$ and $\omega : [0, +\infty) \to \mathbb{R}$ is a nondecreasing continuous function such that $\omega(0) = 0$. This variant of the previous known conditions leads us to modify the domain of starting points for Newton's method, so that we can guarantee the semilocal convergence of the method from starting at points where other results fail.

3 The majorant principle

To prove the semilocal convergence of Newton's method, we consider the conditions

(C1) There exists the operator $\Gamma_0 = [F'(x_0)]^{-1} \in \mathcal{L}(Y, X)$ with $\|\Gamma_0\| \leq \beta$ and $\|\Gamma_0 F(x_0)\| \leq \eta$; moreover, $\|F^{(i)}(x_0)\| \leq b_i$ with $i = 2, 3, \ldots, k-1$ and $k \geq 3$,

(C2) There exists $\widetilde{x} \in \Omega$ such that $\|x_0 - \widetilde{x}\| = \gamma$, where $x_0 \in \Omega$, and $\|F^{(k)}(\widetilde{x})\| \leq \delta$,

(C3) There exists a nondecreasing continuous function $\omega : [0, +\infty) \longrightarrow \mathbb{R}$ such that $\|F^{(k)}(x) - F^{(k)}(\widetilde{x})\| \leq \omega(\|x - \widetilde{x}\|)$ for $x \in \Omega$ and $\omega(0) = 0$,

and use "the majorant principle" of Kantorovich, that consists of looking a scalar sequence $\{t_n\}$,

$$t_0 = 0, \quad t_{n+1} = t_n - \frac{f(t_n)}{f'(t_n)}, \quad n \geq 0,$$

that *majorizes* Newton's sequence $\{x_n\}$ in the Banach space X. As a consequence of this fact, the convergence of $\{x_n\}$ follows immediately from the convergence of $\{t_n\}$, see [3].

So, we then look for a real function $f \in \mathcal{C}^j([\widetilde{t}, +\infty))$, with $\widetilde{t} \in \mathbb{R}_+$ and $j \geq k$, such that

$$\|F^{(k)}(x) - F^{(k)}(\widetilde{x})\| \leq f^{(k)}(t) - f^{(k)}(\widetilde{t}) \text{ with } \|x - \widetilde{x}\| \leq t - \widetilde{t}, x \in \Omega \text{ and } t \in [\widetilde{t}, +\infty).$$

So, from (C3) and the last, it follows

$$\|F^{(k)}(x) - F^{(k)}(\widetilde{x})\| \leq \omega(\|x - \widetilde{x}\|) \leq \omega(t - \widetilde{t}) = f^{(k)}(t) - f^{(k)}(\widetilde{t})$$

if $\|x - \widetilde{x}\| \leq t - \widetilde{t}$, since ω is a nondecreasing continuous function, and then

$$f^{(k)}(t) = f^{(k)}(\widetilde{t}) + \omega(t - \widetilde{t}).$$

In addition, if we consider $\widetilde{t} = -\gamma$, $f^{(k)}(\widetilde{t}) = \delta$ and take into account (C1)-(C2), we can solve the initial value problem

$$\begin{cases} y^{(k)}(t) = \delta + \omega(t + \gamma), \\ y(0) = \dfrac{\eta}{\beta}, \quad y'(t_0) = -\dfrac{1}{\beta}, \\ y''(0) = b_2, \quad y'''(0) = b_3, \quad \ldots, \quad y^{(k-1)}(0) = b_{k-1}, \end{cases}$$

to find $f(t)$, since we can choose, from (C1), $-\frac{1}{f'(0)} = \beta$, $-\frac{f(0)}{f'(0)} = \frac{\eta}{\beta}$ and $f^{(i)}(0) = b_i$, for $i = 2, 3, \ldots, k-1$. So, next result is given.

Theorem 1. *Suppose that the function $\omega(t + \gamma)$ is continuous in $[0, +\infty)$. Then, for any nonnegative real numbers γ, δ, $\beta \neq 0$, η, $b_2, b_3, \ldots, b_{k-1}$, the last initial value problem has a unique solution $f(t) \in \mathcal{C}^j([-\gamma, +\infty))$, with $j \geq k \geq 3$, which is given by*

$$f(t) = \int_0^t \int_0^{\theta_{k-1}} \cdots \int_0^{\theta_1} \omega(s + \gamma)\, ds\, d\theta_1 \cdots d\theta_{k-1} + \frac{\delta}{k!} t^k + \sum_{i=2}^{k-1} \frac{b_i}{i!} t^i - \frac{t}{\beta} + \frac{\eta}{\beta}.$$

 ISBN: 978-84-617-8694-7

4 Semilocal convergence

In the following result, we prove that the sequence $\{t_n\}$, defined from the function $f(t)$ given in Theorem 1, majorizes sequence $\{x_n\}$ in the Banach space X.

Theorem 2. *Let X and Y be two Banach spaces and $F : \Omega \subseteq X \longrightarrow Y$ a nonlinear q ($q \geq 2$) times continuously differentiable operator on a nonempty open convex domain Ω and $f(t)$ be function defined in Theorem 1. Suppose that conditions (C1)–(C3) are satisfied, there exists a root $\alpha > 0$ of $f'(t) = 0$ such that $f(\alpha) \leq 0$, and $B(x_0, t^*) \subset \Omega$, where t^* is the smallest positive root of $f(t) = 0$. Then, Newton's sequence $\{x_n\}$ satisfies:*

$$\|x_n - x_{n-1}\| \leq t_{n+1} - t_n, \quad \text{for all} \quad n \geq 0.$$

Once we have proved that $\{t_n\}$ majorizes $\{x_n\}$, we can prove the semilocal convergence of $\{x_n\}$ in the Banach space X.

Theorem 3. *Let X and Y be two Banach spaces and $F : \Omega \subseteq X \longrightarrow Y$ a nonlinear q ($q \geq 2$) times continuously differentiable operator on a nonempty open convex domain Ω and $f(t)$ be function defined in Theorem 1. Suppose that conditions (C1)–(C3) are satisfied, there exists a root $\alpha > 0$ of $f'(t) = 0$ such that $f(\alpha) \leq 0$, and $B(x_0, t^*) \subset \Omega$, where t^* is the smallest positive root of $f(t) = 0$. Then, Newton's sequence $\{x_n\}$ converges to a solution x^* of $F(x) = 0$ starting at x_0. Moreover, $x_n, x^* \in \overline{B(x_0, t^*)}$ and*

$$\|x^* - x_n\| \leq t^* - t_n, \quad \text{for all} \quad n \geq 0.$$

where $t_n = t_{n-1} - \frac{f(t_{n-1})}{f'(t_{n-1})}$, with $n \in \mathbb{N}$ and $t_0 = 0$.

Abstract

Conjugacy and orthogonality of Latin squares have been widely studied in the literature not only for their theoretical interest in combinatorics, but also for their applications in distinct fields as experimental design, cryptography or code theory, amongst others. This paper deals with a series of binary constraints that characterize the sets of partial Latin squares of a given order for which their six conjugates either coincide or are all of them distinct and pairwise orthogonal. These constraints enable us to make use of a SAT solver to enumerate both sets. As an illustrative application, it is also exposed a method to construct totally symmetric partial Latin squares that gives rise, under certain conditions, to new families of Lie partial quasigroup rings.

Key words: Partial Latin square, conjugacy, orthogonality.
MSC 2000: 05B15, 20N05.

1 Introduction

A *quasigroup* [22] is a pair $(S, \cdot)$ formed by a nonempty set S endowed with a product $\cdot$ such that, if any two of the three symbols a, b and c in the equation $a \cdot b = c$ are given as elements of S, then the third one is uniquely determined. The size of S is the *order* of the quasigroup. The multiplication table of a quasigroup of order n constitutes a *Latin square* of the same order, that is, an $n \times n$ array in which each cell contains one symbol chosen from the set S, such that each symbol occurs exactly once in each row and in each column. The number of Latin squares is known [24, 26, 29, 30] for order up to 11.

Bruck [12] introduced the concept of *totally symmetric quasigroup* as a quasigroup $(S, \cdot)$ for which the equation $a \cdot b = c$ remains valid under every permutation of the three symbols $a, b, c \in S$. There exist six such permutations and each one of them gives rise to a new quasigroup, which is said to be *conjugate* to $(S, \cdot)$. Hence, a quasigroup is totally symmetric if its six conjugates coincide. If besides, the quasigroup is *idempotent*, that is, if $a \cdot a = a$, for all $a \in S$, then this notion is equivalent to that of a *Steiner triple system*. The distribution of totally symmetric quasigroups and Steiner triple systems into isomorphism classes is known [1, 25] for orders up to 10 and 19, respectively.

Two quasigroups of order n are said to be *orthogonal* if the juxtaposition of their corresponding multiplication tables gives rise to an $n \times n$ array containing n^2 distinct ordered pairs. Stein [34] posed the problem of constructing a quasigroup or Latin square that is orthogonal to one of its conjugates. It is known in this regard [6, 7, 11, 31] the existence of quasigroups that are orthogonal to the conjugate under consideration, distinct of themselves, for any order $n \notin \{2, 3, 6\}$. Much more recently, Bennett and Zhang [10] dealt with Latin squares for which each one of their conjugates is orthogonal to its transpose. They proved the existence of such Latin squares for all prime powers $n \notin \{2, 3, 5\}$. Further, Lindner et al. [28] focused on idempotent Latin squares for which their six conjugates are distinct and pairwise orthogonal. They proved in particular the existence of such Latin squares for every order being a prime power $n \geq 8$ and also for all sufficiently large orders n. Bennett [4] established $n > 5594$ as an upper bound for this last condition except possibly $n = 6810$, and enumerate a series of smaller orders for which these Latin squares also exist. Four years later, he improved [5] the previous upper bound to $n > 5074$. Much more recently, Belyavskaya and Popovich [3] introduced the equivalent notion of *totally conjugate orthogonal quasigroup* as a quasigroup for which its six conjugates are distinct and pairwise orthogonal. They proved the existence of such quasigroups for any order $n \geq 11$ that is relatively prime to 2, 3, 5, and 7. Their motivation to study this kind of quasigroups was mainly based on their application in error detecting codes [2].

The concept of quasigroup is straightforwardly generalized to that of *partial quasigroup* of order n, for which (a) the law $\cdot$ is a partial binary operation on a finite set S of n elements, and (b) if the equations $a \cdot x = b$ and $y \cdot a = b$, with $a, b \in S$, have solutions for x and y in S, then these solutions are unique. The multiplication table of a partial quasigroup of order n constitutes a *partial Latin square* of the same order, that is, an $n \times n$ array in which each cell is either empty or contains one element chosen from S, such that each symbol occurs at most once in each row and in each column. The number of partial Latin squares is known [17, 18, 19, 20] for order up to seven.

