In order to test the hypothesis $H_0 : \boldsymbol{\mu}_q = \mathbf{0}_{mp}, q = 1,\ldots,k$ vs. $H_1 : \exists q, \boldsymbol{\mu}_q \neq \mathbf{0}_{mp}$, we consider the likelihood ratio test statistic $T = \left(\prod_{i=0}^{2}\frac{|\mathbf{W}_i|}{|\mathbf{W}_i+\mathbf{W}_{i,F}|}\right)^{-\frac{1}{2}}$, with $\mathbf{W}_i = \mathbf{Z}_{\mathbf{\Delta}_i}\mathbf{Z}'_{\mathbf{\Delta}_i}$ and $\mathbf{W}_{i,F} = \mathbf{Z}_{\mathbf{\Delta}_i,F}\mathbf{Z}'_{\mathbf{\Delta}_i,F}$.

Abstract

In dynamical systems a particular solution is completely determined by the parameters considered and the initial conditions. Indeed, when the model shows a multistability, starting from different initial state, the trajectories can evolve towards different attractors. The invariant manifolds of the saddle points separate the vector field into the basins of attraction of different stable equilibria.
The aim of this work is the reconstruction of these separation surfaces in order to know in advance the geometry of the basins. In this paper three-dimensional models with three or more stable fixed points is investigated. To this purpose a procedure for the detection of the scattered data lying on the manifolds is proposed. Then a Moving Least Squares meshfree method is involved to approximate the surfaces. Numerical results are presented in order to assess the method.

Key words: Dynamical systems, Invariant manifolds, Separatrix, Meshfree method, Moving Least Squares.

1 Introduction

Mathematical modeling and experimental investigations in biomedical sciences are popular instruments to explain the biological or physics process developed from a particular observed phenomenon. The systems of ordinary differential equations are analyzed in order to predict the temporal evolutions of the involved variables.
For a designated set of parameters, the solutions of the models evolve towards a set of numerical values called "*attractor*" [10]. Althought persistent oscillations or chaotic behaviors can happen, in this work we focus only on fixed stable points. When the model presents

more than one stable equilibrium (multistability), the analysis of the basins of attraction is fundamental for a detailed knowledge of the different evolutions of the trajectories. In fact, nearby the boundaries of the basins, initial points could indeed lead to completely different system's outcomes [2], [3].
To this purpose we analyze the invariant manifolds of the saddle points, which represent the separatrices for the vector field.
Extending our preliminary results [6], we proceed on the reconstruction of the basins boundaries for 3D models with three or more equilibria concurrently stable. In order to find the points lying on the invariant manifolds we operate by employing the eigenspace generated by the saddle node's eigenvectors.
Therefore we reconnect the manifolds points by using the Moving Least Squares meshless method presented in [7],[8]. Finally the study of a tristable epidemiological model is proposed [5].

2 Invariant manifolds reconstruction

In order to approximate the basins of attraction, the general idea is finding the points of the invariant manifolds of the saddle points.
We focus our attention on three-dimensional dynamical models where a saddle node is a fixed point which admits three eigenvalues such that at least one of them has real part positive and at least one has real part negative.
To integrate the separatrix surface of a saddle E_s, we consider M equispaced points on an ellipse centered on E_s whose semi-axes are the eigenvectors corresponding to the eigenvalues with the same sign. Therefore the ellipse lies on the eigenspace V that is tangent to the invariant manifold W of the saddle . Furthermore we backward integrate the model starting from the M seeding points obtaining the separatrix points ([11], [12],[9]) that we reconnect by using the Moving Least Squares method.
We start projecting the scattered data on the plane xy: $X = \{\mathbf{x}_i, i = 1, ..., N\} \in \mathbb{R}^2$ and considering z_i as the corresponding height. To approximate the manifolds we have to construct the quasi-interpolant [1]:

$$P(\mathbf{y}) = \sum_{i=1}^{N} z_i \Phi_i(\mathbf{y}) \tag{1}$$

where $\Phi_i(\mathbf{y}) = \Phi(x_i, \mathbf{y})$ are the *generating functions*.
Let $Q = span\{p_1, ..., p_m\}$ with $m < N$ the approximation space with $p_m \in \prod_2^s$, the bivariate polynomial of degree at most d.

 ISBN: 978-84-617-8694-7

The generating functions are [4]:

$$\Phi_i(\mathbf{y}) = \omega(\mathbf{x}_i, \mathbf{y}) \sum_{j=1}^{m} \lambda_j p_j(\mathbf{x}_i),\ i = 1, ...N \tag{2}$$

where ω represent the weighted functions governing the influence of the scattered data X and λ_j are the Lagrangian multipliers that solve the system:

$$\sum_{i=1}^{N} p_k(\mathbf{x}_i) p_l(\mathbf{x}_i) \omega(\mathbf{x}_i, \mathbf{y}) \lambda(\mathbf{y}) = p(\mathbf{y})\ k, l = 1, ..., m. \tag{3}$$

This meshfree approximant is very attractive especially when one is only interested in a few evaluations. Indeed it is not necessary to set up and solve a large interpolation system [13]. Furthermore when $m < 3$ it is possible find the explicit formulas for the Lagragian multipliers avoiding the resolution of the system (3).

3 Tristable model analysis

In order to test the algorithm presented in the previous section, we consider the following model [5]:

$$\frac{dS}{dt} = S\left[(S-\theta)(1-S-I) - \beta I - aP\right], \tag{4}$$

$$\frac{dI}{dt} = \beta SI - aIP - \mu I, \tag{5}$$

$$\frac{dP}{dt} = P\left[bs + \alpha I - d\right] \tag{6}$$

that analyzes a predator-prey interaction with prey subjected to Allee effect and disease. Therefore these latter are divided into susceptible (S) and infected (I) individual and P represents the predators. We resume all the parameters on the following table:

Parameter	Biological Meaning
θ	Allee threshold
β	Infection Rate
a	Attack rate of predator
b	Total effect to predator by consuming susceptible prey
μ	Death rate of infected prey
α	Total effect to predator by consuming infected prey
d	Natural death rate of predator.

 ISBN: 978-84-617-8694-7

Letting $\beta = 1.5$, $\theta = 0.2$, $a = 2$, $b = 1.35$, $\mu = 1$ and $d = 1$ the system admits three stable equilibria: the origin $E_0 \equiv (0, 0, 0)$, the disappearance of the disease $E_1 \approx (0.7407, 0, 0.0701)$ and the predator extinction $E_2 \approx (0.6667, 0.0791, 0)$.
For the reconstruction of their basins of attraction we consider the invariant manifolds of the attractive saddle points $E_{s_1} \equiv (\theta, 0, 0)$ and $E_{s_2} \approx (0.7329, 0.0211, 0.0497)$.
We start with the first saddle that admits the stable eigenvectors $v_1 \approx (0.4099, 0, 0.9121)$ and $v_2 \approx (0.329, 0.9442, 0)$. We integrate the separatrix considering $M = 20$ equispaced on the ellipse generated by v_1 and v_2 rescaled by a factor 0.7. Then, throught a backward integration we obtain all the scattered data on the manifold (Figure 1A).
Applying the same procedure to the saddle E_{s_2} we generate the separatrix points on the second manifold by rescaling the stable complex conjugated eigenvectors $v_{1,2} \approx (0.9817, -0.0088 \pm 0.08731i, -0.0552 \pm 0.1599i)$ with a factor 0.6 (Figure 1B).
Finally we approximate the two surfaces (Figure 1C) applyng the MLS approximant using the Wendland C2 compactly supported function:

$$\omega(\mathbf{x}_i, \mathbf{y}) = (1 - \epsilon||\mathbf{y} - \mathbf{x}_i||_2)_+^4 (4\epsilon||\mathbf{y} - \mathbf{x}_i||_2 + 1) \tag{7}$$

where the *shape parameter* $\epsilon = 3$ and 60 evaluation points $\mathbf{y}$ are taking into account (Figure 1D).

4 Conclusions

In this work we have presented a method for the reconstruction of the invariant manifolds of the saddle points. These surfaces play an important role on the analysis of the vector field because they partition it into the basins of attraction of the different fixed stable equilibria. Therefore, studying a dynamical model, when the parameters involved are chosen, one can understand a priori the possible evolution of the initial state. In this paper we have investigated the basins of attraction of a tristable model, but also systems with more stable equilibria can be treated.

Abstract

Wavelet-based estimation methodologies are considered for spatial prediction from strong correlated high-dimensional date. Different approaches are proposed for spatial estimation of annual mean ocean surface temperature maps. Specifically, spatial wavelet kernel penalized nonparametric regression and wavelet shrinkage are applied on daily ocean surface temperature curves from the Hawaii ocean stations, available at latitude-longitude interval $[22.7, 22.8] \times [-158.1, -157.94]$, during the period 2000 – 2007, from *The World-Wide Ocean Optics Database (WOOD).*

Key words: Wavelet-based estimation methodology, spatial models, ocean surface temperatures maps, functional data.

1 Introduction

Nowadays, prediction of future climate change based on statistical models play a key role in climate sciences. Alterations in sea-surface temperatures may lead to changes in atmospheric circulation and precipitation, causing more hurricanes and drought, particularly in the tropics. Statistical techniques for high- dimensional data can be applied to analyze long records of observations available at different stations of ocean islands. In this context, when only sample information from long records is incorporated in the estimation procedure, the most important issue is the application of estimation procedures adequate to the nature of the data, e.g., spatial correlation structure and spatial regularity through time, among others characteristics.

ISBN: 978-84-617-8694-7

The present paper provides an extended formulation of the wavelet kernel penalized univariate nonparametric regression approach studied in [1] to the bivariate spatial design point case, applied to ocean surface temperature estimation. Wavelet shrinkage is also considered here for spatial estimation of ocean surface temperature (see, for example, [2] and [3]). The results obtained are compared with those ones derived, under the spatial autoregressive Hilbertian framework (SARH(1) framework), considered in [6], [7], [8] and [9], and under the semiparametric approach presented in [10], based on Gaussian linear processes with heavy tail covariance functions.

2 Non-linear estimation methods

2.1 Wavelet kernel penalized nonparametric regression

Let us consider the following spatial nonparametric regression model:

$$Y_i = f(x_1^i, x_2^i) + \sigma\varepsilon(x_1^i, x_2^i), \quad i = 1, \ldots, N^2,$$

where f is a deterministic function to be estimated or approximated, and $\varepsilon(x_1^i, x_2^i)$, $(x_1^i, x_2^i) \in I \subset \mathbb{R}^2$, $i = 1, \ldots, N^2$, are independent and identically distributed standard Gaussian random variables. Here, parameter σ^2 is considered unknown, and estimated from the data. Furthermore, the following model is assumed to be satisfied by function f :

$$f(x_1, x_2) = \mu(x_1, x_2) + \sqrt{b}z(x_1, x_2),$$

where μ is a spatial deterministic function, and z is a spatial Gaussian process, both defined on $I = [a, b]\times[c, d] \subset \mathbb{R}^2$, with $[0, 1]\times[0, 1] \subseteq I = [a, b]\times[c, d]$. Function μ and spatial process z respectively admit the following orthogonal series representations: For all $(x_1, x_2) \in [0, 1]\times[0, 1]$,

$$\begin{aligned} \mu(x_1, x_2) &= \sum_{k_1=0}^{2^J-1}\sum_{k_2=0}^{2^J-1} \alpha_{J,k_1,k_2}\phi_{J,k_1,k_2}(x_1, x_2) \\ \sqrt{b}z(x_1, x_2) &= \sum_{s=h,v,d}\sum_{j\geq J}\sum_{k_1=0}^{2^j-1}\sum_{k_2=0}^{2^j-1} \beta^s_{j,k_1,k_2}\psi^s_{j,k_1,k_2}(x_1, x_2), \end{aligned}$$

where β^s_{j,k_1,k_2} are independent random variables satisfying $\beta^s_{j,k_1,k_2} \sim N(0, \lambda_j)$, $k_1 = 0, \ldots 2^j - 1,\ k_2 = 0, \ldots 2^j - 1,\ j \geq J,\ s = h, v, d$. Here, $\{\phi_{J,k_1,k_2},\ k_1 = 0, \ldots 2^J - 1,\ k_2 = 0, \ldots 2^J - 1\}$ denotes the compactly supported scaling function basis on the interval $[0, 1] \times [0, 1]$, generating the space V_J, and $\{\psi^s_{j,k_1,k_2},\ k_1 = 0, \ldots 2^j-1,\ k_2 = 0, \ldots 2^j-1,\ j \geq J,\ s = h, v, d\}$ are compactly supported wavelet bases, respectively generating the spaces $\{W_j,\ j \geq J\}$.

 ISBN: 978-84-617-8694-7

The predictor $\hat{f}$ can be expressed in the form,

$$\hat{f}(\mathbf{x}) = \Phi_{\mathbf{x}}\hat{\alpha} + b^{1/2}\hat{z}(\mathbf{x}), \quad \mathbf{x} \in [0,1] \times [0,1],$$

where

$$\hat{\alpha} = (\Phi' M^{-1}\Phi)^{-1}\Phi' M^{-1}\mathbf{Y}$$

is the least square weighted predictor for the model

$$Y(\mathbf{x}) = \Phi_{\mathbf{x}}\alpha + \varepsilon'(\mathbf{x}), \quad \mathbf{x} \in [0,1] \times [0,1],$$

with $\varepsilon'(\mathbf{x}) = b^{1/2}z(\mathbf{x}) + \sigma\varepsilon(\mathbf{x}), \quad \mathbf{x} \in [0,1] \times [0,1]$, and

$$b^{1/2}\hat{z}(\mathbf{x}) = \Sigma_{\mathbf{x}} M^{-1}(I - \Phi_{\mathbf{x}}(\Phi' M^{-1}\Phi)^{-1}\Phi' M^{-1})\mathbf{Y}, \quad \mathbf{x} \in [0,1] \times [0,1],$$

is the plug-in predictor of the centered Gaussian random effect, based on the least square weighted estimation of the fixed effect parameter vector α. Φ is the $n \times 2^{2J}$, with $\Phi_{i,\mathbf{k}} = \phi^2_{J,\mathbf{k}}(\mathbf{x}^i) = \phi^2_{J,\mathbf{k}}(x^i_1, x^i_2) = \phi_{J,k_1}(x^i_1)\phi_{J,k_2}(x^i_2)$, for $i = 1, \ldots, n$, and $\mathbf{k} = (k_1, k_2)$, $k_1 = 0, \ldots, 2^J - 1$, $k_2 = 0, \ldots, 2^J - 1$, and, for each $\mathbf{x} = (x_1, x_2) \in [0,1] \times [0,1]$, $\Phi_{\mathbf{x}}$ is then the 1×2^{2J} row matrix, with entries $(\Phi_{1,\mathbf{k}} = \phi^2_{J,\mathbf{k}}(\mathbf{x}))_{\mathbf{k}=(k_1,k_2),k_1=0,\ldots,2^J-1,k_2=0,\ldots,2^J-1}$. For each $\mathbf{x} = (x_1, x_2) \in [0,1]\times[0,1]$, matrix $\Sigma_{\mathbf{x}}$ is the $1\times n$ row matrix with entries $(K^1(\mathbf{x}, \mathbf{x^t}))_{t=1,\ldots,n}$, where,

$$\begin{aligned} K^1(\mathbf{x^r}, \mathbf{x^t}) &= \sum_{s=h,v,d} \sum_{j\geq J} \sum_{k_1=0}^{2^j-1} \sum_{k_2=0}^{2^j-1} \lambda_j \psi^s_{j,\mathbf{k}}(\mathbf{x_r})\psi^s_{j,\mathbf{k}}(\mathbf{x_t}) \\ &= \sum_{j\geq J} \sum_{k_1=0}^{2^j-1} \sum_{k_2=0}^{2^j-1} \lambda_j \phi_{j,k_1}(x^r_1)\psi_{j,k_2}(x^r_2)\phi_{j,k_1}(x^t_1)\psi_{j,k_2}(x^t_2) \\ &\quad +\lambda_j \psi_{j,k_1}(x^r_1)\phi_{j,k_2}(x^r_2)\psi_{j,k_1}(x^t_1)\phi_{j,k_2}(x^t_2) \\ &\quad +\lambda_j \psi_{j,k_1}(x^r_1)\psi_{j,k_2}(x^r_2)\psi_{j,k_1}(x^t_1)\psi_{j,k_2}(x^t_2). \end{aligned}$$

Finally, $M = \Sigma + (\sigma^2/b)I_n$, with Σ the $n \times n$ matrix, with entries $(\Sigma_{\mathbf{r},\mathbf{t}})_{r=1,\ldots,n,\ t=1,\ldots,n} = (K^1(\mathbf{x^r}, \mathbf{x^t}))_{r=1,\ldots,n,\ t=1,\ldots,n}$, with $\mathbf{x^r} = (x^r_1, x^r_2)$, $r = 1, \ldots, n$, and $\mathbf{x^t} = (x^t_1, x^t_2)$, $t = 1, \ldots, n$, (see, [4]).

2.2 Spatial shrinkage and thresholding

In this section, we briefly introduce an alternative wavelet-based nonparametric regression framework in space, based on the application of spatial non-linear *shrinkage* rules, that allows to eliminate the additive Gaussian white noise ε, in the following equation:

$$Y_i = f(x^i_1, x^i_2) + \sigma\varepsilon(x^i_1, x^i_2), \quad i = 1, \ldots, n. \tag{1}$$

 ISBN: 978-84-617-8694-7

Specifically, the shrinkage estimator $\hat{f}$ of function f minimizes the empirical mean-square error

$$E(\hat{f}) = \frac{1}{n}\sum_{i=1}^{n} E\left(\hat{f}(x_1^i, x_2^i) - f(x_1^i, x_2^i)\right)^2.$$

In the next section, spatial *wavelet thresholding* will be applied (see, for example, [2]). The following steps will then be implemented for the computation of the spatial wavelet thresholding estimators of function f in equation (1):

Step 1 The two-dimensional discrete wavelet transform is computed.

Step 2 A nonlinear *shrinkage* rule is applied. In particular, hard-thresholding or soft-thresholding could be applied (see, for example, [11]). We can also distinguish between *global thresholding* and *level dependent thresholding*.

Step 3 The corresponding shrinkage estimator is obtained from the inverse two-dimensional discrete wavelet transform, given by

$$\begin{aligned}\hat{f}(x_1^i, x_2^i) &= \sum_{k_1=0}^{2^{J_0}-1}\sum_{k_2=0}^{2^{J_0}-1} \hat{\alpha}_{J_0,\mathbf{k}}\phi_{J_0,\mathbf{k}}(x_1^i, x_2^i) \\ &+ \sum_{s=h,v,d}\sum_{j=J_0}^{J}\sum_{k_1=0}^{2^j-1}\sum_{k_2=0}^{2^j-1} \hat{\beta}^s_{j,\mathbf{k}}\psi^s_{j,\mathbf{k}}(x_1^i, x_2^i).\end{aligned}$$

3 Estimation of ocean surface temperature of Hawaii ocean

Here, ocean surface temperature is estimated in Hawaii Ocean by applying different wavelet-based methodologies. Data are collected from the oceanographic bio-optical database: *The Worldwide Ocean Optics Database (WOOD)*. Particularly, the area analyzed corresponds to the latitude-longitude interval $[22.7, 22.8] \times [-158.1, -157.94]$, during the period 2000 – 2007. In that area and period, 1564 weather stations are available, approximately between 190 and 292 stations are available per year, in the period studied. Spatial interpolation method based on exponential covariance function is applied to allocating data on a 16×16 spatial regular grid. The influence of the spatial interpolation technique in the wavelet-based methodologies studied here is investigated in [4]. Moreover, they show the presence of strong correlations in space and time in annual mean ocean surface temperature data in the area studied here. Specifically, the spatial dependence structure of the yearly averaged data reflects spatial and temporal correlations of daily data within each year studied. Then, kriging with exponential covariance model is suitable for interpolate yearly averaged ocean surface temperature values because it takes into account the spatial dependence structure. Figure 1 displays boxplots of the absolute error spatial L^∞-norms for the wavelet-based

 ISBN: 978-84-617-8694-7

non parametric regression techniques describes in sections 2.1 and 2.2. The yearly averaged ocean surface temperature maps estimated with the referred estimation methods can be found in Figure 2. Spatial wavelet thresholding methods at coarser resolution levels seems to provide the best estimation results against spatial wavelet kernel penalized regression, where local smoothing is performed. Table 1 shows mean and standard deviation of the absolute error spatial L^∞-norms of the methodologies considered in section 2 compared with two linear model based estimation methodologies implemented in the wavelet domain, previously proposed in the literature. Specifically, in the linear model context, we consider here curve estimation under the SARH(1) model framework (see [5]). The semiparametric estimation methodology, based on fractional-order pseudodiffential models, proposed in [10], is considered as well. The means of L^∞-norms of the absolute error curves, obtained from the application of the selected spatial wavelet thresholding technique, and the semiparametric estimation methodology proposed in [10], are lower than in the case of the wavelet kernel penalized nonparametric regression and SARH(1) prediction. Whether stations in tropical and subtropical ocean islands are very concentrated in space. Hence, the linear or non-linear character of the spatial functional statistical model fitted to the data is not as important as its capability for spatial decorrelation, i.e., for efficient processing of strong spatial correlated functional data, by removing redundant information (see, [4]).

Estimation Method	Mean (standard deviation) of L^∞-norms of the absolute error curves
SARH(1)	0.5911 (0.0994)
SEM	0.192 (0.1142)
SWKPR	0.4792 (0.2829)
SWTHR (db2, 1°)	0.1782 (0.0809)
SWTHR (db2, 2°)	0.4582 (0.2188)
SWTHR (db4, 1°)	0.1051 (0.0463)
SWTHR (db4, 3°)	0.6573 (0.3178)

4 Conclusions

In order to find an optimal non-linear estimation of ocean surface temperature in a nonparametric framework, from the discrete wavelet transform of data, we have explained two different methodologies, spatial wavelet thresholding and spatial wavelet kernel penalized regression. The smooth local variation of ocean surface daily temperature in tropical and subtropical regions through the year allows annual spatial prediction of averaged daily temperature, from a coastal station network, covering a very small latitude-longitude interval, when a suitable statistical model is applied. Thus, in that case, the patterns observed in a small area can be reproduced in an extensive area of ocean, in certain subtropical and tropical regions. The results derived here illustrate the fact that, the most important property required on spatial estimation from slow varying strong correlated high-dimensional data is the capability for eliminating redundant information and avoiding over smoothing. While spatial wavelet kernel penalized nonparametric regression methods, like the one derived here, are required, for the analysis of high-dimensional data displaying singular (erratic) spatial patterns over time, to avoid, for example, false positives in risk assessment. Alternatively, a flexible wavelet-based non-linear methodology, allowing the adaptation of scale to the the dependence range of the data, for performing a suitable decorrelation, can be considered to solve the filtering problem. This is the case of spatial wavelet level-dependent thresholding methods considered here, leading to an optimal selection of the most relevant features of the data for estimation, removing redundant information.

Existence and multiplicity results for systems of first order differential equations

Marlène Frigon[1]

[1] *Department of Mathematics and Statistic, University of Montréal*

emails: frigon@dms.umontreal.ca

Abstract

We present existence and multiplicity results for systems of first order differential equations. To this aim, we introduce the method of solution-regions. It generalizes the method of upper and lower solutions and the method of solution-tubes. Our results can also be seen as viabily results since we obtain solutions remaining in suitable regions. We give conditions insuring the existence of at least three viable solutions of a system of first order differential equations.

Abstract

Equivalence transformations and Lie symmetries are found for a generalized Fisher equation.

1 Introduction

In recent years, interactions between the mathematical and biological sciences have been increasing rapidly. Consequently, it has stimulated developments in the theory of non-linear differential equations with a variety of challenging problems. Many physicists and mathematicians have paid much attention to the Fisher equations due to their importance in mathematical physics. The equation analyzed in this work is a generalized Fisher equation with variable coefficients

$$u_t = f(u) + \frac{1}{c(x)} \left(c(x)g(u)u_x\right)_x , \tag{1}$$

where $u(x,t)$ denote the density of tumor cells, g is the diffusion coefficient depending on the variable u, being x and t the independent variables, $f(u)$ an arbitrary function and $c(x)$ an arbitrary function depending on the space variable x. For special cases, this equation has been studied by other authors using symmetry analysis and equivalence transformations [1, 3, 8] has attracted considerable interest in studies of tumor growth and their applications [4, 7, 5, 2]. For a particular case of equation (1), a complete classification of the classical symmetries and exact solutions of was obtained in [6]. In this paper, a generalized Fisher equation is studied from the point of view of the theory of symmetry reductions in partial differential equations.

 ISBN: 978-84-617-8694-7

2 Lie symmetries

We perform the Lie group classification for equation (1) in the case $fg_uc' \neq 0$. That is we classify all the Lie symmetries depending on the form of the arbitrary elements (functions $f(u)$, $g(u)$, and $c(x)$). For the sake of simplicity, in the following analysis we prefer to introduce the new function $\alpha(x) = \frac{c'(x)}{c(x)}$ In this way equation (1) can be written as

$$u_t = f(u) + \alpha g u_x + g_u u_x^2 + g u_{xx}. \tag{2}$$

We look for infinitesimal generator of the equivalence transformations of equation (2) of the form

$$\mathbf{Y} = \Xi^1\partial_t + \Xi^2\partial_x + \phi\partial_u + \mu^1\partial_f + \mu^2\partial_\alpha + \mu^3\partial_g \tag{3}$$

where the infinitesimal components Ξ^1, Ξ^2, and ϕ, are depending on t, x, and u, while the infinitesimal components μ^i, $(i = 1, 2, 3)$ can also depend on f, g, and α. We find that the class (2) admits a continuous group of equivalence transformations generated by the following operators

$$\begin{aligned} &\mathbf{Y_1} = \partial_t, \quad \mathbf{Y_2} = \partial_x, \quad \mathbf{Y_3} = \partial_u, \\ &\mathbf{Y_4} = t\partial_t - f\partial_f - g\partial_g, \quad \mathbf{Y_5} = x\partial_x - \alpha\partial_\alpha + 2g\partial_g, \quad \mathbf{Y_6} = u\partial_u + f\partial_f. \end{aligned} \tag{4}$$

To apply the classical method to equation (2), one looks for infinitesimal generators of the form

$$V = \xi(x,t,u)\partial_x + \eta(x,t,u)\partial_t + \psi(x,t,u)\partial_u,$$

that leave invariant this equation. For f, g and α arbitrary the only symmetry generator admitted by (2) is $\mathbf{v}_1 = \partial_t$. Moreover whenever the function $\alpha(x)$ is constant, the equations (2) admit also the symmetry generator $\mathbf{v}_2 = \partial_x$.
Now, we look for the functional forms of f, g and α which yield extra symmetry generators and we distinguish the following four cases depending on the function g. We write the corresponding results in the following tables:

Table 1: $g = g_0u^{g_1}$

i	α	f	$\mathbf{v}_k$
1.1	$\forall$	$f_0u^{g_1+1}$	$\mathbf{v}_3 = t\partial_t - \frac{u}{g_1}\partial_u$
1.2	$\forall$	$f_0u^{g_1+1} + f_1u,\ f_1 \neq 0$	$\mathbf{v}_4 = \frac{e^{-f_1g_1t}}{f_1}\partial_t + e^{-f_1g_1t}u\partial_u$
1.3	(1)	$f_0u^{g_1+1},\ g_1 \neq -4/3$	$\mathbf{v}_5 = c_2\mathbf{v}_3 + c_4\mathbf{v}_{51} + \frac{c_2+c_1g_1}{g_1(4+3g_1)}\mathbf{v}_{52}$, (2) $\mathbf{v}_{51} = e^{-A}\left(\partial_x - \frac{2\alpha u}{3g_1+4}\partial_u\right)$, with $A = \frac{g_1}{3g_1+4}\int \alpha\, dx$ $\mathbf{v}_{52} = \left(2g_1e^{-A}\int e^A\, dx\right)\partial_x + 4u\left(1 - \frac{g_1\alpha e^{-A}}{3g_1+4}\int e^A\, dx\right)\partial_u$
1.4	(3)	$f_0u^{g_1+1} + f_1u,\ f_1 \neq 0,\ g_1 \neq -4/3$	$\mathbf{v}_4, \mathbf{v}_5 = c_4\mathbf{v}_{51} + \frac{c_1}{4+3g_1}\mathbf{v}_{52}$, (4)
1.5	$\frac{\alpha_1}{x}$	$f_0u^{f_1},\ f_1 \neq g_1 + 1$	$\mathbf{v}_6 = \frac{2(1-f_1)t}{1+g_1-f_1}\partial_t + x\partial_x + \frac{2u}{1+g_1-f_1}\partial_u$

Recursive filtering algorithm from observations with delays modeled by finite state Markov chains

M.J. García-Ligero[1], A. Hermoso-Carazo[1] and J. Linares-Pérez[1]

Abstract

This paper addresses the least-squares linear filtering problem of signals from measurements which can be randomly delayed by one or two sampling times. The delays are modeled by homogeneous discrete-time Markov chains to capture the dependence between them. Assuming that the evolution equation generating the signal is not available and that only the first and second-order moments of the processes involved in the observation model are known, a recursive filtering algorithm is derived using an innovation approach. Recursive formulas for filtering error covariance matrices are obtained to measure the goodness of the proposed estimators.