Since Evans [15] introduced the problem of embedding a partial quasigroup of order n into a quasigroup of order $2n$, a wide amount of authors have dealt with the embedding of distinct types of partial quasigroups; particularly, that of a partial totally symmetric quasigroup into a totally symmetric quasigroup [13, 27, 32, 33]. Further, the orthogonality

 ISBN: 978-84-617-8694-7

among conjugates of a partial Latin square was indirectly contemplated [8, 9, 23] by focusing on the existence of incomplete Latin squares that are orthogonal to one of their conjugates and have an empty subsquare that can be filled by means of a Latin square that is orthogonal in turn to its corresponding conjugate. A more general case was recently proposed by the first author [18], who makes use of computational algebraic geometry to enumerate the set of self-orthogonal partial Latin squares of order $n \leq 4$. This paper delves into this topic by dealing with the sets of partial Latin squares of a given order for which their six conjugates either coincide or are all of them distinct and pairwise orthogonal, respectively. In order to improve the computational efficiency, it is proposed to focus on techniques to solve Boolean satisfiability problems instead of those on algebraic geometry.

As an illustrative application of the exposed study, we also delve into a recent work developed by the authors [16] about the enumeration of partial quasigroup rings over finite fields derived from partial Latin squares. Bruck [12] introduced the concept of *quasigroup ring* related to a quasigroup $(S, \cdot)$ as an algebra of basis $\{e_a \mid a \in S\}$ over a base field $\mathbb{K}$ such that $e_a e_b = e_{a \cdot b}$, for all $a, b \in S$. This concept is straightforwardly generalized to that of *partial quasigroup ring* in case of being the pair $(S, \cdot)$ a partial quasigroup. In this paper, we describe a totally symmetric partial Latin square of order $3n$, derived from a given partial Latin square of order n, that enables us to introduce in turn a Lie partial quasigroup ring over a finite field of characteristic two.

The paper is organized as follows. In Section 2, we expose some preliminary concepts and results on partial Latin squares that are used throughout our study. In Section 3, we introduce a pair of series of binary constraints that characterize, respectively, the sets of totally symmetric and totally conjugate orthogonal partial Latin squares of given order and weight. Finally, Section 5 deals with an illustrative example that enables us to construct a family of Lie partial quasigroup rings from a totally symmetric partial Latin square satisfying certain conditions.

2 Preliminaries

This section deals with some basic concepts and notations on partial Latin squares that are used throughout the paper. We refer the reader to the monographs of Dénes and Keedwell [14] for more details about this topic.

Hereafter, the set of partial Latin squares of order n is denoted as PLS_n, whereas the set of symbols of any such a partial Latin square $P = (p_{ij}) \in \mathrm{PLS}_n$ is assumed to be the set $[n] = \{1, \ldots, n\}$. An *entry* of P is any triple $(i, j, p_{i,j}) \in [n] \times [n] \times [n]$. The partial Latin square P is uniquely determined by the set of all its entries, which is called its *entry set* and denoted as $E(P)$. The size of this set coincides, therefore, with the number of non-empty cells of P, which constitutes its *weight*. From here on, $\mathrm{PLS}_{n;m}$ denotes the set of partial Latin squares of order n having weight m. Thus, for instance, the partial

 ISBN: 978-84-617-8694-7

Latin square P in Figure 1 belongs to the set $\mathrm{PLS}_{3;4}$ and has as entry set the set $E(P) = \{(1,1,2),(1,2,1),(2,1,1),(3,3,3)\}$.

$$P \equiv \begin{array}{|c|c|c|}\hline 2 & 1 & \\ \hline 1 & & \\ \hline & & 3 \\ \hline \end{array}$$

Figure 1: Partial Latin square in $\mathrm{PLS}_{3;4}$.

Let S_3 denote the symmetric group of three elements. Let P be a partial Latin square in $\mathrm{PLS}_{n;m}$ and let π be a permutation in S_3. The π-*conjugate* of P is defined as the partial Latin square $P^\pi \in \mathrm{PLS}_{n;m}$ such that $E(P^\pi)\{(p_{\pi(1)}, p_{\pi(2)}, p_{\pi(3)}) \colon (p_1,p_2,p_3) \in E(P)\}$. There exist, therefore, six conjugates: $P^{\mathrm{Id}} = P$, $P^{(12)} = P^t$, $P^{(13)}$, $P^{(23)}$, $P^{(123)} = (P^{(23)})^t$ and $P^{(132)} = (P^{(13)})^t$, where the notation ^{t} denotes the transpose of the corresponding partial Latin square. In order to illustrate these conjugates, let us consider the partial Latin square $P \in \mathrm{PLS}_{3;4}$ in Figure 2. Particularly, $E(P) = \{(1,1,1),(1,2,2),(2,2,3),(3,3,1)\}$ and hence, once the corresponding permutations among the three components of each entry are done, we obtain the conjugates therein exposed. Observe that all of them are distinct. Figure 1 shows instead a partial Latin square in $\mathrm{PLS}_{3;4}$ for which all its conjugates coincide. In this case, the partial Latin square under consideration is said to be *totally symmetric*. Hereafter, the set of totally symmetric partial Latin squares of order n and its subset of partial Latin squares of weight m are respectively denoted as TSPLS_n and $\mathrm{TSPLS}_{n;m}$.

$$P \equiv \begin{array}{|c|c|c|}\hline 1 & 2 & \\ \hline & 3 & \\ \hline & & 1 \\ \hline \end{array} \qquad P^{(12)} \equiv \begin{array}{|c|c|c|}\hline 1 & & \\ \hline 2 & 3 & \\ \hline & & 1 \\ \hline \end{array} \qquad P^{(13)} \equiv \begin{array}{|c|c|c|}\hline 1 & & 3 \\ \hline & 1 & \\ \hline & 2 & \\ \hline \end{array}$$

$$P^{(23)} \equiv \begin{array}{|c|c|c|}\hline 1 & 2 & \\ \hline & & 2 \\ \hline 3 & & \\ \hline \end{array} \qquad P^{(123)} \equiv \begin{array}{|c|c|c|}\hline 1 & & 3 \\ \hline 2 & & \\ \hline & 2 & \\ \hline \end{array} \qquad P^{(132)} \equiv \begin{array}{|c|c|c|}\hline 1 & & \\ \hline & 1 & 2 \\ \hline 3 & & \\ \hline \end{array}$$

Figure 2: Partial Latin square in $\mathrm{PLS}_{3;4}$ and its conjugates.

Let $P = (p_{ij})$ and $Q = (q_{ij})$ be two partial Latin squares of order n. They are said to be *orthogonal* if all the ordered pairs on non-empty entries that are obtained when both arrays are superimposed are distinct. Equivalently, given $i, i', j, j' \in [n]$ such that $p_{ij} = p_{i'j'} \in [n]$, then q_{ij} and $q_{i'j'}$ are not the same symbol of $[n]$. Thus, for instance, the partial Latin squares P and $P^{(13)}$ in Figure 2 are orthogonal, but the partial Latin squares P and $P^{(12)}$ in the same figure are not. In this regard, given a permutation $\pi \in S_3 \setminus \{\mathrm{Id}\}$, a partial Latin square $P \in \mathrm{PLS}_n$ is said to be π-*orthogonal* if it is orthogonal to its π-conjugate.

 ISBN: 978-84-617-8694-7

Particularly, if $\pi = (12)$, then P is said to be *self-orthogonal*. Thus, for instance, the partial Latin square $P^{(23)}$ in Figure 2 is self-orthogonal. Finally, we say that a partial Latin square is *totally conjugate orthogonal* if its six conjugates are distinct and pairwise orthogonal. This is the case, for instance, of the partial Latin square shown in Figure 3. From here on, the set of totally conjugate orthogonal partial Latin squares of order n and its subset of partial Latin squares of weight m are respectively denoted as TCOPLS_n and $\mathrm{TCOPLS}_{n;m}$.

$$P \equiv \begin{array}{|c|c|c|}\hline & & 3 \\ \hline & & 2 \\ \hline 1 & 3 & \\ \hline \end{array} \quad P^{(12)} \equiv \begin{array}{|c|c|c|}\hline & & 1 \\ \hline & & 3 \\ \hline 3 & 2 & \\ \hline \end{array} \quad P^{(13)} \equiv \begin{array}{|c|c|c|}\hline 3 & & \\ \hline & & 2 \\ \hline & 3 & 1 \\ \hline \end{array}$$

$$P^{(23)} \equiv \begin{array}{|c|c|c|}\hline & & 3 \\ \hline & 3 & \\ \hline 1 & & 2 \\ \hline \end{array} \quad P^{(123)} \equiv \begin{array}{|c|c|c|}\hline & & 1 \\ \hline & 3 & \\ \hline 3 & & 2 \\ \hline \end{array} \quad P^{(132)} \equiv \begin{array}{|c|c|c|}\hline 3 & & \\ \hline & & 3 \\ \hline & 2 & 1 \\ \hline \end{array}$$

Figure 3: Totally conjugate orthogonal partial Latin square in $\mathrm{PLS}_{3;4}$.

The set PLS_n is identified [18] with the set of zeros of the following system of equations in the set of n^3 variables $\{X\} = \{x_{ijk} \mid i, j, k \in [n]\}$.

$$\begin{cases} x_{ijk}x_{i'jk} = 0, \text{ for all } i, i', j, k \leq n \text{ such that } i \neq i', \\ x_{ijk}x_{ij'k} = 0, \text{ for all } i, j, j', k \leq n \text{ such that } j \neq j', \\ x_{ijk}x_{ijk'} = 0, \text{ for all } i, j, k, k' \leq n \text{ such that } k \neq k', \\ x_{ijk} \in \{0, 1\}, \text{ for all } i, j, k \leq n. \end{cases} \tag{1}$$

Specifically, every partial Latin square $P = (p_{ij}) \in \mathrm{PLS}_n$ is uniquely identified with a zero $(x_{111}, \ldots, x_{nnn})$, where $x_{ijk} = 1$ if $p_{ij} = k$ and 0, otherwise. Hereafter, in order to avoid degeneracy, partial Latin squares are assumed to have at least one entry in each row, at least one entry in each column, and at least one copy of each symbol. To get this condition, the following inequations are added to (1)

$$\begin{cases} \sum_{j,k\in[n]} x_{ijk} \geq 1, \text{ for all } i \in [n], \\ \sum_{i,k\in[n]} x_{ijk} \geq 1, \text{ for all } j \in [n], \\ \sum_{i,j\in[n]} x_{ijk} \geq 1, \text{ for all } k \in [n]. \end{cases} \tag{2}$$

Based on (1) and (2), we establish in Section 3 some equations to deal, respectively, with the sets TSPLS_n and TCOPLS_n. To this end, let us introduce the following notation

$$x^{\pi}_{i_1 i_2 i_3} := x_{i_{\pi(1)} i_{\pi(2)} i_{\pi(3)}},$$

for all $\pi \in S_3$ and $x_{i_1 i_2 i_3} \in \{X\}$. Besides, we label the six permutations in S_3 as

$$S_3 := \{\pi_1 = \mathrm{Id}, \pi_2 = (12), \pi_3 = (13), \pi_4 = (23), \pi_5 = (123), \pi_6 = (132)\}.$$

3 Binary constraints related to the sets TSPLS_n and TCOPLS_n

This section deals with a series of binary constraints that characterize the sets of totally symmetric and totally conjugate orthogonal partial Latin squares of given order and weight.

Lemma 3.1. *Let n and m be two positive integers such that $n \leq m \leq n^2$.*

a) If $m > n$, then every pair of orthogonal conjugates of a partial Latin square in the set $\mathrm{TCOPLS}_{n;m}$ are distinct.

b) If $|\mathrm{TCOPLS}_{n;m}| = 0$, then $|\mathrm{TCOPLS}_{n;m'}| = 0$, for all $m' \in \{m+1, \ldots, n^2\}$.

Proof. Let us prove each statement separately.

a) Let $P \in \mathrm{PLS}_{n;m}$ and $\pi, \pi' \in S_3$ be such that $\pi \neq \pi'$ and $P^\pi = P^{\pi'}$. Since $m > n$, there exists one symbol $k \in [n]$ and a distinct pair of elements (i_1, j_1) and, (i_2, j_2) in $[n] \times [n]$ such that $\{(i_1, j_1, k), (i_2, j_2, k)\} \subseteq E(P^\pi) \cap E(P^{\pi'})$. As a consequence, $P^\pi = P^{\pi'}$ is not orthogonal to itself.

b) Otherwise, the partial Latin square that results after emptying any $m' - m$ filled cells of the partial Latin square in $\mathrm{TCOPLS}_{n;m'}$ would be in $\mathrm{TCOPLS}_{n;m}$, which is a contradiction. □

Proposition 3.2. *Let n and m be two positive integers such that $n < m \leq n^2$. Then,*

a) The set TSPLS_n is identified with the set of zeros of (1)–(2) and

$$x_{ijk}^{\pi_s} = x_{ijk}, \text{ for all } i, j, k \in [n] \text{ and } s \in \{1, 2, 3\}. \tag{3}$$

b) The set $\mathrm{TSPLS}_{n;m}$ is identified with the set of zeros of (1)–(3) and

$$\sum_{i,j,k \in [n]} x_{ijk} \leq m. \tag{4}$$

c) The set TCOPLS_n is identified with the set of zeros of (1)–(2) and

$$x_{ijp}^{\pi_s} x_{klp}^{\pi_s} x_{ijq}^{\pi_t} x_{klq}^{\pi_t} = 0, \text{for all } i, j, k, l, p, q \leq n; s, t \leq 3; \text{ such that } (i, j) \neq (k, l), s \leq t. \tag{5}$$

d) The set $\mathrm{TCOPLS}_{n;m}$ is identified with the set of zeros of (1), (2), (4) and (5).

Proof. The result follows straightforwardly from the definitions exposed in Section 2 once each partial Latin square $P = (p_{ij}) \in \mathrm{PLS}_{r,s,n}$ is identified with a zero $(x_{111}, \ldots, x_{rsn})$ such that $x_{ijk} = 1$ if $p_{ij} = k$ and 0, otherwise. Thus, for instance, if we focus on the proof of statement (c), then, given $1 \leq s < t \leq 3$, the system of equations determined by (5) involves the π_s^{-1}- and π_t^{-1}-conjugates of P to be orthogonal. Besides, from Lemma 3.1.a, both conjugates are distinct. □

4 Lie partial quasigroup rings derived from the conjugate-extension of a partial Latin square

The inclusion of new binary constraints into (1)–(5) enables us to determine families of partial Latin squares in the sets TSPLS_n and TCOPLS_n with possible applications in distinct fields. As an illustrative example, we conclude this paper by describing in this section a new family of Lie partial quasigroup rings related to a totally symmetric partial Latin square of order $3n$, which is derived in turn from a given partial Latin square of order n. Recall that a *Lie algebra* is an anti-commutative algebra A that holds the so-called *Jacobi identity*

$$J(a,b,c) := (ab)c + (bc)a + (ca)b = 0, \text{ for all } a,b,c \in A. \tag{6}$$

 ISBN: 978-84-617-8694-7

n	m	Run time (seconds) $\mathrm{TSPLS}_{n;m}$	Run time (seconds) $\mathrm{TCOPLS}_{n;m}$
5	5	0	22
	10	0	3
6	6	0	8561
	12	0	10
	15	0	74
10	10	69	Out of memory
	50	0	”
15	15	> 3 hours	”
	60	2	”
20	100	Out of memory	”

Table 2: Run times required to get exactly one totally symmetric or totally conjugate orthogonal partial Latin square of a given order and weight.

Let $P = (p_{ij}) \in \mathrm{PLS}_{n;m}$. We define the $n \times n$ arrays $P' = (p'_{ij})$ and $P'' = (p''_{ij})$ such that

$$p'_{ij} := \begin{cases} p_{ij} + n, \text{ if } p_{ij} \in [n], \\ 0, \text{ otherwise.} \end{cases} \quad \text{and} \quad p''_{ij} := \begin{cases} p_{ij} + 2n, \text{ if } p_{ij} \in [n], \\ 0, \text{ otherwise.} \end{cases} \tag{7}$$

Then, we define the partial Latin square $\overline{P} = (\overline{p}_{ij}) \in \mathrm{PLS}_{3n;6m}$ by means of nine $n \times n$ blocks as

$$\overline{P} :\equiv \begin{array}{|c|c|c|} \hline \mathbf{0} & P'' & P'^{(23)} \\ \hline P''^{(12)} & \mathbf{0} & P^{(132)} \\ \hline P'^{(123)} & P^{(13)} & \mathbf{0} \\ \hline \end{array} \tag{8}$$

where $\mathbf{0}$ denotes the $n \times n$ array with all its entries being zero. We call this new partial Latin square the *conjugate-extension* of P. Thus, for instance, Figure 4 shows the conjugate-extension of the partial Latin square exposed in Figure 2.

Lemma 4.1. *If $P \in \mathrm{PLS}_{n;m}$, then $\overline{P} \in \mathrm{TSPLS}_{3n;6m}$.*

Proof. The result follows from the entry set $E(\overline{P})$ once we keep in mind (7) and (8). □

Let $A_{\mathbb{K}}(P)$ denote the partial quasigroup ring over a finite field $\mathbb{K}$ of characteristic two that is related to $\overline{P}$. Particularly, we focus on the case of being $P \in \mathrm{TSPLS}_n$. If this is the case, then the definition (8) of the partial Latin square $\overline{P}$ results

$$\overline{P} \equiv \begin{array}{|c|c|c|} \hline \mathbf{0} & P'' & P' \\ \hline P'' & \mathbf{0} & P \\ \hline P' & P & \mathbf{0} \\ \hline \end{array} \tag{9}$$

	5			2				

Figure 4: Conjugate-extension of the partial Latin square $P \in \mathrm{PLS}_3$ of Figure 2.

Theorem 4.2. *Let $\mathbb{K}$ be a finite field of characteristic two and let $P \in \mathrm{TSPLS}_n$ be the multiplication table of a quasigroup $([n], \cdot)$ satisfying the* left invertive law

$$(a \cdot b) \cdot c = (c \cdot b) \cdot a, \text{ for all } a, b, c \in [n]. \tag{10}$$

Then, the partial quasigroup ring $A_{\mathbb{K}}(P)$ is a Lie algebra.

Proof. The symmetry of the partial Latin square $\overline{P} = (\overline{p}_{ij})$, with $p_{ii} = 0$, for all $i \leq 3n$, together with the fact of being $\mathbb{K}$ a finite field of characteristic two, involves $A_{\mathbb{K}}(P)$ to be anti-commutative. Now, in order to prove that the Jacobi identity (6) holds, suppose $\{e_1, \ldots, e_{3n}\}$ to be the basis of $A_{\mathbb{K}}(P)$, which we partition into the three sets $\{e_1, \ldots, e_n\}$, $\{e_{n+1}, \ldots, e_{2n}\}$ and $\{e_{2n+1}, \ldots, e_{3n}\}$. Let $S(e_i)$ denote which one of these three sets contains each basis vector e_i. From (9), we have that, if $S(e_i) = S(e_j)$, then $e_i e_j = 0$. Besides, if $S(e_i) \neq S(e_j)$ and $e_i e_j \neq 0$, then $S(e_i) \neq S(e_i e_j) \neq S(e_j)$. As a consequence, $J(e_i, e_j, e_k) = 0$, for all $i, j, k \leq 3n$ such that the three sets $S(e_i)$, $S(e_j)$ and $S(e_k)$ either coincide or are pairwise distinct. Then, from the symmetry of the Jacobi identity, it is enough to focus on the expression $J(e_i, e_j, e_k)$ in case of being $S(e_i) = S(e_j) \neq S(e_k)$. If this is the case, $e_i e_j = 0$ and hence, $J(e_i, e_j, e_k) = (e_j e_k)e_i + (e_k e_i)e_j = e_{(j \cdot k) \cdot i} + e_{(k \cdot i) \cdot j}$. The result follows from the symmetry of the partial Latin square $\overline{P}$ and the left invertive law. □

Every totally symmetric partial Latin square satisfying (10) constitutes the multiplication table of a partial totally symmetric group. In order to compute this kind of partial Latin squares, we include the following equations to (1)–(4)

$$x_{ijk} x_{kls} x_{ljt} (x_{tis} - 1) = 0, \text{ for all } i, j, k, l, s, t \in [n] \tag{11}$$

$$\left(\sum_{k \leq n} x_{ijk} - 1 \right) \left(\sum_{k \leq n} x_{ljk} \right) x_{ljt} \left(\sum_{k \leq n} x_{tik} \right) = 0, \text{ for all } i, j, l, t \in [n] \tag{12}$$

$$x_{ijk} \left(\sum_{s \leq n} x_{kls} - 1 \right) \left(\sum_{s \leq n} x_{ljs} \right) x_{ljt} \left(\sum_{s \leq n} x_{tis} \right) = 0, \text{ for all } i, j, k, l, t \in [n] \tag{13}$$

 ISBN: 978-84-617-8694-7

The implementation of these equations into our SAT solver determines, for instance, the pair of partial Latin squares exposed in Figure 5, which give rise in turn, according to Theorem 4.2, to a pair of Lie partial quasigroup rings as we have previously described.