Key words: Markovian delays, filtering
MSC 2000: 60G35, 62M20, 93E10, 93E11

1 Introduction

An unavoidable problem in communication networks is the existence of delays in the arrival measurements. Indeed, in practical situations such as wireless communication channels is common the existence of errors during the transmission due to heavy network traffic, which can lead delayed measurements. The delay may be deterministic or random, although in the most practical cases, such as mobil communications, exploration seismology, between others, the delay is random, being modeled by a stochastic process.

The problem of signal estimation in linear stochastic systems has been widely studied considering different delayed observation models. Most papers on signal estimation from randomly delayed measurements assume the delay is modeled by independent random variables. In this context, attention has been focused on investigating estimation problems from

 ISBN: 978-84-617-8694-7

measurement subject to a random delay which does not exceed one sample time; so, the available observation at any time is considered to be either the current or previous one. In this line, Hounkpevi and Yaz [1] derived a centralized linear minimum variance unbiased filter considering that the delays are modeled by independent Bernoulli variables with different delay probabilities, indicating that the model considered could be generalized to the case of multiple-sample delay. Thus recently, the research is addressed to signal estimation problem from measurements that can be randomly delayed by more one sampling time. In this situation, Linares-Pérez et al. [2] derived a recursive filtering algorithm from observations which can be randomly delayed by one or two sampling times.

On the other hand, in real communication systems, current time delays are usually correlated with the previous ones; a reasonable way to model the dependence on the delays is to consider them as homogeneous Markov chains. State estimation algorithms from measurements with Markovian delays have been derived considering that the delay steps were known on-line via time-stamped data (see, for example, [3]). Later, García-Ligero et al. [4] proposed recursive filtering and smoothing algorithms when the measurements can be delayed by one sampling time assuming known the statistic characteristics of the Markov chain without the need to know if a particular measurement is delayed or updated.

In this paper, a recursive algorithm is proposed for the least-squares linear filter of signals from measurements that can be randomly delayed by one or two sampling times. Assuming the state-space model of the signal is not available and that the delay is modeled by a homogeneous discrete-time Markov chain with three states, the filter is derived by using the information provided by the covariance functions of the process involved in the observations, as well as the probability distribution of Markov chain modeling the delay.

2 Observation model

Consider an n-dimensional signal, x_k, whose scalar measured output, z_k, at each sampling time is perturbed by an additive noise:

$$z_k = H_k x_k + v_k, \quad k \geq 1,$$

where H_k is a known matrix and v_k is the measurement noise.

A common problem in communication theory is the existence of failures during the transmission, which can lead to delays in the arrivals of the measurements. In this paper, it is assumed that the measurements may be randomly delayed by one or two sampling time during the transmission; that is, the observed measurement at time k is $z_{k-a},\ a = 1, 2$, if there is delay, or z_k, if there is not. The delay is modeled by a homogeneous Markov chain, $\{\theta_k,\ k \geq 1\}$, that takes values in the state space $S = \{0, 1, 2\}$. If $\theta_k = a,\ a = 1, 2$, means that the k-th measurement is delayed by a sampling periods; otherwise, if $\theta_k = 0$, there is

 ISBN: 978-84-617-8694-7

not delay in arrival. This situation can be modeled by the following observation model:

$$y_k = \sum_{a=0}^{(k-1)\wedge 2} \delta(\theta_k, a) z_{k-a}, \quad k \geq 1,$$

where $\delta(\cdot,\cdot)$ is the Kronecker delta function.

The aim of this paper is to study the least-squares linear estimation problem of the signal, x_k, from the randomly delayed observations $y_1, \cdots, y_k$. This problem is addressed using the information provided by the covariance functions of the signal and involved noises in the observation model. For this purpose, the following hypotheses about the signal and noise processes are assumed:

(i) The signal process, $\{x_k,\ k \geq 1\}$, has zero mean and its covariance function is given by

$$E[x_k x_s^T] = A_k B_s^T,\ s \leq k,$$

where A and B are known $n \times M$ matrix functions.

(ii) The measurement noise, $\{v_k,\ k \geq 1\}$, is a white process with zero mean and known variances $E[v_k^2] = R_k$.

(iii) $\{\theta_k,\ k \geq 1\}$ is a homogenous Markov chain that takes values in $S = \{0, 1, 2\}$, with known probability distribution $\pi_a^{(k)} = P[\theta_k = a],\ a \in S$, and transition probability matrix $\mathbf{P} = \begin{pmatrix} p_{00} & p_{01} & p_{02} \\ p_{10} & p_{11} & p_{12} \\ p_{20} & p_{21} & p_{22} \end{pmatrix}$, where $p_{ab} = P\left[\theta_k = b/\theta_{k-1} = a\right],\ a, b \in S$.

(iv) The signal process, $\{x_k,\ k \geq 1\}$, the noise, $\{v_k,\ k \geq 1\}$, and $\{\theta_k,\ k \geq 1\}$, are mutually independent.

Given the randomly delayed measurements up to time k, $y_1, \cdots, y_k$, our aim is to determine the least-squares linear estimator, $\widehat{x}_{k/k}$, of the signal, x_k. For this purpose an innovation approach is used.

The innovation approach is based on an orthogonalization procedure by means of which the observation process is transformed into an equivalent one, the innovation process, defined as the differences between each observation and its estimation from the previous ones; the linear estimation problem is then approached by replacing the observation process by the innovation one since both processes provide the same information. As the innovation process is white, the estimator calculated as linear combination of innovations provides a simpler form to obtain the algorithms than that obtained when it is expressed as linear combination of observations. In order to apply this approach, the first step is to calculate the explicit

 ISBN: 978-84-617-8694-7

expression for the innovation and its covariance matrix, and afterwards determining the estimator expression.

According to this approach, the estimator, $\widehat{x}_{k/k}$, is expressed as a linear combination of the innovation, $\mu_h = y_h - \widehat{y}_{h/h-1}$, where $\widehat{y}_{h/h-1}$ is the one-stage predictor of the observation y_h; specifically, the least-squares linear estimator, $\widehat{x}_{k/k}$, is given as follows:

$$\widehat{x}_{k/k} = \sum_{h=1}^{k} E[x_k \mu_h] \Pi_h^{-1} \mu_h, \quad k \geq 1$$

where $\Pi_h = E[\mu_h^2]$ denotes the innovation covariance matrix.

In order to simplify the expressions of the filtering algorithm, the following notations are used:

$$\mathbb{A}_k = \begin{cases} (H_1 A_1 \mid 0 \mid 0)\,(\mathbf{P} \otimes I_M)^T, & k = 1 \\ (H_2 A_2 \mid H_1 A_1 \mid 0)\,(\mathbf{P}^2 \otimes I_M)^T, & k = 2 \\ (H_k A_k \mid H_{k-1} A_{k-1} \mid H_{k-2} A_{k-2})\,(\mathbf{P}^k \otimes I_M)^T, & k \geq 3 \end{cases}$$

$$\mathbb{B}_k = \begin{cases} \left(\pi_0^{(1)} H_1 B_1 \mid 0 \mid 0\right)(\mathbf{P}^{-1} \otimes I_M)^T, & k = 1 \\ \left(\pi_0^{(2)} H_2 B_2 \mid \pi_1^{(2)} H_1 B_1 \mid 0\right)(\mathbf{P}^{-2} \otimes I_M)^T, & k = 2 \\ \left(\pi_0^{(k)} H_k B_k \mid \pi_1^{(k)} H_{k-1} B_{k-1} \mid \pi_2^{(k)} H_{k-2} B_{k-2}\right)(\mathbf{P}^{-k} \otimes I_M)^T, & k \geq 3 \end{cases}$$

$$\mathbb{F}_k = \begin{cases} p_{01}^{(1)} \pi_0^{(1)} R_1, & k = 1 \\ p_{02}^{(1)} \pi_0^{(k)} H_{k-1}(B_{k-1} A_k^T - A_{k-1} B_k^T) H_k^T + p_{01}^{(1)} \pi_0^{(k)} R_k + p_{12}^{(1)} \pi_1^{(k)} R_{k-1}, & k \geq 2 \end{cases}$$

where $\otimes$ denotes the Kronecker product and I_M is the $M \times M$ identity matrix.

3 Filtering algorithm

The filter, $\widehat{x}_{k/k}$, of the signal x_k is obtained by

$$\widehat{x}_{k/k} = A_k O_k^x, \ k \geq 1,$$

where the vectors O_k^x are recursively calculated as

$$O_k^x = O_{k-1}^x + J_k^x \Pi_k^{-1} \mu_k, \ k \geq 1; \quad O_0^x = 0,$$

with

$$J_k^x = \sum_{a=0}^{(k-1)\wedge 2} \pi_a^{(k)} B_{k-a}^T H_{k-a}^T - r_{k-1}^{xy} \mathbb{A}_k^T - \sum_{j=1}^{(k-1)\wedge 2} J_{k-j}^x \Pi_{k-j}^{-1} \mathbb{G}_{k-j}^{(j)}, \quad k \geq 2;$$
$$J_1 = \pi_0^{(1)} B_1^T H_1^T,$$

 ISBN: 978-84-617-8694-7

being

$$\mathbb{G}_k^{(1)} = \mathbb{F}_k + \mathbb{G}_{k-1}^{(2)}\Pi_{k-1}^{-1}(\mathbb{A}_k J_{k-1}^y + \mathbb{G}_{k-1}^{(1)}), \quad k \geq 2;\ \mathbb{G}_1^{(1)} = \mathbb{F}_1,$$
$$\mathbb{G}_k^{(2)} = p_{02}^{(2)}\pi_0^{(k)} R_k, \quad k \geq 1.$$

The innovation, μ_k, is given by

$$\mu_k = y_k - \mathbb{A}_k O_{k-1}^y + \sum_{j=1}^{(k-1)\wedge 2} \mathbb{G}_{k-j}^{(j)}\Pi_{k-j}^{-1}\mu_{k-j},\ k \geq 2; \quad \mu_1 = y_1,$$

where the vectors O_k^y are recursively calculated as

$$O_k^y = O_{k-1}^y + J_k^y \Pi_k^{-1}\mu_k,\ k \geq 1; \quad O_0^y = 0,$$

with

$$J_k^y = \mathbb{B}_k^T - r_{k-1}^y \mathbb{A}_k^T - \sum_{j=1}^{(k-1)\wedge 2} J_{k-j}^y \Pi_{k-j}^{-1}\mathbb{G}_{k-j}^{(j)}, \quad k \geq 2; \quad J_1^y = \mathbb{B}_1^T.$$

The matrices $r_k^{xy} = E[O_k^x O_k^{yT}]$ and $r_k^y = E[O_k^y O_k^{yT}]$ are obtained by

$$r_k^{xy} = r_{k-1}^{xy} + J_k^x \Pi_k^{-1} J_k^{yT}, \quad k \geq 1; \quad r_0^{xy} = 0,$$
$$r_k^y = r_{k-1}^y + J_k^y \Pi_k^{-1} J_k^{yT}, \quad k \geq 1; \quad r_0^y = 0.$$

The innovation covariance matrix, Π_k, is given by

$$\Pi_k = \sum_{a=0}^{(k-1)\wedge 2} \pi_a^{(k)}[H_{k-\theta}A_{k-a}B_{k-a}H_{k-a}^T + R_{k-a}] - \mathbb{A}_k\left[\mathbb{B}_k^T - J_k^y\right]$$
$$- \sum_{j=1}^{(k-1)\wedge 2} \mathbb{G}_{k-j}^{(j)}\Pi_{k-j}^{-1}\left[\mathbb{A}_k J_{k-j}^y + \mathbb{G}_{k-s}^{(j)}\right]^T, \quad k \geq 2;$$
$$\Pi_1 = \pi_0^{(1)}[H_1 A_1 B_1 H_1^T + R_1].$$

The filtering covariance matrix, $\Sigma_{k/k}$, verifies

$$\Sigma_{k/k} = A_k(B_k - A_k r_k^x)^T,\ k \geq 1.$$

where $r_k^x = E[O_k^x O_k^{xT}]$ is recursively calculated by

$$r_k^x = r_{k-1}^x + J_k^x \Pi_k^{-1} J_k^{xT}, \quad k \geq 1; \quad r_0^x = 0.$$

 ISBN: 978-84-617-8694-7

4 Numerical simulation results

In this section, the efficiency of the proposed filtering algorithm is illustrated by a numerical example. For the simulation, a zero-mean scalar signal $\{x_k,\ k \geq 0\}$ with covariance function

$$E[x_k x_s] = 1.025641 \times 0.95^{k-s}, \quad s \leq k,$$

is considered. Clearly this covariance function, according to Hypothesis (i), can be factorized taking

$$A_k = 1.025641 \times 0.95^k \text{ and } B_s = 0.95^{-s}.$$

The measured outputs are affected by a white noise, $\{v_k,\ k \geq 1\}$, with zero mean and variances $R_k = 0.9, \forall k$.