Figure 5: Totally symmetric partial Latin squares satisfying the left invertive law.

5 Conclusion and further studies

We have described in this paper a series of binary constraints that enable us to determine the distribution of the sets TSPLS_n and TCOPLS_n of totally symmetric and totally conjugate partial Latin squares of order n, respectively, according to their weights. By means of the SAT solver Minion, we have computed the former, for all $2 \leq n \leq 6$, and the latter, for all $2 \leq n \leq 4$. A further study to improve the efficiency of the proposed method is required to deal with higher orders. Besides, we have introduced the conjugate-extension of a given partial Latin square, which gives rise to a totally symmetric partial Latin square. Particularly, the description of a family of Lie partial quasigroup rings derived from the conjugate-extension of a totally symmetric partial Latin square that holds the left invertive law has enabled us to delve into the open problem of constructing examples of this type of Lie algebras.

Abstract

Advances in High Performance Computing (HPC) have led to an improvement in modelling multi-physic systems because of the capacity to solve complex numerical systems in a reasonable time. WRF-SFIRE is a multi-physics system that couples the atmospheric model WRF and the forest fire spread model called SFIRE with the objective of considering the interactions atmosphere-fire. In systems like WRF-SFIRE, the trade off between result accuracy and time required to deliver that result is crucial. So, in this work, we analyze the influence of the WRF-SFIRE settings (grid resolutions) into the forecasts accuracy and into the execution times on multi-core platform.

Key words: forest fire simulation, multi-physic model, HPC.

1 Introduction

There are several factors that affect the evolution of a wildland fire. It is well known that one of the parameters that most affects forest fire propagation is the wind. Intuitively, the meteorological wind speed and wind velocity tend to drive the main direction and the rate of spread of forest fires. However, in large forest fires that take place in complex terrain where the wind fluxes can vary due to the topography and the wind convections produced by the heat generated by the fire, the effective wind speed and wind direction can

 ISBN: 978-84-617-8694-7

be unpredictable. For that reason, a multi-physics forest fire spread model that considers the feedback between the atmospheric model and the forest fire spread model could capture the micro-weather generated by a large forest fire and provide more accurate wildland fire propagations. However, this improvement in accuracy has a cost in terms of execution time. This limitation could be a serious drawback when trying to use those complex systems as operational tools for being used during a real event. However, the predictability potential of a multi-physic forest fire spread system is supposed to be better than considering the atmosphere and the forest fire as two isolate systems. There are many works that analyze this problem [6] [2] showing that any strategy that takes into account the atmosphere effect into the forest fire evolution provides better forecasted results. In fact, there are three different approaches to tackle this relationship: the unidirectional, the bidirectional and the integration strategy. The unidirectional approach uses static meteorological information, such as wind speed and direction, to drive the fire propagation, but does not consider the effect of the fire on the atmosphere [1] [4]. The second approach, the bidirectional scheme, is a coupled system where the fire propagation considers meteorological information and also on the other way round, so that the effect of heat fluxes from the fire on the atmosphere evolution is also captured [6] [3]. Finally, the third approach, the integration scheme, tries to integrate all the processes using only one simulator which combines everything [5] [7]. In this work, we focuses on the multi-physics system WRF-SFIRE with the aim of analyzing its predictability capacity compared to the time incurred in delivering the results. The main objective is to determine the viability of using WRF-SFIRE as an operational tool. The main constraint of these complex multi-physic systems is their execution time. Fortunately, some of them have been parallelized using different parallel programming paradigms such as OpenMP and MPI. Therefore, an exhaustive analysis about the trade off between results accuracy and time incurred in provide those results should be done.
Section 2 describes the WRF-SFIRE system. In section 3 a real forest fire is used to analyze the time requirements when running on a multi-core platform and the accuracy of the results depending on the WRF-SFIRE initialization settings. Finally, the main conclusions of this work are reported in section 4.

2 WRF-SFIRE

WRF-SFIRE is a forest fire simulator which couples the meteorological model WRF-ARW and the fire spread model resolving Rothermel's equation through the level set method called SFIRE. Particularly, WRF-SFIRE solves the multi-physical problem related to forest fire propagation in a cyclic fashion. That is, meteorological data is obtained by running WRF for a certain period of time and, the obtained WRF data is used to expand the fire front numerically. In order to solve these two models properly, it is necessary to do a discretization of the domain where the hazard is taking place. This domain discretization is done in two

 ISBN: 978-84-617-8694-7

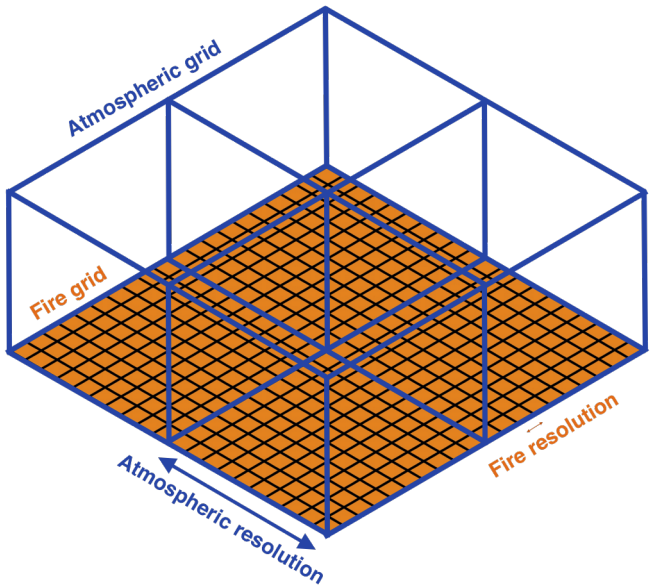

Figure 1: 3D atmospheric grid and 2D fire grid with a mesh ratio of 1:10

different meshes in order to distinguish atmospheric and fire processes. The atmospheric models works on a logically quadrilateral 3D grid on the Earth surface, whereas the fire model uses a refined 2D fire mesh posed in the Earth surface level. The recommended mesh ratio is $1:10$, so the fire grid resolution is 10 times thee atmospheric grid resolution. This grid scheme is depicted in figures 1

In order to capture the small scale meteorological processes, the atmospheric grid resolution should be as small as possible. However, reducing the grid resolution implies to increase the total system points (atmospheric points and, consequently, fire points) what has a direct effect in the WRF-SFIRE execution time. Therefore, the elections of the proper grid resolution is a critical feature to analyze. In the subsequently section, a real case has been used to study this relation, trying to highlight the weak points and the good features in order to determine a trade off among them.

 ISBN: 978-84-617-8694-7

3 Experimental study

The real case analyzed is a forest fire occurred in Catalonia (North-East of Spain) on 8th July 2005. The 2005 Cardona fire burned a total surface of 1439 ha. and it lasted 6 hours. The fire started at 14:30 and it keeps until 20:30 approximately. This particular case was labeled by the firefighter as a forest fire driven by the winds generated by the fire itself, thus, it is a perfect example to show the benefits of using a multi-physics system that takes into account the feedback between the atmosphere and fire processes. To run WRF-SIFRE, it is required to determine the domain to simulate, that is, to define a 3D cut of the Earth surface where the evolution of the forest fire is going to be forecasted. Once the domain has been determined, the equations of the atmospheric model are resolved in all domain points, so, a smart cutting would, eventually, save unnecessary execution time. The relationship between the domain size and the atmospheric and fire grid resolutions used is not the focus of this work, therefore, in this study, we used a fixed domain size of a 49 Km^2 (7 Km $\times$ 7 Km) forest area that surrounds the real fire perimeters and allows to properly simulate the propagation of the fire.

Regarding the atmospheric mesh initialization, the initial weather data used as initial conditions for the simulations is a weather data set provided by the SMC (Servei Meteorologic de Catalunya), which are at 3 Km horizontal resolution and interpolated at 19 vertical levels. The atmosphere grid resolution tested have been 236, 118, 100 and 59 meters and, consequently, the corresponding fire grid resolutions used have been 24, 12, 10 and 6 meters respectively. The coarser grid resolutions has been selected as initial grid resolutions because it corresponds to the minimum data resolution used in the system, in particular, the fuel map resolution, which has a resolution of 25 meters.

The main objectives of the experimental study reported in this section, consist of analyzing the relation between the prediction quality and the time incurred to obtain it. WRF-SFIRE has been parallelized using OpenMP and MPI but, in this work, we focused on the OpenMP parallelization. In particular, we have studied the relationship between the scalability improvements in terms of execution time due to the used of shared memory versus the quality improvements due to the different grid resolution used to solve the system.

3.1 Quality results

The main advantage of using a coupled multi-physic system to predict the evolutions of a forest fire is the ability of capturing the effect of meteorological events that happens a high resolution and, on the way back, the capacity to observe the influence of the heat fluxes generated by the fire into the atmosphere. Figure 2 shows the forest fire spread predicted by WRF-SFIRE when using different grid resolutions. The green shape corresponds to the final burnt area and the doted lines are the forecasted forest fire spread. As we can observe,

 ISBN: 978-84-617-8694-7

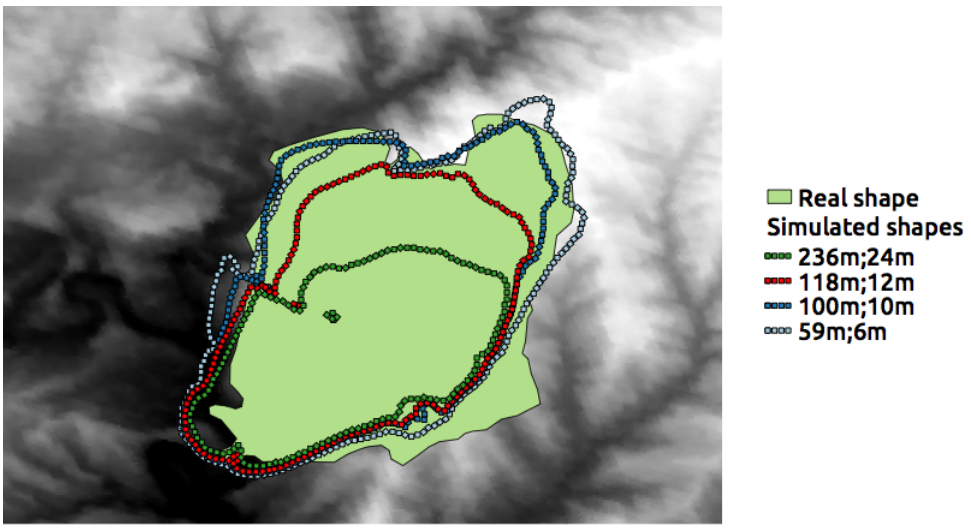

Figure 2: Cardona forest fire final burnt area compared to the forest fire prediction when using WRF-SFIRE with atmospheric grid resolutions equal to 236, 118, 100 and 59 meters

the atmospheric grid resolution plays a relevant role in the final results in terms of quality. Lower resolutions provide forest fire evolutions that are more similar to the real fire spread than the ones obtained using higher resolutions. The main reason of these results is the capacity of WRF to better detect local winds convections due, not only to the atmosphere effects but also because of the forest fire. However, a question that arises at this point is, can we increase the mesh resolution as much as we want in order to obtain better prediction results? The answer is not straight forward. Figure 2 depicts the predicted fire evolutions when using 236, 118, 100 and 59 meters as atmospheric grid resolution. If we focus on the cases where this value is 236, 118 and 59 meters, we can observe that each grid resolution is half the previous one. This variation clearly affects the quality of the results. However, as we will see in the next section, low resolution simulations imply higher execution times, for that reason, we also test an intermediate case with the atmospheric grid resolution equal to 100 meters. As we can see, this case provides a forest fire spread similar to the one obtained with a grid resolutions equal to 59 meters but, as it is following explained, the execution time is significantly lower. Therefore, it is important to be able to determine a relation between grids resolutions and quality if we want to use this multi-physics system in an operational way.

 ISBN: 978-84-617-8694-7

3.2 WRF-SFIRE scalability

As it has been introduced, WRF-SFIRE is a multi-physics system that couples the WRF atmospheric model and the SFIRE forest fire spread model. WRF requires a 3D grid to solve the atmospheres processes, meanwhile SFIRE works in a 2D mesh. The execution platform used for the experiments reported in this section is a multi-core system composed of 2 sockets integrating Intel Xeon processors with 8 cores and multithreading. Figure 3 shows the execution time spent when simulating the Cardona fire using a single thread approach for all tested grid resolutions. Moreover, the execution time spent for each individual model is also depicted. As we can see, lower resolutions imply higher executions times varying from, approximately, 1000 to 10000 minutes depending on the resolution used. Whatever grid resolution we use, the execution times obtained are prohibitively for operational purposes. It is also remarkable what happened when using a atmospheric grid resolution of 236 meters. As we can see, the total execution time for this case and for the experiment with atmospheric grid resolution equal to 118 meters are quite similar. This could be seen as an anomaly, however, there is a reason to explain this behavior. As it was previously mentioned, WRF uses a 3D grid to solve the atmospheric equations and, for all the experiments, the number of vertical level was initially set to 29. However, when executing the case with a grid resolution equal to 236 meters the system was not able to converge to a solution due to the reduce number of grid points used. For that reason, in this particular case, the number of vertical level was increased to 200 to include the minimum required number of points that allows the system to converge. Since the final number of points in the atmospheric grid has been similar to the case where the grid resolution is equal to 118 with 19 vertical levels, the total execution time is quite similar. However, if we analyze the execution times of WRF and SFIRE separately, we can observe that for the case of 236 meters grid resolution the time required to execute WRF is almost 90% of the total execution time, whereas in the case of 118 meters grid resolution the total execution time is balanced among both models.

Fortunately, WRF-SFIRE has been parallelized using OpenMP and MPI so, in order to be able to use the system during an ongoing event, we have studied the behavior of the multi-physics system on multi-core platforms. Since the simulations that provide better quality results are the ones with atmospheric grid resolutions equal to 100 and 59 meters, we have focused the study on these two cases. Figures 4 and 5 show, respectively, the ideal execution time, the real total execution time and the execution time of the two models (WRF and SFIRE) when using 2, 4, 8 and 16 threads locating each thread in a different core. As we can observe, the scalability of the system is quite good because the total execution time has almost the same tendency that the ideal case.

However, in terms of absolute execution time incurred in both cases, it is clear that the one that could reach the execution time requirements for operational purposes, is the experiment with atmospheric grid resolution equal to 100 and running using either 8 or 16

 ISBN: 978-84-617-8694-7

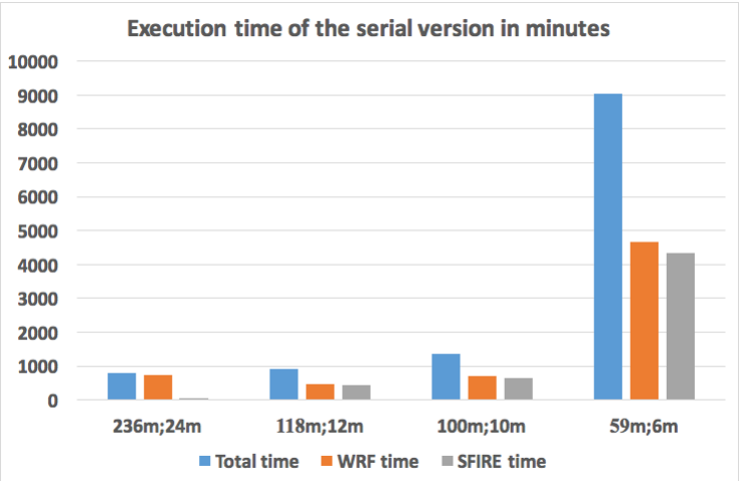

Figure 3: Total serial execution time of simulating the Cardona fire using WRF-SFIRE with atmospheric grid resolutions equal to 236, 118, 100 and 59 meters

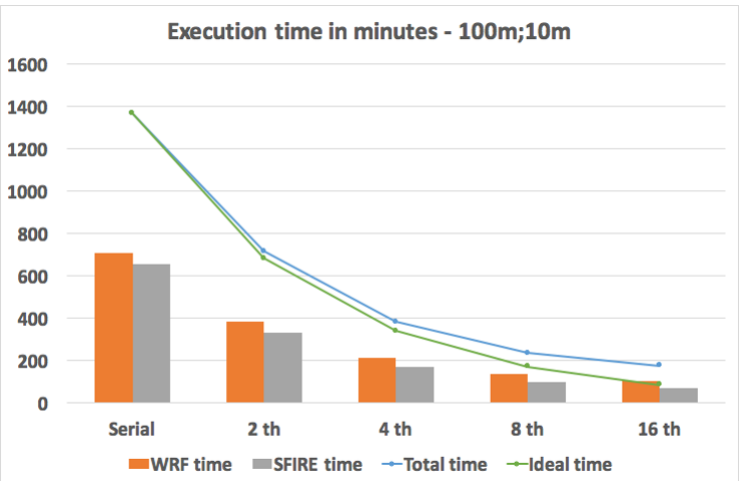

Figure 4: Execution time of simulation Cardona fire using WRF-SFIRE with atmospheric grid resolutions 100 meters and OpenMP with 2, 4, 8 and 16 threads

threads. Consequently, a deeper study to be able to asses in advance the appropriate grid settings and the hardware requirements to cope with operational constraints must be done.

 ISBN: 978-84-617-8694-7

Figure 5: Execution time of simulation Cardona fire using WRF-SFIRE with atmospheric grid resolutions 59 meters and OpenMP with 2, 4, 8 and 16 threads

4 Conclusions

Atmospheric wind is one of the parameters that most affect the forest fire behavior. However, this atmospheric phenomenon can be hardly affected by the forest fire micro-weather generated by the fire itself. WRF-SFIRE is a coupled atmospheric-fire system that takes into account the continuous relation between both models. However, the penalty of continuously evaluating the evolution of the atmosphere processes and the fire processes is the execution time. WRF-SFIRE has an OpenMP parallel implementation that allows to exploit multi-core systems. This parallel approach has been tested using as study case: the Cardona fire. This forest fire was a fire driven by the winds generated by the fire itself, so to run the simulations with low resolutions is the best approach to cope the local effect of the fire in the atmosphere. However, to reach operational times, it is necessary to exploit to the maximum the OpenMP parallelization of WRF-SFIRE taking into account convergence features of the system that can go from modifying the grid resolutions to improve the vertical levels of the meteorological grid in order to have enough point to allow the system to converge. Therefore, a further analysis of this relation is required to be able to develop a model that could predict in advance the required grids settings and number of threads required to accomplish the predetermined deadline times.

Abstract

In this work, we deal with the optimization of a High-Pressure Thermal (HPT) process for treating food samples. In particular, this industrial problem has several conflicting objectives as the vitamin retention and the enzymatic reduction or the temperature control. Recently, this optimization problem has been solved by using a multi-objective optimization algorithm called WASF-GA. Its main objective is to provide a good size approximation of the Pareto-front, i.e., a fixed number of well-distributed solutions which cover a region of interest determined by the preferences of a decision maker. WASF-GA works with a list of individuals, which evolves during the optimization procedure. In this scenario, the evaluation of a single individual is really high from a computational point of view, since it consists of solving a partial differential equation system that simulates the HPT treatment. Therefore, when the set approximating the Pareto-front must have many points (because a high precision is required), the number of function evaluations can explode and hence, the computational time needed by WASFGA may not be negligible at all. Furthermore, the computational resources needed may be so high that a PC may run out of memory. In those cases, parallelizing the algorithm and running it in a supercomputer may be the best way forward. In this work, we propose a parallelization of the optimization algorithm by using a master-slave strategy based on assigning a fraction of the population to each available processing element. The efficiency of this parallel strategy has been analyzed and the preliminary results are optimistic.

Key words: high-performance computing, multi-objective optimization, genetic algorithms, food industry, high-pressure

1 Introduction

High-Pressure (HP) technology is widely used in food treatment processes. In the last decades, its popularity has grown significantly due to the increasing demand for healthy and safe products, minimally processed, and at the same time, ready for immediate consumption. Among other food treatments, HP stands out for the two following advantages: it does not use additives that consumers prefer to avoid, and it is not based on extremely high or low temperatures, which can affect nutritional and organoleptic properties of the food.

In this work, we focus on a particular food treatment device (a cylindrical chamber) which is used to apply a combination of High-Pressure and Thermal processes to treat food samples. We model the behavior of this device by considering the heat transfer equations, to model the variations of pressure and temperature, coupled with a first–order kinetic equation, that describes the effect of such variations on the activity of certain enzymes and vitamins [5]. Consequently, given the pressure profile and the initial and refrigeration temperature, this model simulates the variation of temperatures and the evolution of enzymatic and vitamin activities in the food sample. Then, based on this mathematical model, we define a multi-objective optimization problem, associated with this High-Pressure Thermal treatment, which consists of determining the initial and refrigeration temperatures and the pressure profile provided to the equipment in order to minimize the final enzymatic activity and the maximum temperature reached during the whole process and to maximize the final vitamin activity.