According to the proposed observation model, it is assumed that the available measurements of the signal can be delayed by one or two sample periods during the transmission; that is, the processed observations are modeled by

$$y_k = \sum_{a=0}^{(k-1)\wedge 2} \delta(\theta_k, a) z_{k-a}, \quad k \geq 1.$$

As in Hypothesis (iii), it is assumed that $\{\theta_k,\ k \geq 1\}$ is a homogeneous Markov chain with initial distribution $\pi_0^{(1)} = 1,\ \pi_1^{(1)},\ \pi_2^{(1)} = 0$, (the first observation is not delayed) and transition probability matrix $\mathbf{P} = \begin{pmatrix} 0.99 & 0.006 & 0.004 \\ 0.15 & 0.98 & 0.005 \\ 0.002 & 0.028 & 0.97 \end{pmatrix}$.
Moreover, the signal and noise processes are assumed to be mutually independent.

In order to realize the simulation process, the signal is assumed to be generated from the following first-order autoregressive model,

$$x_{k+1} = 0.95 x_k + w_k$$

where $\{w_k,\ k \geq 0\}$ is a zero-mean white Gaussian noise with $E[w_k^2] = 0.1,\ \forall k$.

Figure 1 shows a simulated signal together with the filtering estimates, $\widehat{x}_{k/k}$. In this figure, we notice the closeness between the evolution of filtering estimates and the signal, which reveals the good performance of the proposed estimators.

Moreover, we have also calculated the filtering error variances assuming that the delay is modeled by different Markov chains. Concretely, we assume the same initial distribution (first observation is not delay) and the following transition probability matrices:

$$\mathbf{P_1} = \begin{pmatrix} 0.95 & 0.03 & 0.02 \\ 0.05 & 0.89 & 0.06 \\ 0.03 & 0.07 & 0.9 \end{pmatrix}, \quad \mathbf{P_2} = \begin{pmatrix} 0.9 & 0.04 & 0.06 \\ 0.07 & 0.87 & 0.06 \\ 0.05 & 0.06 & 0.89 \end{pmatrix}.$$

 ISBN: 978-84-617-8694-7

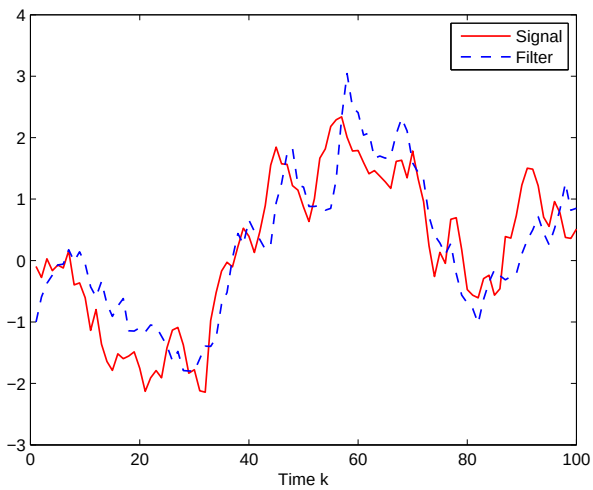

Figure 1: Simulated signal, filtering estimates

The properties of the Markov chains lead us to conclude that the no delay probabilities converge to constant values; in our case these values are $0.58, 0.44$, and 0.37, for the different considered transition probability matrices, $\mathbf{P}, \mathbf{P_1}$ and $\mathbf{P_2}$, respectively. Figure 2 shows the filtering error variances for these models; this figure reveals that as the limit probability of no delay increases, the filtering error variances become smaller and, consequently, the performance of the estimator improves.

Abstract

The symmetric matrices have particular spectral properties, that is, with respect to their eigenvalues (they are real) and eigenvectors (they are orthogonal and form a basis for diagonalization). In particular we are interested in the partitioning of symmetric graphs through a specific eigenvector of the Laplacian matrix. In this work we expose similar spectral properties regarding skew-symmetric matrices, some known, such that their eigenvalues are purely imaginary and not defective, and other seemingly new, that they verify a minimax variational formula. As application we use it in the problem of partitioning non-symmetric, oriented graphs in two parts of equal number of vertices, with the minimum number of edges between the parts.

Key words: Variational Eigenvalue, Spectral Graph Partition

1 Introduction

Among the spectral properties of the symmetric matrices are that they have real eigenvalues and eigenvectors forming an orthonormal basis, in addition to the extreme minimax relations. We propose to generalize these properties to skew-symmetric matrices. Some results are known, but the variational formula of Theorem 2, as far as we know, is not. This is the main development of the paper, and it is motivated by a problem of oriented graph partition that we will describe.

On terminology, we speak of matrices instead of operators (or of symmetric matrices instead of self-adjoint operators) for convenience. Also, although the matrices, of real

entries, are considered as operators in $\mathbb{R}^n$, it will sometimes be considered as operators in $\mathbb{C}^n$. For example, when speaking about the eigenvector corresponding to a complex eigenvalue.

In the following section we recall the spectral properties of symmetrical matrices of interest for us. In the section 3 we develop the results for skew-symmetric matrices, although the formulation of the statements requires some modifications, like the extremal formula containing pairs of purely imaginary eigenvalues. Another modification is the use of real Jordan blocks, instead of diagonal form, to have a real orthonormal basis. Finally in section 4 we suggest the application of these results to the problem of partition of oriented graphs. We delay until that section the exposition of the problem.

2 Spectral Properties of Symmetric Matrices

A generic real matrix A of size $n \times n$ is expressed as:

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots \\ a_{21} & \ddots & \\ \cdots & & a_{nn} \end{pmatrix} = (a_{ij})_{\substack{i=1,\ldots,n \\ j=1,\ldots,n}}$$

with $a_{ij} \in \mathbb{R}$. We will consider the Euclidean scalar product, defined for vectors $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$ of $\mathbb{R}^n$ as $(x, y) = \sum_{i=1}^n x_i y_i$. We will also use the Hermitian product, if $x, y \in \mathbb{C}^n$, defined as $(x, y) = \sum_{i=1}^n x_i \bar{y_i}$. Both products are denoted equally, the context identify the meaning. The Euclidean product allows us to characterize symmetric and skew-symmetric matrices:

Lemma 1. *Let A be a real matrix $n \times n$. $(Ax, y) = (x, Ay)$ for all $x, y \in \mathbb{R}^n$ if and only if A is symmetric. $(Ax, y) = -(x, Ay)$ for all $x, y \in \mathbb{R}^n$ if and only if A is skew-symmetric.*

The proof of the facts of this section can be found in almost any standard book of Linear Algebra, for example [3].

We will denote as λ an eigenvalue of A, that is, a number $\lambda \in \mathbb{C}$ such that there is a non null vector $v \in \mathbb{C}^n$ (called eigenvector corresponding to λ) with $Av = \lambda v$. As it is know a real matrix can have complex eigenvalues, in conjugate pairs because they are the roots of the characteristic polynomial. The set of eigenvalues $\{\lambda_1, \lambda_2, \ldots, \lambda_n\}$ (not necessarily different) is called the spectrum of A. We resume some spectral properties of symmetrical matrices in the following:

Proposition 1. *If A is a $n \times n$ symmetric matrix:*

a) The eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_n$ are reals.

b) The eigenvectors corresponding to different eigenvalues are orthogonal.

 ISBN: 978-84-617-8694-7

c) There is a basis of eigenvectors (that is, the matrix A is diagonalizable).

In order to calculate the eigenvalues effectively, for example in numerical analysis [2] or in the theory of vibrations [4], variational methods like the following theorem are often used.

The Rayleigh quotient of a symmetric matrix A is

$$R_A(x) = \frac{(Ax, x)}{(x, x)}$$

defined for $x \neq 0$ in $\mathbb{R}^n$.

Theorem 1. *(Courant-Fisher). Let $\mathcal{S}_k$ be the set of subspaces of $\mathbb{R}^n$ of dimension lesser or equal than k, for $k = 1, 2, \ldots, n$. If the eigenvalues are sorted $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$,then*

$$\lambda_k = \min_{E \in \mathcal{S}_k} \max_{\substack{x \in E \\ ||x||=1}} R_A(x)$$

and, dually,

$$\lambda_{n-k+1} = \max_{E \in \mathcal{S}_k} \min_{\substack{x \in E \\ ||x||=1}} R_A(x)$$

Besides, the extreme value is reached in a corresponding eigenvector.

3 Spectral Properties of Skew-symmetric Matrices

We will follow the path outlined by the above results, but in the case of skew-symmetric matrices. Being this an extended abstract, the proofs are omitted. In this section, A will be a real skew-symmetric matrix. We consider it both an lineal operator in $\mathbb{R}^n$ or in $\mathbb{C}^n$. For example a non real eigenvalue $\lambda \notin \mathbb{R}$ has a corresponding eigenvector with non null imaginary part in some components.

Proposition 2. *The eigenvalues λ_k of A are purely imaginary, that is $\lambda_k = \tau_k i$, $\tau_i \in \mathbb{R}$.*

Note that 0 is purely imaginary. In particular, as the eigenvalues appear in conjugate pairs, if the order n is odd the real 0 must be an eigenvalue.

Proposition 3. *Two eigenvectors v_{k_1}, v_{k_2} corresponding to different eigenvalues $\lambda_{k_1}, \lambda_{k_2}$, respectively, are orthogonal.*

In the following proposition, the index starts from zero to ease the notation that will be used later to match pairs of vectors.

 ISBN: 978-84-617-8694-7

Proposition 4. *(Spectral Decomposition). For a skew-symmetric matrix A there exists an orthonormal basis of $\mathbb{C}^n$ that consists of eigenvectors $v_0, v_1, \ldots, v_{n-1}$ corresponding to the eigenvalues $\lambda_0, \lambda_1, \ldots, \lambda_{n-1}$. Moreover, for every $x \in \mathbb{C}^n$ we have:*

$$Ax = \sum_{k=0}^{n-1} \lambda_k (x, v_k) v_k$$

and

$$(Ax, x) = \sum_{k=0}^{n-1} \lambda_k (x, v_k)^2.$$

Propositions 3 and 4 are standards results for normal complex matrices, in particular for skew-symmetric real ones [4]. We have chosen to explicitly state it because, in conjunction with Proposition 2 and the following lemmas, we can arrive at the variational Theorem 2, which is the new result that we need for graph partitioning.

The above expression of Ax and of the quadratic form (Ax, x) in Proposition 4 is diagonal, but of complex coefficients in a basis of complex vectors. We will modify it to have a real expression, on a real orthonormal basis of $\mathbb{R}^n$. It will not be diagonal, but in the form of real Jordan blocks, that is, tridiagonal.

3.1 Orthonormal Real Basis

For a set of vectors $e_1, \ldots, e_k \in \mathbb{R}^n$, $E = \langle e_1, \ldots, e_k \rangle$ is the subspace generated over $\mathbb{R}$ by these vectors. Likewise, if the vectors belong to $\mathbb{C}^n$, $\langle e_1, \ldots, e_k \rangle_{\mathbb{C}}$ is the subspace generated over $\mathbb{C}$. We also denote with $E_\lambda = \mathrm{Ker}(A - \lambda I)$ the eigenspace of the eigenvalue λ.

Lemma 2. *If A is a skew-symmetric real matrix:*

a) If λ is a simple eigenvalue of A, $\bar{\lambda}$ is also simple. If v_λ is a unit vector with $E_\lambda = \langle v_\lambda \rangle_{\mathbb{C}}$, then there is a unit vector $v_{\bar{\lambda}}$ with $E_{\bar{\lambda}} = \langle v_{\bar{\lambda}} \rangle_{\mathbb{C}}$ and such that $u_0 = (v_\lambda + v_{\bar{\lambda}}) \dfrac{\sqrt{2}}{2}$ and $u_1 = (v_\lambda - v_{\bar{\lambda}}) i \dfrac{\sqrt{2}}{2}$ are unit real vectors with $E_\lambda \oplus E_{\bar{\lambda}} = \langle u_0, u_1 \rangle_{\mathbb{C}}$.

b) If λ is an eigenvalue with multiplicity n_λ, $\bar{\lambda}$ has the same multiplicity. For each unit $v_\lambda \in E_\lambda$ there is a unit $v_{\bar{\lambda}} \in E_{\bar{\lambda}}$ such that $u_0 = (v_\lambda + v_{\bar{\lambda}}) \dfrac{\sqrt{2}}{2}$ and $u_1 = (v_\lambda - v_{\bar{\lambda}}) i \dfrac{\sqrt{2}}{2}$ are unit real vectors. Besides if $v_\lambda, v'_\lambda \in E_\lambda$ are linearly independent, its corresponding $v_{\bar{\lambda}}, v'_{\bar{\lambda}}$ are also linearly independent.

We order the complex vector of the orthonormal basis $v_0, v_1, \ldots, v_{n-1}$ of proposition 4 in such a way that the corresponding eigenvalues $\lambda_0, \lambda_1, \ldots, \lambda_{n-1}$ verify $\lambda_{2p} = \bar{\lambda}_{2p+1}$ for

$p = 0, \ldots, \frac{r}{2} - 1$, being r the rank of A, necessarily even. If n is odd, the last eigenvalue is 0. We also consider that $\lambda_{2p} = \tau_p i$ with $\tau_0 \geq \tau_1 \geq \cdots \geq 0$. In this way $\lambda_{2p+1} = -\tau_p i$.