In multi-objective optimization problems, as the one considered here, there is usually no single optimal solution, but a set of alternative results with different trade-offs. Such a set of solutions is called the Pareto set (or efficient set), and the corresponding set of objective vectors, the Pareto front. Then, solving a multi-objective optimization problem consists of finding the nondominated subset formed by the efficient decision vectors whose corresponding objective vectors represent the Pareto optimal front.

For the problem at hand, obtaining an exact description of the efficient set (or Pareto front) is practically impossible, since those sets are usually a continuum and include an infinite number of points. Furthermore, the computing cost may be excessive, and this is an important aspect, mainly for hard-to-solve optimization problems, such as the one considered in this work. In this context, the Preference-based Multi-Objective Evolutionary Algorithms (PMOEAs) allow us to obtain 'good approximations' of the region of interest (ROI). A good *Pareto front approximation* is defined as a finite set of non-dominated objective vectors which cover the whole ROI evenly.

In particular, to solve our optimization problem, we have used the preference-based algorithm called WASF-GA. Nevertheless, even when WASF-GA focuses on a region of interest and, thus, avoids unnecessary computations, its execution time is not negligible. On the contrary, WASF-GA needs nearly 55 hours to find the Pareto front approximation with 300 individuals and 36 iterations (i.e. 10800 evaluations), and more than 100 hours for

 ISBN: 978-84-617-8694-7

obtaining an approximated set composed by 500 individuals in 40 iterations of the algorithm (i.e. 20000 evaluations)). This is mainly due to the evaluation of the objective function is very costly.

Nevertheless, it is important to achieve a representative set of optimal individuals so that the food engineer receives as many solutions as possible for covering the industry requirements at each particular moment. Therefore, once the Pareto front approximation is computed, the decision maker (DM) has available a set of points that are individually good solutions for many different constrained mono-objective problems. Then, the DM can choose the most preferable one depending on the specific quality requirements that he/she wants to satisfy at each moment without having to execute a new optimization procedure. This translates into popupulations with larger number of individuals and hence, longer computing times. A parallelization of WASF-GA may allow us to deal with these inconvenients. In this work, WASF-GA is parallelized by considering a a master-slave paradigm.

The rest of the paper is structured as follows. First of all, in Section 2, we present the multi-objective optimization problem under study. Next, in Section 3, we describe the sequential algorithm WASF-GA used to solve it. Then, in Section 4, we explain the master-slave strategy proposed for parallelizing WASF-GA. Finally, Section 5 is devoted to summing up the preliminary results and the main conclusions.

2 The multi-objective problem

The industrial problem concerning us is obtaining the best configuration for a particular HPT equipment and a specific food sample so that, after the treatment, the food satisfies some quality requirements. More precisely, the HPT configuration that we are interested in determining is given by the initial and refrigeration temperatures and the pressure profile provided to the equipment. Additionally, the considered quality requirements are based on the inactivation of the enzyme called *Bacillus Subtilis* α*–Amylase* (BSAA) [2], the preservation of the vitamin C [7], and the control of the food temperature for maintaining it as lower as possible. Remember that high temperatures damage the food properties, and, in particular, the vitamins. However, the pressure has to be increased for fighting against the enzyme and, as a consequence, the temperature also experiments a rise.

Therefore, for managing those conflicting objectives and optimizing them simultaneously, our problem is formulated as a multi-objective problem as follows:

$$\begin{cases} \min & f_{\text{bsaa}}(T_0, T_r, P), \\ \max & f_{\text{vit}}(T_0, T_r, P), \\ \min & f_{\text{Tmax}}(T_0, T_r, P), \end{cases} \tag{1}$$

where the decision variables are the initial, T_0, and refrigeration, T_r, temperatures and a piece-wise linear function P (depending on time), defining the equipment pressure evolution.

 ISBN: 978-84-617-8694-7

Additionally, those decision variables are constrained due to the equipment restrictions detailed below (e.g., temperature and pressure admissible range).

Given a particular configuration (T_0, T_r, P), it determines a specific HPT process whose behavior is simulated solving numerically the heat transfer system explained at [5]. Moreover, two first-order kinetic equations for describing the activity evolution of both the considered enzyme and vitamin are also involved. As a consequence, the activity values of enzyme A_{bsaa} and vitamin A_{vit} at the end of the process (i.e. at time t_f) can be obtained from this numerical simulation. Then, they are averaged in the food sample domain Ω_{F} to evaluate the first and the second objective functions, respectively:

$$f_{\text{bsaa}}(T_0, T_r, P) = \frac{1}{|\Omega_{\text{F}}|} \int_{\Omega_{\text{F}}} A_{\text{bsaa}}(r, z, t_f) dr dz,$$

$$f_{\text{vit}}(T_0, T_r, P) = \frac{1}{|\Omega_{\text{F}}|} \int_{\Omega_{\text{F}}} A_{\text{vit}}(r, z, t_f) dr dz.$$

The third objective function f_{Tmax} is the maximum temperature reached in the food sample during the whole HPT treatment, which can be expressed by:

$$f_{\text{Tmax}}(T_0, T_r, P) = \max_{(r,z)\in\Omega_{\text{F}},\ t\in[t_0,t_f]} T(r, z, t).$$

In order to design the pressure evolution function P, we consider an initial equipment pressure $P_0 = 0.1$ (MPa) (i.e., atmospheric pressure) at time $t_0 = 0$ seconds. Then, we consider $n+1$ time intervals $[t_i, t_{i+1}]$, with $t_i = i \cdot \frac{900}{n}$, $i \in \{1, \cdots, n\}$, and, at each interval, we consider a constant pressure variation $\Delta P_i \in [\Delta P_{n,\text{dec}}, \Delta P_{n,\text{inc}}]$ (MPa), where $\Delta P_{n,\text{dec}}$ and $\Delta P_{n,\text{inc}}$ are the maximum variations allowed by the equipment for the decrease and for the increase in pressure, respectively, during $900/n$ seconds. However, those pressure variations cannot generate pressure out of the equipment admissible pressure range $[P_{\min}, P_{\max}]$ (MPa). Finally after 900 seconds, the pressure is decreased at a constant fixed rate of $\Delta P_{n,\text{dec}} \cdot (n/900)$ (MPa$\cdot$s^{-1}) up to reaching 0.1 MPa. Thus, $P(t)$ is built by considering the linear interpolation through the points $\{(i*900/n\ (\text{s}), P_i\ (\text{MPa})\ )\}_{i=0}^{n} \cup \{(900+(P_n-0.1)/|\Delta P_{n,\text{dec}}|\ (\text{s}), 0.1\ (\text{MPa})\ )\}$, with $P_i = P_{i-1} + \Delta P_i$ for $i \in \{1, \cdots, n\}$.

In this work, taking into account the restriction of the considered pressure vessel, we consider that the range of admissible temperature is [10, 50] (°C), the range of admissible pressure is [0.1, 900] (MPa) and the range of admissible variations for the pressure is $[\Delta P_{n,\text{dec}}, \Delta P_{n,\text{inc}}] = [-250, 250]$ (MPa).

Thus, the optimization problem considered is the following discrete version of Problem (1):

$$\begin{cases} \min & f_{\text{bsaa}}(T_0, T_r, \Delta P_1, \ldots, \Delta P_n), \\ \max & f_{\text{vit}}(T_0, T_r, \Delta P_1, \ldots, \Delta P_n), \\ \min & f_{\text{Tmax}}(T_0, T_r, \Delta P_1, \ldots, \Delta P_n). \\ \text{s.t.} & T_0, T_r \in [10, 50](^\circ\text{C}) \\ & \Delta P_1, \ldots, \Delta P_n \in [-250, 250](\text{MPa}) \end{cases} \tag{2}$$

3 The sequential method: the weighting achievement scalarizing function genetic algorithm

The weighting achievement scalarizing function genetic algorithm, shortly called WASF-GA, is a preference-based evolutionary algorithm aimed at multi-objective optimization. For taking into account the decision maker preferences, it considers a reference point (RP) $\mathbf{q} = (q_1, \ldots, q_m)$, consisting of a desirable value q_i for each one of the objective functions f_i, with $i = 1, \ldots, m$.

Additionally, the DM should provide a set of N_μ weight vectors $\{\mu^1, \ldots, \mu^{N_\mu}\}$, where each weight vector has a number of components equal to the number m of objective functions, i.e., $\mu^j = (\mu_1^j, \ldots, \mu_m^j)$ and $\mu_i^j > 0$ for $j = 1, \ldots, N_\mu$ and $i = 1, \ldots, m$.

Then, WASF-GA uses the following Wierzbicki's achievement scalarizing function (ASF) based on the L_∞ distance:

$$s(\mathbf{q}, \mathbf{f}(\mathbf{x}), \mu^j) = \max_{i=1,\ldots,m} \{\mu_i^j (f_i(\mathbf{x}) - q_i)\} + \eta \sum_{i=1}^{m} \mu_i^j (f_i(\mathbf{x}) - q_i), \tag{3}$$

where the parameter $\eta > 0$, called augmentation coefficient, must be a small positive value.

According to Equation (3), for evaluating the ASF, $\mathbf{q}$ is projected onto the optimal front in the direction determined by the inverses of the weights. Therefore, in order to obtain a well-distributed approximation of the region of interest, the set of weight vectors must be selected so that the inverse of its components μ_i^j must be evenly distributed in the space $(0, 1)^m$.

The general behaviour of the WASF-GA can be summarized as follows. First of all, an initial population of N individuals is randomly generated with a uniform distribution. Next, at each iteration, an offspring population with the same number of individuals is obtained from the previous population by applying the crossover and mutation operators. Then, the individuals belonging to both parent and offspring populations are classified into different fronts. To do so, all of those individuals are evaluated through the objective function and, for each one, the N_μ values of the ASFs for the N_μ weight vectors are calculated. Attending to those values, for each weight vector, the individual with the lowest value of its ASF is selected and copied into the first front. Once a particular individual is chosen for minimizing an ASF associated to a weight vector, this individual will not be considered for the remaining ASFs. Thus, the first front will be complete when it contains N_μ individuals, one minimizing each ASF. For filling the following fronts, the same procedure is carried out. Finally, the parent population for the next iteration is composed of the N first selected individuals belonging to the first fronts. In our study, we have considered $N = N_\mu$, so that, at each iteration, the parent population will be the first front of the previous iteration.

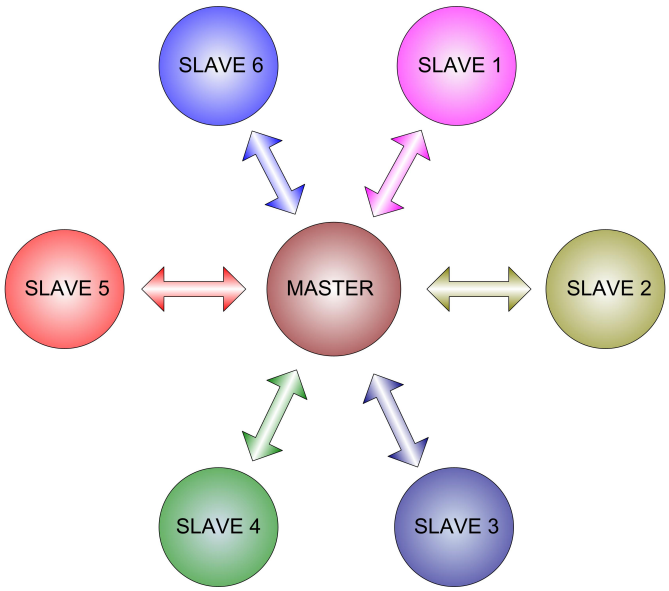

Figure 1: Master-slave model

4 Parallelization Approach: A master-slave strategy

Master-slave is a parallel communication model where one processing element called the *master* has unidirectional control over one or more processing elements known as the *slaves*. This technique is a "global parallel model" in the sense that all the decisions taken during the algorithm consider the whole population. Indeed, the global decisions are made by the master processor which also distributes the information among all the processing elements (including itself) [1]. On the other hand, the slave processors are in charge of run specific tasks as the evaluation of the assigned population.

Figure 1 depicts the communication procedure among processors. The central core is the *master*, which interchanges some information with the *slaves*. Such interchanges are carried out using communications, that are represented by arrows.

The execution time of a master-slave model has three basic components: the time used in computations, the time used to communicate information among processing elements, and the waiting time due to the synchronization points. The first one is largely determined by the size of the population. However, the population size is also a major factor in the effectiveness of population-based methods and if the population is reduced, then the probability that the algorithm will find good solutions would decrease [3, 4]. The second one depends directly on the number of slaves, on the particular hardware used to execute the algorithm and on the size of the messages. Finally, the third one depends on the degree of parallelism of the

 ISBN: 978-84-617-8694-7

algorithm, i.e. if there exist or not parts that have to be executed in a sequential way, and if the different parallel subtasks can evolve independently or, on the contrary, they need some information from the other ones to continue.

In the master-slave strategy that we have implemented, the master processor executes WASF-GA sequentially. The parallelism derives from the simultaneous resolution of the HPT system to evaluate the new candidate solutions. This is because the evaluation of an individual is independent from the rest of the population, and there is no need to communicate during this phase. The evaluation of individuals is parallelized by assigning a fraction of the population to each available processing element (master and slaves processors). Communications occur only as each slave receives its subset of individuals for evaluation and when the slaves return the objective function values. In our proposal, the master processor, after evaluating its assigned subpopulation, receives those objective function values from the slave processors. This is a synchronization point due to the necessity of having the objective function values of the whole population before applying the selection procedure to compose the different fronts. However, this selection task is not as time-consuming as the evaluation stage. Therefore, it is important to emphasize that, the master-slave method does not affect the behavior of the algorithm, i.e. the selection mechanism takes into account the entire population and it is possible to mate with any individual.

5 Preliminary results and conclusions

The preliminary results are promising, i.e. for the instances considered, the proposed master-slave strategy applied to WASF-GA allows to reduce significantly the computational time. This is an important aspect, mainly for hard-to-solve optimization problems, such as the one considered in this work. Thanks to the proposed parallelization, we can solve our industrial problem using a larger number of evaluations. As a consequence, the set of optimal points provided to the food engineer could have more individuals, since we can use larger populations, and it could be more accurate since we can carry out more iterations of the optimization algorithm.

Abstract

This paper deals with estimation and hypothesis testing in multivariate mixed linear models in which observation vectors have block compound symmetry covariance structure.

Key words: block compound symmetry, hypothesis testing, multivariate mixed linear models

1 Unstructured Mean Vector Within k Groups

1.1 Model

Consider an observations vector of size mp with distribution $\mathbf{Y}_{ij} \sim \mathrm{N}(\boldsymbol{\mu}_0 + \boldsymbol{\mu}_i, \boldsymbol{\Sigma})$, $i = 0, \ldots, k$, $j = 1, \ldots, n_i$, such that $\sum_{i=1}^{k} n_i \boldsymbol{\mu}_i = \mathbf{0}_{mp}$, where $\boldsymbol{\mu}_i = \begin{bmatrix} \mu_{i,1} & \ldots & \mu_{i,mp} \end{bmatrix}'$, $m = m_1 m_2$ and $n = \sum_{i=1}^{k} n_i$. The joint distribution of the model will be $\mathbf{Y} \sim \mathrm{N}\big(\boldsymbol{\mu}, \mathrm{diag}_{i=1}^{k}(\mathbf{I}_{n_i} \otimes \boldsymbol{\Sigma})\big)$, with $\boldsymbol{\mu} = \begin{bmatrix} \big(\mathbf{1}_{n_1} \otimes (\boldsymbol{\mu}_0 + \boldsymbol{\mu}_1)\big)' & \cdots & \big(\mathbf{1}_{n_k} \otimes (\boldsymbol{\mu}_0 + \boldsymbol{\mu}_k)\big)' \end{bmatrix}'$, vector of size nmp, with $n = \sum_{i=1}^{k} n_i$. The covariance matrix $\boldsymbol{\Sigma}$ has a 2-level BCS structure, with $\boldsymbol{\Sigma}_0, \boldsymbol{\Sigma}_1$ and $\boldsymbol{\Sigma}_2$ matrices of size $p \times p$, with each "layer" of size m_1 and m_2, respectively. In algebraic form:

$$\begin{aligned} \mathbf{I}_{m_1 m_2} \otimes (\boldsymbol{\Sigma}_0 - \boldsymbol{\Sigma}_1 + \boldsymbol{\Sigma}_2) + \mathbf{I}_{m_1} \otimes (m_2 \mathbf{J}_{m_2}) \otimes (\boldsymbol{\Sigma}_1 - \boldsymbol{\Sigma}_2) + (m_1 m_2 \mathbf{J}_{m_1 m_2}) \otimes \boldsymbol{\Sigma}_2 \\ = \mathbf{Q}_0 \otimes \boldsymbol{\Delta}_0 + \mathbf{Q}_1 \otimes \boldsymbol{\Delta}_1 + \mathbf{Q}_2 \otimes \boldsymbol{\Delta}_2, \quad (1) \end{aligned}$$

with

$$\mathbf{Q}_0 = \mathbf{K}_{m_2} \otimes \mathbf{I}_{m_1}, \ \mathbf{Q}_1 = \mathbf{J}_{m_2} \otimes \mathbf{K}_{m_1}, \ \mathbf{Q}_2 = \mathbf{J}_{m_2} \otimes \mathbf{J}_{m_1}, \quad (2)$$

 ISBN: 978-84-617-8694-7

and

$$\boldsymbol{\Delta}_0 = \boldsymbol{\Sigma}_0 - \boldsymbol{\Sigma}_1,\ \boldsymbol{\Delta}_1 = \boldsymbol{\Sigma}_0 - (m_1-1)\boldsymbol{\Sigma}_1 - m_1\boldsymbol{\Sigma}_2,$$
$$\boldsymbol{\Delta}_2 = \boldsymbol{\Sigma}_0 - (m_1-1)\boldsymbol{\Sigma}_1 + m_1(m_2-1)\boldsymbol{\Sigma}_2, \quad (3)$$

where $\mathbf{J}_s$ is a matrix whose elements are all $\frac{1}{s}$ and $\mathbf{K}_s = \mathbf{I}_s - \mathbf{J}_s$. Consider the matrix

$$\mathbf{H} = \begin{bmatrix} \mathbf{H}_{m_2} \otimes \mathbf{I}_{m_1} & \mathbf{H}_{m_2} \otimes \mathbf{J}_{m_1} & \mathbf{J}_{m_2} \otimes \mathbf{J}_{m_1} \end{bmatrix} \quad (4)$$

where $\mathbf{H}_n : \mathbf{H}_n'\mathbf{H}_n = \mathbf{I}_{n-1} \wedge \mathbf{H}_n\mathbf{H}_n' = \mathbf{K}_n$. Taking matrix $\mathbf{D} = \operatorname{diag}_{i=1}^{k}(\mathbf{I}_{n_i} \otimes \mathbf{H} \otimes \mathbf{I}_p)$, which is an orthogonal transformation, we get that

$$\mathbf{D}'\mathbf{Y} \sim \mathrm{N}\left(\underset{i=1}{\overset{k}{\operatorname{diag}}} (\mathbf{1}_{n_i} \otimes \mathbf{I}_{mp}) \begin{bmatrix} (\mathbf{H}' \otimes \mathbf{I}_p)(\boldsymbol{\mu}_0 + \boldsymbol{\mu}_1) \\ \vdots \\ (\mathbf{H}' \otimes \mathbf{I}_p)(\boldsymbol{\mu}_0 + \boldsymbol{\mu}_k) \end{bmatrix}, \underset{i=1}{\overset{k}{\operatorname{diag}}} (\mathbf{I}_{n_i} \otimes \boldsymbol{\Delta}) \right). \quad (5)$$

Note that $\mathbf{H}\boldsymbol{\Sigma}\mathbf{H}' = \operatorname{diag}_{i=0}^{2}(\mathbf{I}_{g_i} \otimes \boldsymbol{\Delta}_i) = \boldsymbol{\Delta}$, where

$$g_i = \begin{cases} m_2(m_1-1), & i = 0 \\ m_1 - 1, & i = 1 \\ 1, & i = 2 \end{cases} \quad (6)$$

Considering the transformation $\mathbf{F} = \mathbf{H}_n \otimes \mathbf{I}_{mp}$, where $\mathbf{H}_s$ is a Helmert matrix of size s, the mean vector of $\mathbf{Z} = \mathbf{F}'\mathbf{D}'\mathbf{Y}$ has the form

$$\mathrm{E}[\mathbf{Z}] = \operatorname{diag} \begin{bmatrix} \boldsymbol{\tau}_0 \\ \left(\left((\mathbf{H}_n)' \operatorname{diag}_{i=1}^{k} \left(\frac{1}{\sqrt{n_i}} \mathbf{1}_{n_i} \mathbf{N} \right) \right) \otimes \mathbf{I}_{mp} \right) \boldsymbol{\tau}_F \end{bmatrix}, \quad (7)$$

with $\boldsymbol{\tau}_0 = (\mathbf{H}' \otimes \mathbf{I}_p)(\sqrt{n}\boldsymbol{\mu}_0)$ and $\boldsymbol{\tau}_F = \begin{bmatrix} \boldsymbol{\tau}_1' & \cdots & \boldsymbol{\tau}_{k-1}' \end{bmatrix}'$, and $\operatorname{Cov}(\mathbf{Z}) = \mathbf{I}_n \otimes \boldsymbol{\Delta}$.