In addition, $\lambda_{2p+1} = \bar{\lambda}_{2p}$ and we can choose the pair of vectors v_{2p}, v_{2p+1} verifying the claim of Lemma 2. If we call u_{2p}, u_{2p+1} to the pair of real vectors that arise from v_{2p}, v_{2p+1} in this Lemma, the set $u_0, u_1, \ldots, u_{n-1}$ is a orthonormal basis of $\mathbb{R}^n$. If we change A to this basis, it results

$$\begin{pmatrix}
0 & \tau_0 & 0 & 0 & & & & & & \\
-\tau_0 & 0 & 0 & 0 & & & & & & \\
0 & 0 & 0 & \tau_1 & & & & & & \\
0 & 0 & -\tau_1 & 0 & & & & & & \\
 & & & & \ddots & & & & & \\
 & & & & & 0 & \tau_{\frac{r}{2}-1} & & & \\
 & & & & & -\tau_{\frac{r}{2}-1} & 0 & & & \\
 & & & & & & & 0 & & \\
 & & & & & & & & \ddots & \\
 & & & & & & & & & 0
\end{pmatrix}$$

The pair u_{2p}, u_{2p+1} verifies $Au_{2p} = \tau_p u_{2p+1}, Au_{2p+1} = -\tau_p u_{2p}$. It is termed a hyperbolic pair in the classification of quadratic forms [5]. Calling $a_k = (x, u_k)$ we have $x = \sum_{k=0}^{n-1} a_k u_k$, as in any basis, but besides

$$Ax = \sum_{p=0}^{r/2-1} \tau_p (a_{2p} u_{2p+1} - a_{2p+1} u_p)$$

Therefore $(x, x) = \sum_{p=0}^{r/2-1} (a_{2p}^2 + a_{2p+1}^2) + \sum_{k=r}^{n-1} a_k^2$ and

$$(Ax, Ax) = \sum_{p=0}^{r/2-1} \tau_p^2 (a_{2p}^2 + a_{2p+1}^2)$$

3.2 Cuadratic Extremal Theorem

With the above expressions we can reach the main result of the paper. We define the quadratic Rayleigh quotient, for $x \neq 0$, as:

$$S_A(x) = \frac{(Ax, Ax)}{(x, x)}$$

Being $u_0, u_1, \ldots, u_{n-1}$ the above orthonormal real basis, we define $F_p = \langle u_0, u_1, \ldots, u_{2p}, u_{2p+1} \rangle$. We can proof:

 ISBN: 978-84-617-8694-7

Proposition 5.

$$\tau_p^2 = \min_{\substack{x \in F_p \\ x \neq 0}} S_A(x)$$

Based on that proposition, we can prove that:

Theorem 2. *If $\mathcal{S}_{2p}$ be the set of subspaces of $\mathbb{R}^n$ of dimension lesser or equal than $2p$, then*

$$\tau_p^2 = \max_{E \in \mathcal{S}_{2p}} \min_{\substack{x \in E \\ ||x||=1}} S_A(x)$$

and, dually,

$$\tau_{n-2p+1}^2 = \min_{E \in \mathcal{S}_{2p}} \max_{\substack{x \in E \\ ||x||=1}} S_A(x)$$

Besides, the extreme value is reached in a corresponding eigenvector.

4 Partition of Oriented Graphs

Our main motivation for developing the above variational formula of Theorem 2 is its use in spectral partition of oriented graphs. An undirected graph, commonly called graph without further specification, is a set V of vertices and a set E of edges. Each edge is a set $\{p_1, p_2\}$ of two vertices of V. Its graphic representation associates each vertex to a point of the representation medium and each edge to a line that joins the corresponding vertices. An oriented graph is an undirected graph in which in each edge $\{p_1, p_2\}$ has been chosen an orientation, or arrow, either (p_1, p_2) or (p_2, p_1). It is different from the concept of directed graph, where between two vertices can go both arrows (or also one of them, or none at all).

In this work we study oriented graphs, well represented by the oriented incidence matrix A, skew-symmetric, with entries:

$$a_{ij} = \begin{cases} +1 \text{ if the orientation is } (p_i, p_j) \\ -1 \text{ if the orientation is } (p_j, p_i) \\ 0 \text{ in other case} \end{cases}$$

We briefly describe now the spectral partition of non-directed graphs [7], and then sketch how Theorem 2 allows to develop an analogous theory for oriented graphs. The problem of graph partitioning is to divide the set of vertices in two equal parts, so that the total number of edges between the two parts is minimized. One of the fields where this problem arises is in high performance computing (HPC). The distributed HPC applications are composed of many processes, each with its computational load. These processes must communicate with each other, and that slows the computation. The application is modeled by a graph where the vertices are the processes and the edges represent the communications. When assigning

 ISBN: 978-84-617-8694-7

the processes to the different processors of a parallel architecture, this assignment must be done in equal parts (so that the computational load is balanced), but also minimizing the number of edges between parts (so that the communication delays are minimized) [1].

An approximate solution to this combinatorial optimization problem, in the case of non-directed graphs, is obtained by the spectral theory of the Laplacian matrix L. This matrix is $L = D - M$, where M is the adjacency matrix, of entries:

$$m_{ij} = \begin{cases} 1 \text{ if } \{p_i, p_j\} \text{ is an edge} \\ 0 \text{ in other case} \end{cases}$$

and D is the diagonal degree matrix: d_{ii} is the number of vertices adjacent to p_i. The meaning of this construction, $D - M$, is to add a valuated loop in each vertex, so that the resulting graph verifies the Kirchhoff's current law: the sum of the incidences in each vertex (the sum of the rows of L) is zero. As a mathematical consequence, one of the eigenvalues of the Laplacian matrix L is $\lambda_1 = 0$ and the corresponding eigenvector is the vector of ones $\mathbf{1} = (1, 1, \ldots, 1)$. This causes that the eigenvectors corresponding to nonzero eigenvalues are orthogonal to $\mathbf{1}$. The Fiedler eigenvector v_f is the corresponding to the minimum nonzero eigenvalue λ_2. By the extremal Theorem 1, $\lambda_2 = \min\limits_{E \in \mathcal{S}_2} \max\limits_{x \in E}(Lx, x)$, and the minimum of (Lx, x) between those x orthogonal to $\mathbf{1}$ is precisely the Fiedler eigenvector v_f. If c is the characteristic vector of a vertex partition (that is, the i-th component of c is $+1$ if p_i belongs to the first part, -1 if p_i belongs to the second), it can be viewed that (Lc, c) is proportional to the number of edges between the two parts. That is, the negative and positive components of the Fiedler vector approximates the characteristic vector of a partition that minimizes the number of edges. A bound on the error of this approximation is given by [6].

To transfer this spectral partitioning scheme, from the case of non-directed graphs to the case of oriented graphs, is the practical application that we search when developing Theorem 2. To make a construction similar to that of Kirchhoff, obtaining a matrix with $\mathbf{1}$ as eigenvector, keeping the skew-symmetry, we consider the vector d of total degrees, that is, the i-th component is the number of arrows coming out of p_i minus those coming in. The total degree can be negative, if there are more arrows arriving at the vertex than coming out. We define the skew-symmetric Laplacian L_s as the matrix with the following blocks:

$$L_s = \begin{pmatrix} A & d \\ -d^t & 0 \end{pmatrix}$$

being d^t the vector of total degrees considered as a row matrix. The skew-symmetric Laplacian has eigenvalue 0 and corresponding eigenvector $\mathbf{1}$. By the spectral properties of the skew-symmetric matrices described in section 3, the non null eigenvalues of L_s with minimal imaginary part, λ_{2f} and λ_{2f+1} with $f = \frac{r}{2} - 1$ (r the rank of L_s), have a pair v_{2f}, v_{2f+1} of complex eigenvectors whose real equivalents u_{2f}, u_{2f+1} by Lemma 2 are analogous to

 ISBN: 978-84-617-8694-7

the Fiedler vector: they are orthogonal to **1** (hence approximating the characteristic of a partition) and minimize the expression $(L_s x, L_s x)$, that can be seen proportional to the number of arrows between the two parts.

In summary, the spectral properties of the eigenvalues closest to zero in the matrices of Laplacian type, either symmetric or skew-symmetric, allow us to approximate a solution to the combinatorial problem of graph partitioning.

Abstract

Recently, deep learning techniques based on Convolutional Neural Networks (CNN) have started to be used for the classification of hyperspectral images. These techniques present high computational cost when preprocessing stages are applied. In this paper, a GPU (Graphical Processor Unit) implementation of a spatial-spectral supervised classification scheme based on CNNs and applied to remote sensing datasets is presented. The scheme comprises convolution filters for processing the spectral information and a patch around each pixel to take the spatial information into account. To reduce the size of the filters, the dimensionality of the dataset is previously reduced using Principal Component Analysis (PCA). In order to achieve an efficient GPU projection, different techniques and optimizations have been applied such as the use of the deep learning framework Caffe. Speedups of up to 38.66× over the Pavia University dataset are obtained together with competitive classification accuracies.

1 Introduction

Hyperspectral images contain a large amount of information that can be exploited during the processing. This information is not only spectral but there is also a lot of spatial information in the neighborhood of each pixel. Hyperspectral techniques that can exploit

 ISBN: 978-84-617-8694-7

both types of information are known by the name of spectral-spatial techniques [1]. When these techniques are introduced in the classification of hyperspectral images, experimental results show great improvements in the accuracy results.

Recently, deep-learning techniques have started to be introduced in the field of classification of hyperspectral datasets [2, 3, 4, 5, 6]. These classifiers consist of several layers with nonlinear processing units to extract and transform different features. Each layer uses the output of the previous layer as input and the network can be trained in a supervised or unsupervised manner. Applications include pattern recognition and statistical classification. The proposed methods extract spatial information using structures such as Multilayer Perceptrons (MLP) or Convolutional Neural Networks (CNN). Usually before the extraction of spatial information, a dimensionality reduction is performed using techniques such as Principal Component Analysis (PCA), Independent Component Analysis (ICA) or wavelets in order to obtain moderately small vectors.

A CNN contains convolutional layers that can be used to perform spatial convolutions on the hyperspectral image bands. Usually pooling layers are also included in order to apply some kind of decimation and reduce the number of coefficients. A CNN may have one or more convolutional layers, but the final classification is performed using one or more fully-connected layers. Activation functions to introduce non-linearity, usually of sigmoid type, can be included in convolutional layers. Such functions are similar to those used in MLPs. Usually the backpropagation algorithm is used to set the coefficients of both, neurons of fully-connected layers and convolution filters.

Some published deep-learning schemes applied to hyperspectral images use only the spectral information. Thus, Hu *et. al* [4] propose a scheme based on CNNs, which does not consider spatial information since each input is a single pixel-vector. Other schemes incorporate the spectral and spatial information separately to the classifier, often constructing a stack-vector for input to the neural network and using PCA [2, 3, 6, 5].

Remote sensing hyperspectral applications are computationally demanding and, therefore, good candidates to be projected in high performance computing infrastructures such as clusters or specialized hardware devices [7]. GPUs provide a cost-efficient solution to carry out onboard real-time processing of remote sensing hyperspectral data for performing hyperspectral unmixing, classification or change detection, among others [8]. In the case of deep learning techniques, different high-level frameworks optimized for GPU computing are available, such as Theano, Caffe [9], TensorFlow or Torch. The implementations of deep learning methods for hyperspectral images are in some cases presented in terms of execution times but without an analysis of the computational cost [10]. In other cases the use of an optimized framework such as Caffe [11] is mentioned but without including execution times or a detailed analysis of the implementations.

In this paper we propose a CUDA GPU spectral-spatial classification scheme for hyperspectral images based on CNNs and implemented mainly by using the Caffe analyzing

 ISBN: 978-84-617-8694-7

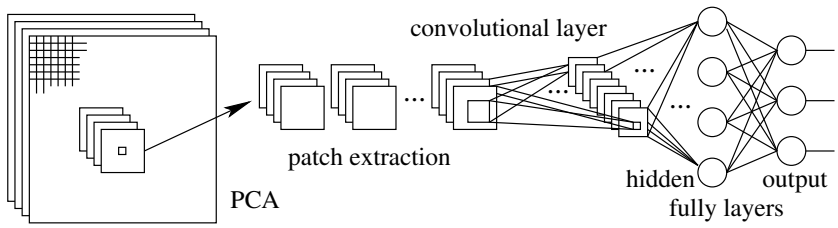

Figure 1: HYCNN scheme for the classification of hyperspectral images.

the details of the implementation. In order to reduce the size of the convolution filters, the image dimensionality is previously reduced using PCA, as it will be explained in the next section.

The paper is organized as follows: section 2 presents the proposed spectral-spatial classification scheme in CPU, section 3 presents the GPU code. The evaluation is performed in section 4, and, finally, section 5 presents the conclusions.

2 Spectral-Spatial CNN-Based Classification

In this section we present a scheme for the classification of hyperspectral images based on PCA, patch extraction, and CNNs, that we called HYCNN. Fig. 1 shows the operations performed and the network structure. These are described in more detail in the pseudocode of Algorithm 1, which also indicates the adjustable parameters in the scheme.

Algorithm 1 Steps of the HYCNN scheme

Input: Hyperspectral image
Output: Classification map
Parameters:
N_1: number of principal components
$H \times V$: patch size
N_2: number of convolution filters
$F_1 \times F_2$: spatial size of filters
$D_1 \times D_2$: decimation factor
N_3: number of neurons in hidden layer
η: learning parameter

1. Preprocessing
1.1 PCA on the image
2. Patch extraction
2.1 Patch around each pixel
3. Convolutional layer
3.1 Convolution filtering
3.2 Pooling (average)
3.3 Activation function (sigmoid)
4. Fully-connected layers
4.1 Hidden layer (with sigmoid)
4.2 Output layer (with sigmoid)

As a first step, HYCNN performs a reduction of image dimensionality using PCA. It extracts the most significant information from the hyperspectral image in the spectral dimension and reduces the number of components, which progress to the next step of the algorithm.

A patch is then extracted around each pixel to be classified. This step aims at getting the spatial information in the neighborhood of a pixel in addition to the spectral information. Accordingly, the patch has the same number of components as those retained from the PCA, and comprises a window around the pixel. The window size is an adjustable parameter of the classification. Each patch is considered a sample and used as the unit of information during the training and classification phases by the CNN.

The next step is the processing of each patch by the CNN. This consists of three parts: convolutional filters, pooling layer and activation function. A convolutional layer is a locally connected structure which is convolved with the image to produce several feature maps, one for each filter. Each filter consists of a rectangular grid of neurons. Unlike a fully-connected layer, the filter coefficients used in all the nodes are the same.

The convolutional layer of our scheme processes several components (spectral bands). The inputs to the filters are the patches, which we assume to have in this sequential algorithm a size of $H \times V \times N_1$, being H and V the size of the spatial dimensions, and N_1 the number of bands. In order to extract multiple features, the convolutional layer comprises N_2 filters, so we will have this same number of maps (planes) at the output. Regarding the size of the filters, if $F_1 \times F_2$ is the size of the spatial grid, each filter will have $F_1 \times F_2 \times N_1$ coefficients.

The pooling layer takes small rectangular blocks from the convolutional layer and subsamples them to produce a single output from each block. For the pooling layers each map is subsampled with mean pooling over blocks of size $D_1 \times D_2$. After the subsampling, a sigmoidal nonlinearity is applied to each feature map.

The last part of the scheme consists of fully-connected layers, which perform the high-level reasoning of the CNN. A fully connected layer takes all the outputs in the previous layer and connects then to every single neuron it has. This type of layer is arranged in one dimension, so they are not spatially located operations anymore. In this paper we use the typical two-layer MLP, with hidden and output layers. The number of neurons in the hidden layer is the adjustable parameter N_3, while the output layer has a number of neurons equal to the number of classes in the hyperspectral image. The activation function in both, convolutional and fully-connected layers, is of sigmoid type.

The learning of all the layers of the CNN in this scheme is conducted using a backpropagation algorithm. The error is computed at the output of the network using the training samples and comparing the results to the reference data. Then, the error is propagated backwards through the network. The backpropagation is used in conjunction with an optimization method, in this case a gradient descent. It calculates the gradient of a cost function with respect to all the weights of the network, and then updates the weights in an attempt to minimize the cost function. The learning parameter, usually denoted as η, indicates how much the weights are adjusted at each update.

3 Spectral-Spatial CNN-Based Classification in GPU

In this section we introduce some Compute Unified Device Architecture (CUDA) programming fundamentals as well as the CUDA GPU implementation of the scheme proposed in Sect. 2.

3.1 CUDA GPU programming fundamentals

CUDA is a parallel computing platform and programming model that enables NVIDIA GPUs to execute programs invoking parallel functions called kernels [12]. Each kernel launches a user-defined number of threads that are organized into blocks. The blocks are arranged in a grid that is mapped to a hierarchy of CUDA cores in the GPU. Threads can access data from multiple memory spaces. Each block has a shared memory that is visible exclusively to the threads within this block and whose lifetime is equal to the block lifetime. The shared memory lifetime makes it difficult to share data among thread blocks. This implies the use of global memory whose access is slower than shared memory access. The new Pascal architecture has introduced changes regarding the memory hierarchy [13].

Different performance optimization strategies have been applied in this work. The most important is to reduce the data transfers between the CPU and the GPU memories. Another key is to improve the efficiency in the use of the memory hierarchy by performing the maximum number of computations on the data already stored in shared memory. The search for the best kernel configurations is also fundamental. To get the highest possible occupancy is the only way to hide latencies and keep the hardware busy. To achieve this, the maximum block size for each kernel is selected with the requirement that the number of registers and the shared memory usage do not act as occupancy limiters. Finally, the existing CUDA optimized libraries must be used. CULA [14], MAGMA [15], and CUBLAS [16] are used for algebra operations. For the deep learning calculations the Caffe framework is used. It performs calls to CuDNN [17], CUBLAS and MAGMA. CuDNN is a GPU-accelerated library for deep neural networks.

3.2 CUDA implementation

In this section the GPU implementation of the HYCNN algorithm described in section 2 is detailed. The pseudocode in Algorithm 2 shows a detailed description of the classification scheme. The kernels executed in GPU are placed between <> symbols. The pseudocodes also include the GM and SM acronyms to indicate kernels executed only in global memory and kernels that only use shared memory, respectively. The whole forward-backward process for the training phase of the algorithm is detailed. The CNN is implemented using Caffe. Since the calls to Caffe functions produce a high number of calls to libraries, these are grouped in the pseudocode by steps of the scheme and only the most repeated kernels are

included pointing out the call sequence.

As a first step, the PCA algorithm using EVD (EVD-PCA) is applied to reduce the dimensionality of the dataset. For details of the GPU implementation see [18].

A patch is then extracted around each pixel and stored into a two different Lightning Memory-Mapped Databases (LMDBs) to be accessed from the Caffe framework. The first database stores the training patches whereas the second one stores the test patches. As shown in the pseudocode, both, the CNN steps and the fully-connected layers steps are applied to each patch N times (epochs).

The training phase is divided into two main steps: forward and backward. The forward step computes all the training patches through the full network to obtain a classification result and the backward step updates the network weights to adjust the obtained classification result.

The forward step starts applying the convolution filters to each training patch. Unlike in the CPU version where the $H \times V$ pixels of the patch are computed through the convolution filters sequentially, in the GPU version the patch is converted first into a matrix using the im2col_gpu function (line 3 in the pseudocode 2). Then, it is multiplied by a matrix containing the convolutional values using the cublasSgemm function (line 4).

Next, a pooling substep is performed using a Caffe kernel called AvePoolForward. This function computes the pooling over all the training patches at the same time. The last substep of the CNN is the activation. The CuDNNSigmoidLayer::Forward_gpu() calls the CuDNN funtion to perform the sigmoid activation (line 7).

Once the CNN has finished, two fully-connected layers perform the classification. First, an inner product function (line 8) that uses CuBLAS multiplies the CNN output matrix by a matrix of learned weights. Next, a sigmoid activation function (line 9) is applied over the previous result using a CuDNN function. The previous two operations are repeated over the last fully-connected layer (lines 10 and 11).

At this point, the output of the full network contains the classification of each training patch. Then, a softmax function (line 12) is applied to get a probability distribution over classes. This function takes a vector of arbitrary real-valued scores and converts it to a vector of values between zero and one that sum one. The last substep of the forward is to compute the loss of the network using the function SoftmaxLossForwardGPU (line 13).

Regarding the backward step, it includes all the substeps of the forward step but applied in reverse order (lines 14-26). This allows to update the values of all the neurons in the full network based on the results of the loss function computed in the forward step. At the end of the loop, the update of all the weights of the full network is performed (line 27). This task is carried out by a Caffe function.

4 Results

This section shows the experimental results obtained for the GPU HYCNN scheme comparing to the CPU scheme in terms of computation time and classification accuracy.

The proposed algorithms have been evaluated on a PC with a quad-core Intel i5-6600 at 3.3GHz and 32 GB of RAM. The codes have been compiled using the gcc 4.8.4 version with OpenMP (OMP) 3.0 support under Linux using four threads. The OPENBLAS library has been used to accelerate the algebra operations included in the algorithms. Regarding the GPU implementation, CUDA codes run on an Pascal NVIDIA GeForce GTX 1070 with 15 Streaming Multiprocesors (SMs) and 128 CUDA cores each. The CUDA codes have been compiled under Linux using the nvcc version 8.0.26 of the toolkit. As usual in remote sensing [19], measures of classification accuracy are given in terms of overall accuracy (OA), which is the percentage of correctly classified pixels comparing to the reference data information available. The computational performance results are expressed in terms of execution times and speedups. The results are the average of 10 independent executions.

The algorithms have been used over two remote sensing datasets: a 103-band ROSIS image of the University of Pavia (Pavia Univ.) and a 220-band AVIRIS image taken over Northwest Indiana (Indian Pines). The images and the corresponding reference data are shown in Fig. 2.

For each dataset the samples are randomly distributed between the training [18] and testing sets. During the testing stage all pixels of the image are classified, but the samples used in the training stage are excluded for the calculation of the accuracy results (see Table 1).

Datasets	Sensor	classes	Dimensions	samples	training samples
Pavia Univ.	ROSIS	9	610×340×103	42776	3921 (9.17%)
Indian Pines	AVIRIS	16	145×145×220	10249	695 (6.78%)

Table 1: Information for the test remote sensing datasets.

The configuration parameters were determined by performing experiments varying the number of principal components, the batch size and the filter size for the code executed in CPU. These parameters are also used for the GPU implementation when both codes are compared from the computational point of view. The base parameters considered for the comparison are $H = V = 28$ (patch size), $N_1 = 4$ (number of principal components), $N_2 = 16$ (number of filters), $N_3 = 100$ (neurons in the hidden layer), $F_1 = F_2 = 5$ (filter size), and $D_1 = D_2 = 2$ (decimation factor). The backpropagation algorithm was performed with learning parameter $\eta = 0.2$, batch size equal to the number of training samples, and a total of 200 epochs. The Caffe framework using a block size of 512 is used to execute the GPU version of the HYCNN scheme except for the initial PCA algorithm.

 ISBN: 978-84-617-8694-7

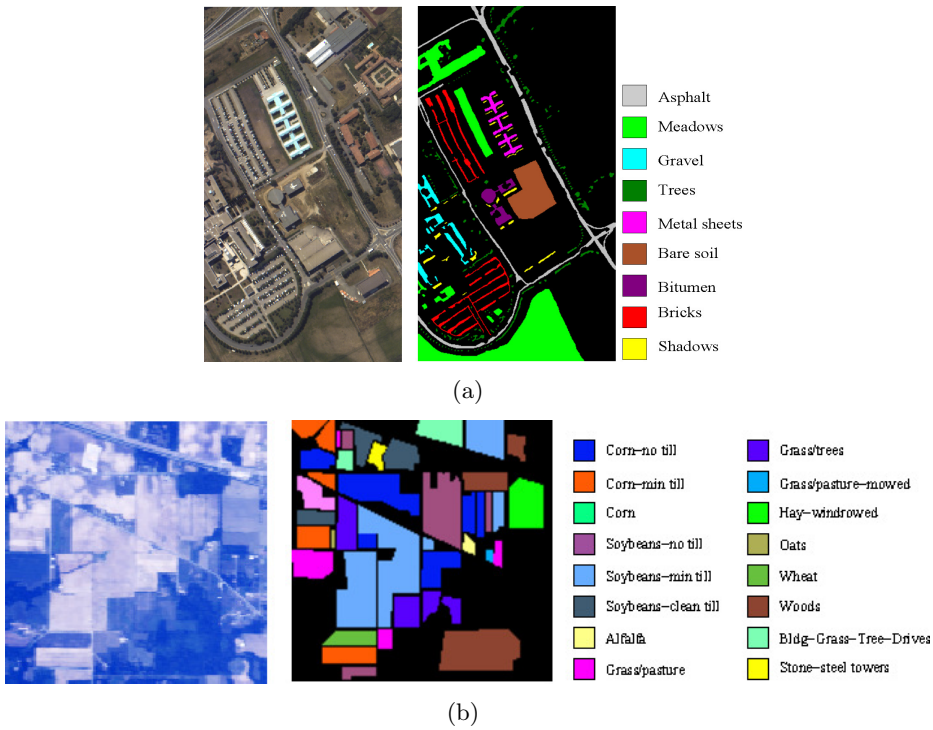

Figure 2: Hyperspectral datasets: (a) *Pavia Univ.*, (b) *Indian Pines*.

Table 2 shows the comparison between the CPU and the GPU implementations of the scheme when it is applied to the Pavia Univ. image. For a better understanding of the results, different parts of the code have been grouped into higher abstraction level functions. The times are split following the functions of the pseudocode in Algorithm 2 but aggregating the results for the backward step. The speedups are calculated as the number of times that the GPU code is faster than the CPU code. The biggest speedup is observed for the First Inner function that comprises the update of the hidden layer neurons in the fully-connected network. The speedup for the Second Inner is lower because the size of the matrix by matrix multiplication is smaller as it corresponds to layers with fewer neurons. The most time consuming function is the Convolution in the Forward step. Its speedup is only 47.41× because this function includes a group of kernels with low occupancy.

Table 3 shows the execution times and speedups for the whole classification scheme for the two test datasets (including the training and testing steps and also the PCA step) as well as the classification accuracies for both implementations. It is important to enhance that the same configuration parameters were used for both implementations in order to compare the computational time in the same conditions. Nevertheless, for the GPU accuracies the

Step	Lines	CPU	GPU	Speedup

Total		6.87742s	0.11939s	57.60×

Table 2: CPU and GPU execution times and speedups for the training step of the HYCNN scheme for Pavia Univ. dataset. The column Lines shows the lines in Algorithm 2

	CPU		GPU		Speedup
Dataset	Time	Accuracy (%)	Time	Accuracy (%)	
Pavia Univ.	1404.26s	98.50	36.32s	97.15	38.66×
Indian Pines	252.33s	97.14	7.60s	84.84	33.20×

Table 3: Execution times,speedups and classification accuracies for the HYCNN scheme.

parameters were optimized for the GPU code separately. The patch size was reduced to 256. In addition, the number of epochs was set to 1300 and 3683 for the Pavia Univ. and the Indian Pines images respectively. The differences in classification accuracy among the CPU and the GPU schemes are produced by the weights update during the backpropagation. For the CPU case the update is carried out for each sample separately, on the contrary for the GPU case the updates are performed by blocks of samples.