1.2 Maximum Likelihood Estimators

The log-likelihood ℓ of $\mathbf{Z}$ can be expressed as

$$-2\ell = nmp\log(2\pi) + n\sum_{i=0}^{2} g_i \log\left(|\boldsymbol{\Delta}_i|\right) + \operatorname{tr}\left((\mathbf{z}_0 - \boldsymbol{\tau}_0)'\boldsymbol{\Delta}^{-1}(\mathbf{z}_0 - \boldsymbol{\tau}_0)\right)$$
$$+ \operatorname{tr}\Big(\left(\mathbf{z}_F - (\mathbf{X}_F \otimes \mathbf{I}_{mp})\boldsymbol{\tau}_F\right)'(\mathbf{I}_{n-1} \otimes \boldsymbol{\Delta}^{-1})(\mathbf{z}_F - (\mathbf{X}_F \otimes \mathbf{I}_{mp})\boldsymbol{\tau}_F) \Big), \quad (8)$$

with

$$\mathbf{z}_0 = \operatorname{diag}(\mathbf{I}_{mp}, \mathbf{0}_{(n-1)mp,(n-1)mp})\mathbf{z}, \quad (9)$$
$$\mathbf{z}_F = \operatorname{diag}(\mathbf{0}_{mp,mp}, \mathbf{I}_{(n-1)mp})\mathbf{z}, \quad (10)$$
$$\mathbf{X}_F = (\mathbf{H}_n^{\perp})' \underset{i=1}{\overset{k}{\operatorname{diag}}} \left(\frac{1}{\sqrt{n_i}} \mathbf{1}_{n_i} \mathbf{N} \right). \quad (11)$$

 ISBN: 978-84-617-8694-7

Taking

$$\mathbf{B} : \mathbf{B}'\mathbf{B} = \mathbf{I}_{k-1} \wedge \mathbf{B}\mathbf{B}' = \mathbf{X}_F(\mathbf{X}_F'\mathbf{X}_F)^{-1}\mathbf{X}_F', \tag{12}$$

$$\mathbf{B}^\perp : (\mathbf{B}^\perp)'\mathbf{B}^\perp = \mathbf{I}_{n-1} \wedge \mathbf{B}^\perp(\mathbf{B}^\perp)' = \mathbf{I}_{n-1} - \mathbf{X}_F(\mathbf{X}_F'\mathbf{X}_F)^{-1}\mathbf{X}_F', \tag{13}$$

$$h_s = \begin{cases} 0, & s < 0 \\ \sum_{t=0}^{s} g_t, & s \geq 0 \end{cases}, \ \boldsymbol{\delta}_{r,s}(k,l) = \boldsymbol{\delta}_r(k) \otimes \boldsymbol{\delta}_s(l), \tag{14}$$

$$\mathbf{Z}_{\boldsymbol{\Delta}_i} = \left[\left(\left((\boldsymbol{\delta}_{n-k,m}(1, h_{i-1}+1))'(\mathbf{B}^\perp \otimes \mathbf{I}_m)'\right) \otimes \mathbf{I}_p\right)\mathbf{z} \quad \cdots \quad \left(\left((\boldsymbol{\delta}_{n-k,m}(n-k, h_{i|l}))'(\mathbf{B}^\perp \otimes \mathbf{I}_m)'\right) \otimes \mathbf{I}_p\right)\mathbf{z}\right], \tag{15}$$

it is then possible to rewrite the log-likelihood as

$$\begin{aligned} -2\ell = {} & nmp\log(2\pi) + \operatorname{tr}\big((\mathbf{z}_0 - \boldsymbol{\tau}_0)'\boldsymbol{\Delta}^{-1}(\mathbf{z}_0 - \boldsymbol{\tau}_0)\big) \\ & + \operatorname{tr}\Big(\Big((\mathbf{B}' \otimes \mathbf{I}_{mp})\mathbf{z}_F - \big((\mathbf{B}'\mathbf{X}_F) \otimes \mathbf{I}_{mp}\big)\boldsymbol{\tau}_F\Big)'(\mathbf{I}_{k-1} \otimes \boldsymbol{\Delta}^{-1})\Big((\mathbf{B}' \otimes \mathbf{I}_{mp})\mathbf{z}_F - \big((\mathbf{B}'\mathbf{X}_F) \otimes \mathbf{I}_{mp}\big)\boldsymbol{\tau}_F\Big)\Big) \\ & + n\sum_{i=0}^{2} g_i \log\big(|\boldsymbol{\Delta}_i|\big) + \operatorname{tr}(\boldsymbol{\Delta}_i^{-1}\mathbf{Z}_{\boldsymbol{\Delta}_i}\mathbf{Z}_{\boldsymbol{\Delta}_i}'). \end{aligned} \tag{16}$$

Hence, the parameters that minimize -2ℓ are

$$\hat{\boldsymbol{\tau}}_0 = \mathbf{z}_0, \hat{\boldsymbol{\tau}} = \Big(\big((\mathbf{X}_F'\mathbf{X}_F)^{-1}\mathbf{X}_F\big) \otimes \mathbf{I}_m\Big)\mathbf{z}_F, \hat{\boldsymbol{\Delta}}_i^{(1)} = \frac{1}{ng_i}\mathbf{Z}_{\boldsymbol{\Delta}_i}\mathbf{Z}_{\boldsymbol{\Delta}_i}', \tag{17}$$

taking the value $\ell_1 = -\frac{nmp}{2}\big(\log(2\pi)+1\big) - \sum_{i=0}^{2}\frac{ng_i}{2}\log\big(|\hat{\boldsymbol{\Delta}}_i^{(1)}|\big)$.

As for distributions of these statistics, we can ascertain that

$$\mathbf{z}_0 \sim \mathrm{N}(\boldsymbol{\tau}_0, \boldsymbol{\Delta}), \tag{18}$$

$$\Big(\big((\mathbf{X}_F'\mathbf{X}_F)^{-1}\mathbf{X}_F\big) \otimes \mathbf{I}_m\Big)\mathbf{z}_F \sim \mathrm{N}(\boldsymbol{\tau}, \mathbf{I}_{k-1} \otimes \boldsymbol{\Delta}), \tag{19}$$

$$\mathbf{Z}_{\boldsymbol{\Delta}_i}\mathbf{Z}_{\boldsymbol{\Delta}_i}' \sim \mathrm{W}\big((n-k)g_i, \boldsymbol{\Delta}_l\big), \tag{20}$$

all of these statistics being independent.

2 Unstructured Mean Vector

Consider an observations vector of size mp with distribution $\mathbf{Y}_j \sim \mathrm{N}(\boldsymbol{\mu}_0, \boldsymbol{\Sigma})$, $j = 1, \ldots, n$, where $\boldsymbol{\mu}_0 = \begin{bmatrix}\mu_{0,1} & \ldots & \mu_{0,mp}\end{bmatrix}'$. The joint distribution of the model will be $\mathbf{Y} \sim \mathrm{N}(\mathbf{1}_n \otimes \boldsymbol{\mu}_0, \mathbf{I}_n \otimes \boldsymbol{\Sigma})$.

 ISBN: 978-84-617-8694-7

Taking

$$\mathbf{Z}_{\mathbf{\Delta}_i,F} = \left[\left(\left((\delta_{n-k,m}(1,h_{i-1}+1))'(\mathbf{B}^{\perp}\otimes \mathbf{I}_m)'\right)\otimes \mathbf{I}_p\right)\mathbf{z} \quad \cdots \quad \left(\left((\delta_{n-k,m}(k-1,h_i))'(\mathbf{B}^{\perp}\otimes \mathbf{I}_m)'\right)\otimes \mathbf{I}_p\right)\mathbf{z}\right], \quad (21)$$

we get

$$-2\ell = nmp\log(2\pi) + \mathrm{tr}\big((\mathbf{z}_0-\boldsymbol{\tau}_0)'\mathbf{\Delta}^{-1}(\mathbf{z}_0-\boldsymbol{\tau}_0) + \sum_{i=0}^{2} ng_i \log\left(|\mathbf{\Delta}_i|\right) + \mathrm{tr}\big(\mathbf{\Delta}_i^{-1}(\mathbf{Z}_{\mathbf{\Delta}_i}\mathbf{Z}'_{\mathbf{\Delta}_i} + \mathbf{Z}_{\mathbf{\Delta}_i,F}\mathbf{Z}'_{\mathbf{\Delta}_i,F})\big). \quad (22)$$

The parameters that minimize the above function are

$$\hat{\boldsymbol{\tau}}_0 = \mathbf{z}_0,\ \hat{\mathbf{\Delta}}_i^{(0)} = \frac{1}{ng_i}(\mathbf{Z}_{\mathbf{\Delta}_i}\mathbf{Z}'_{\mathbf{\Delta}_i} + \mathbf{Z}_{\mathbf{\Delta}_i,F}\mathbf{Z}'_{\mathbf{\Delta}_i,F}), \quad (23)$$

with the log-likelihood taking the value $\ell_0 = -\frac{nmp}{2}\big((\log(2\pi)+1\big) - \sum_{i=0}^{2}\frac{ng_i}{2}\log\left(|\hat{\mathbf{\Delta}}_i^{(0)}|\right)$. We also have that

$$\mathbf{z}_0 \sim \mathrm{N}(\boldsymbol{\tau}_0, \mathbf{\Delta}),\ \mathbf{Z}_{\mathbf{\Delta}_i}\mathbf{Z}'_{\mathbf{\Delta}_i} \sim \mathrm{W}\big((n-k)g_i, \mathbf{\Delta}_i\big),\ \mathbf{Z}_{\mathbf{\Delta}_i,F}\mathbf{Z}'_{\mathbf{\Delta}_i,F} \sim \mathrm{W}\big((k-1)g_i, \mathbf{\Delta}_i\big), \quad (24)$$

all independent.

3 Likelihood Ratio Test