5 Conclusions

In this paper we propose a spectral-spatial scheme in GPU based on convolutional neural networks for the classification of hyperspectral images and evaluate its results on several public datasets used in remote sensing for land-cover applications. The scheme consists of principal component analysis, patch extraction, convolution filters and fully-connected layers. The learning is performed using the standard backpropagation algorithm.

 ISBN: 978-84-617-8694-7

The CUDA GPU implementation is based on the use of the Caffe optimized framework for deep learning and other optimization strategies including calls to optimized libraries such as CULA, CUBLAS and MAGMA. Details on the Caffe implementation are given. The experiments obtain speedups of up to 38.66% for the Pavia Univ. dataset with accuracies of up to 97.15%.

emails: agarral@ugr.es, mruizg@ugr.es

Abstract

We analyze the existence of a solution for a quite general variational inequalities system, which includes some variational problems with constraints. The fundamental tool to carry out this study is a minimax theorem. In addition, a stable numerical method is introduced for approximating the solution of such a system.

Key words: Minimax problems, vartiational inequalities.
MSC 2000: 49K35, 49A29.

1 Main results

Although originally, minimax inequalities arose in the context of game theory, they have turned out to be powerful tools in other fields: let us mention, for instance, [2, 3, 6, 7, 8, 9, 10, 11]. We start from the classical minimax inequality of von Neumann–Fan for studying the existence of a solution for a certain system of variational inequalities.

In order to introduce the class of systems that we are going to analyze, let us mention that the study of variational equations with constraints emerges naturally, among others, from the context of the elliptic boundary value problems, when their essential boundary conditions are treated as constraints in their standard variational formulation. For instance, let Ω be an open and bounded subset of $\mathbb{R}^n$ with a Lipschitz boundary $\partial\Omega$, and let $f_0 \in L^2(\Omega)$ and $g_0 \in H^{1/2}(\partial\Omega)$. Let us also assume that $h_0 \in L^\infty(\Omega)$ and that there exists $\delta > 0$ such that

$$\delta \leq h_0 \quad \text{in } \Omega.$$

ISBN: 978-84-617-8694-7

Let us consider the variational problem: find $x_0 \in H^1(\Omega)$ such that

$$x_0 = g_0 \text{ on } \partial\Omega \text{ and for all } x \in H_0^1(\Omega), \quad \int_\Omega h_0 \nabla x_0 \cdot \nabla x = \int_\Omega f_0 x,$$

that is, the weak formulation of the elliptic boundary problem associated with the Poisson equation with non-homogeneous Dirichlet boundary condition

$$\left\{ \begin{array}{rl} -\text{div}\,(h_0 \nabla x) = f_0 & \text{in } \Omega \\ x = g_0 & \text{on } \partial\Omega \end{array} \right. .$$

Equivalently, we can impose weakly the boundary condition: let $X := H^1(\Omega)$, $Y := H^{-1/2}(\partial\Omega)$, $Z := H_0^1(\Omega)$, let $a : X \times X \longrightarrow \mathbb{R}$ and $b : X \times Y \longrightarrow \mathbb{R}$ be the continuous bilinear forms

$$a(x_1, x_2) := \int_\Omega h_0 \nabla x_1 \cdot \nabla x_2, \qquad (x_1, x_2 \in X)$$

and

$$b(x, y) :=< \text{tr}(x), y >, \qquad (x \in X,\ y \in Y)$$

$< \cdot, \cdot >$ being the canonical bilinear form in $H^{1/2}(\Gamma) \times H^{-1/2}(\Gamma)$ and $\text{tr} : H^1(\Omega) \longrightarrow H^{1/2}(\Gamma) \subset L^2(\Gamma)$ the trace operator in $H^1(\Omega)$; and let $f : X \longrightarrow \mathbb{R}$ and $g : Y \longrightarrow \mathbb{R}$ be the continuous and linear functionals defined by

$$f(x) := \int_\Omega f_0 x, \qquad (x \in X)$$

and

$$g(y) :=< g_0, y >, \qquad (y \in Y).$$

Then, the variational formulation coincide with this constrained variational equation:

$$\text{find } x_0 \in X \text{ such that } \left\{ \begin{array}{ll} z \in Z & \Rightarrow f(z) = a(x_0, z) \\ y \in Y & \Rightarrow g(y) = b(x_0, y) \end{array} \right. .$$

In a more general way, we deal with the following problem: let E be a real reflexive Banach space, $n \in \mathbb{N}$ and suppose that for each $j = 1, \ldots, n$, F_j is a real normed space, $y_j^* \in F_j^*$ ("*" stands for "topological dual space"), C_j is a convex subset of F_j with $0 \in C_j$, and $a_j : E \times F_j \longrightarrow \mathbb{R}$ is a bilineal form satisfying

$$y_j \in C_j \Rightarrow a_j(\cdot, y_j) \in E^*;$$

find $x_0 \in E$ such that

$$\left\{ \begin{array}{c} y_1 \in C_1 \Rightarrow y_1^*(y_1) \leq a_1(x_0, y_1) \\ \cdots \\ y_n \in C_n \Rightarrow y_n^*(y_n) \leq a_n(x_0, y_n) \end{array} \right. .$$

 ISBN: 978-84-617-8694-7

As mentioned above, our fundamental tool is the von Neumann–Fan minimax theorem, which allows us to characterize the existence of a solution for this variational inequalities system in terms of that of a positive constant. Moreover, that minimax result implies the stability of numerical schemes of the Galerkin type for approximating the solution. The corresponding finite dimensional subspaces are generated from adequate biorthogonal systems depending on the concrete problem.

The variational systems under consideration are so general that include mixed variational formulations of some elliptic problems, those in the so-called *Babuška–Brezzi theory* (see, for instance [1, 5] and some of its generalizations [4]).

Finally, we illustrate our results with some numerical examples.

Abstract

In the present work we study the generalized Drinfeld-Sokolov equations. Previously, we got its classical Lie symmetries and obtained exact solutions. Now we continue the analysis by applying the nonclassical method proposed by Bluman and Cole to deduce new symmetries of the equation. In addition, we look for nonlocal symmetries by applying the potential symmetry method introduced by Bluman *et al.* Finally, we obtain conservation laws depending on the parameters by using the multiplier method.

Key words: generalized Drinfeld-Sokolov, nonclassical symmetries, potential symmetries, conservation laws.

1 Introduction

Nowadays Drinfeld-Sokolov equations are getting a lot of attention because of their extensive applications. Initially they were presented by Drinfeld and Sokolov in [8] as some examples of generalized KdV and mKdV corresponding to classical Kats-Moody algebras, and these days we have organised them in two categories.

The first one is the Drinfeld–Sokolov–Wilson (DSW) system

$$\begin{cases} u_t + (v^n)_x & = 0 \\ v_t - av_{xxx} + 3bu_xv + 3kuv_x & = 0 \end{cases}$$

where a, b, k and n are constants. This system was introduced by Drinfeld and Sokolov as an example of a system of nonlinear equations possessing Lax pairs of a special form [10]

and it is used to describe nonlinear surface gravity waves propagating over an horizontal sea bed. It has been extensively studied in [3, 11, 16] and so on.

The second one is formed by the generalized Drinfeld-Sokolov equations (gDS) [14]

$$\begin{cases} u_t + \alpha_1 u u_x + \beta_1 u_{xxx} + \gamma \left(v^\delta\right)_x & = 0 \\ V_t + \alpha_2 u v_x + \beta_2 V_{xxx} & = 0 \end{cases} \tag{1}$$

where $\alpha_1, \alpha_2, \beta_1, \beta_2, \gamma$ and δ are constants. This system models one dimensional nonlinear wave processes in two-component media.

In a previous paper, Garrido and Bruzón [9] studied this couple of equations (1) obtaining its classical lie symmetries classification, reductions, and few travelling wave solutions applying the sine–cosine method introduced by Wazwaz [15]. So the aim of the present paper is to continue with the previous research of (1) extending it to the study of nonclassical symmetries, potential symmetries and conservation laws.

There are several reasons to be interested in the study of symmetries admitted by a partial differential equation and probably the most important is that they are useful for finding invariant solutions. Lie group theory provides a method to search for these special group invariant solutions [12]. However, sometimes not all of these invariant solutions can be found by using the Lie classical method and that is why we have looked for the nonclassical and potential symmetries of (1) too.

Bluman and Cole [4] proposed the so–called nonclassical method of group-invariant solutions in which since the number of determining equations is smaller, the set of solutions is larger than the one for the classical method. In the same way in [5] Bluman et al. have introduced the concept of potential symmetry, which is a nonlocal symmetry, for any differential equation which can be written as a conservation law.

To conclude and due to the physical importance of conservation laws in the study of properties that do not change in the course of time, especially for determining conserved quantities and constants of motion, we have applied the multiplier method proposed by Bluman and Anco [1, 2] which provides a general treatment to find all local conservation laws admitted by any given evolution equation. Some examples can be found in [6, 7, 13].

Abstract

The generalized finite difference method (GFDM) has been proved to be a good meshless method to solve several linear partial differential equations (pde's): wave propagation, advection-diffusion, plates, beams, etc.
The GFDM allows us to use irregular clouds of nodes that can be of interest for modelling non-linear parabolic pde's.
This paper illustres that the GFD explicit formulae developed to obtain the different derivatives of the pde's are based in the existence of a positive definite matrix that it is obtained using moving least squares approximation and Taylor series development. Criteria for convergence of fully explicit method using GFDM for different non linear parabolic pdes are given.
This paper shows the application of the GFDM to solving different non-linear problems including applications to heat transfer, acoustics and problems of mass transfer.

Key words: meshless methods, generalized finite difference method, non-linear parabolic partial differential equations.

1 Introduction

Modern numerical methods, in particular those for solving non-linear PDEs, have been developed in recent years using finite differences, finite elements, finite volume or spectral

methods. A review of numerical methods for non-linear partial differential equations is given by Polyanin [1] and Tadmor [2]. In this paper we use a meshless method called generalizad finite difference method (GFDM) for solving different parabolic non-linear pdes.
Benito, Gavete and Ureña [3,4,5] have developed the explicit formulae and h-adaptive method for the solution of the pdes in 2-D.
In this paper, this meshless method is used for solving non-linear parabolic partial differential equations in 2-D. Parabolic equations have been solved using an explicit method and the convergence has been studied taking into account the irregularity of the cloud of points. The numerical results show the high accuracy obtained.
The paper is organized as follows. In section 2 the explicit method and GFDM to solve non-linear parabolic partial differential are showed. In section 3, convergence is studied. Sections 4 exposes the results obtained for solving different non-linear problems. Finally, in section 5, some conclusions are obtained.

2 Explicit method and GFDM: application to non-linear parabolic partial differential equations

Consider the following non-linear problem in the domain $D = [0, T] \times \Omega$ with $\Omega \subset \mathbb{R}^2$

$$\frac{\partial U}{\partial t} = L_\Omega[U] \tag{1}$$

where $L_\Omega[U]$ is a non-linear operator, Γ is the boundary of the domain Ω, with boundary condition:

$$U_\Gamma = f(t) \tag{2}$$

and initial condition

$$U(x, y, 0) = g(x, y) \tag{3}$$

where f and g are two known functions.
To solve the problem described by Eqs.(1), (2) and (3), using the explicit method, time derivative is approximated by

$$\frac{\partial u(x_0, y_0, n\triangle t)}{\partial t} = \frac{u_0^{n+1} - u_0^n}{\triangle t} + \Theta(\triangle t) \tag{4}$$

 ISBN: 978-84-617-8694-7

and spatial derivatives are approximated using GFD [3,4,5], are denoted by

$$\begin{cases} \dfrac{\partial u(x_0,y_0,n\triangle t)}{\partial x} = -\lambda_0 u_0 + \displaystyle\sum_{i=1}^{s} \lambda_i u_i + \Theta(h_i^2,k_i^2),\ with\ \lambda_0 = \sum_{i=1}^{s} \lambda_i \\ \dfrac{\partial u(x_0,y_0,n\triangle t)}{\partial y} = -\mu_0 u_0 + \displaystyle\sum_{i=1}^{s} \mu_i u_i + \Theta(h_i^2,k_i^2),\ with\ \mu_0 = \sum_{i=1}^{s} \mu_i \\ \dfrac{\partial^2 u(x_0,y_0,n\triangle t)}{\partial x^2} + \dfrac{\partial^2 u(x_0,y_0,n\triangle t)}{\partial y^2} = -m_0 u_0 + \displaystyle\sum_{i=1}^{s} m_i u_i + \Theta(h_i^2,k_i^2) \\ with\ m_0 = \displaystyle\sum_{i=1}^{s} m_i \end{cases} \tag{5}$$

3 Convergence of the scheme for non-linear parabolic pde's

In this section convergence of non-linear parabolic pde's, using GFDM, is studied. We will do so by introducing the following definitions:

- A partial differential equation is **semilinear** if the coefficients of its highest derivatives are functions of the spaces variables only.
- A partial differential equation is **quasi-linear** if it is linear in its highest derivatives.

In this paper, the following cases are considered for $L_\Omega[U]$ of Eq.(1), for their importance in applied science and technology:

Semilinear

$$L_\Omega[U] = \frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} + F(U) \tag{6}$$

Quasilinear

$$L_\Omega[U] = K(U)(\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2}) \tag{7}$$

The method which has been used consists in finding an error bound directly from the discretized expressions and, therefore, the concept of stability is not used. However this concept appears when we consider that the error must be limited.

3.1 Semilinear parabolic PDEs

Let us consider Eq.(6) where $F(U)$ is a differentiable function. By considering the non-linear scheme together with the explicit expressions Eqs.(4) and Eq.(5)

$$\frac{u_0^{n+1} - u_0^n}{\Delta t} = -m_0 u_0^n + \sum_{i=1}^{N} m_i u_i^n + F(u_0^n) \tag{8}$$

 ISBN: 978-84-617-8694-7

and let the same expression for the exact solution be

$$\frac{U_0^{n+1}-U_0^n}{\Delta t}=-m_0U_0^n+\sum_{i=1}^{N}m_iU_i^n+F(U_0^n) \tag{9}$$

If we define the error as $e_i^n=u_i^n-U_i^n$ y $e_0^n=u_0^n-U_0^n$, using the mean value theorem for F , it is obtained

$$F(u_0^n)-F(U_0^n)=e_0^n\frac{\partial F}{\partial U}(\chi_j) \tag{10}$$

where $\chi_j=U_0^n+\xi e_0^n,\quad \xi\in[0,1]$ Subtracting Eqs.(8) and (9) and introducing Eq.(10) it is obtained

$$\frac{e_0^{n+1}-e_0^n}{\Delta t}=-m_0e_0^n+\sum_{i=1}^{N}m_ie_i^n+e_0^n\frac{\partial F}{\partial U}(\chi_j) \tag{11}$$

$$e_0^{n+1}=(1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}(\chi_j))e_0^n+\Delta t\sum_{i=1}^{N}m_ie_i^n \tag{12}$$

$$|e_0^{n+1}|\leq|(1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}(\chi_j))||e_0^n|+\Delta t|\sum_{i=1}^{N}m_ie_i^n| \tag{13}$$

Let $e^n=\max_{i=0,..,N}|e_i^n|$, taking into account eq.(4) and eq.(1) it is obtained

$$e^{n+1}\leq e^n(|1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}|+\sum_{i=1}^{N}\Delta t|m_i|)+\Theta_1(\Delta t(h_i^2+k_i^2+\Delta t)) \tag{14}$$

$$\alpha=|1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}|+\sum_{i=1}^{N}\Delta t|m_i| \tag{15}$$

by considering $n=1$ and including a constant C

$$e^1=\alpha e^0+C(\Delta t(h_i^2+k_i^2+\Delta t)) \tag{16}$$

as $e^0=0$ by the initial condition Eq.(3)

$$e^1=C(\Delta t(h_i^2+k_i^2+\Delta t)) \tag{17}$$

and similarly to eq.(17)

$$e^2=\alpha e^1+C(\Delta t(h_i^2+k_i^2+\Delta t))=C(\Delta t(h_i^2+k_i^2+\Delta t))(1+\alpha) \tag{18}$$

$$e^{n+1}=C(\Delta t(h_i^2+k_i^2+\Delta t))(1+\alpha+\alpha^2+\cdots+\alpha^n) \tag{19}$$

 ISBN: 978-84-617-8694-7

$1+\alpha+\alpha^2+\cdots+\alpha^n+\cdots$ is a geometric series, where the condition of convergence is $|\alpha|<1$. Hence, in order for the error not to diverge as time increment tends to 0, it must be:

$$|\alpha|<1 \Leftrightarrow |1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}|+\sum_{i=1}^{N}\Delta t|m_i|<1 \tag{20}$$

Thus,

$$|1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}|<1-\sum_{i=1}^{N}\Delta t|m_i| \tag{21}$$

$$-1+\sum_{i=1}^{N}\Delta t|m_i|<1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}<1-\sum_{i=1}^{N}\Delta t|m_i| \tag{22}$$

by comparing first and second terms of inequality eq.(29) and second and third terms the following two conditions can be obtained.

$$\left\{\begin{array}{l} 1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}<1-\sum_{i=1}^{N}\Delta t|m_i| \\ -1+\sum_{i=1}^{N}\Delta t|m_i|<1-m_0\Delta t+\Delta t\frac{\partial F}{\partial U}\end{array}\right. \Leftrightarrow \left\{\begin{array}{l} \Delta t(\frac{\partial F}{\partial U}+\sum_{i=1}^{N}|m_i|-m_0)<0 \\ \Delta t(\sum_{i=1}^{N}|m_i|+m_0-\frac{\partial F}{\partial U})<2\end{array}\right. \tag{23}$$

as $\Delta t>0$, the criteria of convergence are

$$\left\{\begin{array}{l} \frac{\partial F}{\partial U}+\sum_{i=1}^{N}|m_i|-m_0<0 \\ \Delta t<\frac{2}{\sum_{i=1}^{N}|m_i|+m_0-\frac{\partial F}{\partial U}}\end{array}\right. \tag{24}$$

From first inequality of eq.(24), taking account eq.(5) thus $\frac{\partial F}{\partial U}<0$ is obtained. The second inequality of eq.(24) gives us the limit Δt of convergence of each one of the stars of the domain. Then the minimum value obtained between all the stars is taken as limit of convergence.

3.2 Quasilinear parabolic PDEs

Let us consider eq.(7) representing an heat transmission case where U is the temperature and $K(U)$ is the conductivity.
Using fully explicit approximations

$$\frac{u_0^{n+1}-u_0^n}{\Delta t}=K(u_0^n)(-m_0u_0^n+\sum_{i=1}^{N}m_iu_i^n) \tag{25}$$

and similarly for the exact solution

$$\frac{U_0^{n+1}-U_0^n}{\Delta t}=K(U_0^n)(-m_0U_0^n+\sum_{i=1}^{N}m_iU_i^n) \tag{26}$$

Defining the error $e^n = u^n - U^n$, it is obtained

$$\frac{e_0^{n+1} - e_0^n}{\Delta t} = K(u_0^n)(-m_0 u_0^n + \sum_{i=1}^{N} m_i u_i^n) - K(U_0^n)(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) \tag{27}$$

$$\begin{aligned} e_0^{n+1} = e_0^n + \Delta t[K(u_0^n)(-m_0 u_0^n + \sum_{i=1}^{N} m_i u_i^n) - K(u_0^n)(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) \\ + K(u_0^n)(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) - K(U_0^n)(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n)] \end{aligned} \tag{28}$$

and using the mean value theorem

$$e_0^{n+1} = e_0^n + \Delta t[K(u_0^n)(-m_0 e_0^n + \sum_{i=1}^{N} m_i e_i^n) + e_0^n \frac{\partial K}{\partial U}(\chi_j)(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n)] \tag{29}$$

and rearranging

$$e_0^{n+1} = e_0^n[1 + \Delta t \frac{\partial K}{\partial U}(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) - m_0 \Delta t K(u_0^n)] + \Delta t K(u_0^n) \sum_{i=1}^{N} e_i^n m_i \tag{30}$$

If, again, we make $e^n = \max_{i=0,..,N} |e_i^n|$ in every point of the cloud of points, we shall obtain the relation:

$$\begin{aligned} e^{n+1} \leq e^n(|1 + \Delta t \frac{\partial K}{\partial U}(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) - m_0 \Delta t K(u_0^n)| + \Delta t |K(u_0^n)| \sum_{i=1}^{N} |m_i|) \\ + \Theta_3(\Delta t(h_i^2 + k_i^2 + \Delta t)) \end{aligned} \tag{31}$$

Denoting:

$$R = \Delta t \frac{\partial K}{\partial U}(-m_0 U_0^n + \sum_{i=1}^{N} m_i U_i^n) \tag{32}$$

$$\gamma = |1 + R\Delta t - m_0 \Delta t K(u_0^n)| + \Delta t |K(u_0^n)| \sum_{i=1}^{N} |m_i| \tag{33}$$

$$e^{n+1} \leq e^n \gamma + \Theta_3(\Delta t(h_i^2 + k_i^2 + \Delta t)) \tag{34}$$

Thus,

$$e^1 \leq e^0 \gamma + C_2(\Delta t(h_i^2 + k_i^2 + \Delta t)) = C_2(\Delta t(h_i^2 + k_i^2 + \Delta t)) \tag{35}$$

 ISBN: 978-84-617-8694-7

where $e^0 = 0$ by initial condition eq.(3)

$$e^n \leq C_2(\Delta t(h_i^2 + k_i^2 + \Delta t))(1 + \gamma + \cdots) \tag{36}$$

Taking account that $1+\gamma+\gamma^2+\cdots$ is a geometric series, then the condition of convergence is $|\gamma| < 1$.

$$|1 + R\Delta t - m_0\Delta t K(u_0^n)| + \Delta t|K(u_0^n)| \sum_{i=1}^{N} |m_i| < 1 \tag{37}$$

$$-1 + \Delta t|K(u_0^n)| \sum_{i=1}^{N} |m_i| < 1 + R\Delta t - m_0\Delta t K(u_0^n) < 1 - \Delta t|K(u_0^n)| \sum_{i=1}^{N} |m_i| \tag{38}$$

by relating second and third terms and first and second ones

$$\begin{cases} 1 + R\Delta t - m_0\Delta t K(u_0^n) < 1 - \Delta t|K(u_0^n)| \sum_{i=1}^{N} |m_i| \\ -1 + \Delta t|K(u_0^n)| \sum_{i=1}^{N} |m_i| < 1 + R\Delta t - m_0\Delta t K(u_0^n) \end{cases} \tag{39}$$

then the following two inequalities are obtained

$$\begin{cases} \Delta t(R + |K(u_0^n)| \sum_{i=1}^{N} |m_i| - m_0 K(u_0^n)) < 0 \\ \Delta t(|K(u_0^n)| \sum_{i=1}^{N} |m_i| + K(u_0^n)m_0 - R) < 2 \end{cases} \tag{40}$$

and operating in eq.(40)

$$\begin{cases} -R + m_0 K(u_0^n) > |K(u_0^n)| \sum_{i=1}^{N} |m_i| \\ \Delta t < \dfrac{2}{|K(u_0^n)| \sum_{i=1}^{N} |m_i| + m_0 K(u_0^n) - R} \end{cases} \tag{41}$$

by taking first inequality of the eq.(41) and substituting it in the second one

$$\begin{cases} -R + m_0 K(u_0^n) > |K(u_0^n)| \sum_{i=1}^{N} |m_i| \\ \Delta t < \dfrac{1}{m_0 K(u_0^n) - R} \end{cases} \tag{42}$$

As it is shown in the second inequality of eq.(42) the values of the coefficients (m_o, m_i) are important to determine the Δt for each one of the stars. The limit of convergence Δt for each cloud of nodes is the minimum value obtained considering all the stars of the domain.

4 Numerical results

In this section it will be shown the numerical results obtained by solving five non-linear parabolic pde with Dirichlet boundary conditions the initial conditions (which are obtained

 ISBN: 978-84-617-8694-7

by substitution in the exact solution), which correspond to non-linear problems in physics and engineering: heat equation, diffusion of liquids in porous medium, advection-diffusion, etc.

Firstly we consider 3 examples and apply them in 6 different discretizations (see figure 1), obtaining the solution for $t = 0.25$ sec. To do it we divide the total time into a different number of steps, in particular, 50, 100, 250, 500 and 1000 steps, which is equivalent to use as time increments 0.005, 0.0025, 0.001, 0.0005 and 0.00025 sec. respectively.

In all the cases considered the global error has been calculated according to the formula

$$\%\text{Global Error } = \frac{\sqrt{\sum_{i=1}^{NI}\Big(sol(i) - exac(i)\Big)^2}}{|exac_{max}|} \times 100 \tag{43}$$

where $sol(i)$ is the GFD solution in node i, $exac(i)$ is the exact value of the solution at node i, $exac_{max}$ is the maximum value of the exact values in the cloud of nodes considered and NI is the number of nodes of the domain Ω.

Note that in the numerical results the time step used, Δt, have been selected according to

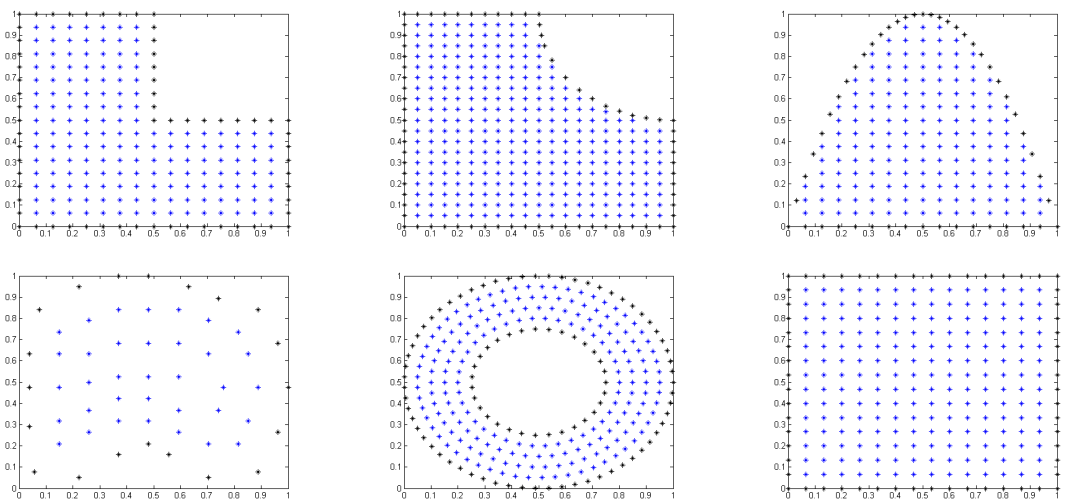

Figure 1: Clouds of points 1, 2, 3, 4 , 5 and 6

the convergence limits defined in eq.(24) and eq.(42). However these limits depend of the stars of nodes, and hence they are different for the six clouds of points considering in fig.1 Then as consequence only the converging cases have been considered in tables [1-3].

 ISBN: 978-84-617-8694-7

Example 1

Let us consider the equation

$$\frac{\partial U}{\partial t} = \frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} - Uln(U) \tag{44}$$

with exact solution:

$$U(x, y, t) = e^{e^{-t}} e^{\frac{x^2}{5} + \frac{xy}{5} + \frac{y^2}{20} + \frac{1}{2}} \tag{45}$$

This example corresponds to a semilinear case whose convergence has been studied in previous section.

Time increments $\triangle t$ calculated by using the rate of convergence for each mesh are,

mesh \ $\triangle t$	0.005	0.0025	0.001	0.0005	0.00025
1	-	-	$2.7582 \cdot 10^{-5}$	$8.2719 \cdot 10^{-6}$	$2.4258 \cdot 10^{-5}$
2	-	-	$2.7802 \cdot 10^{-3}$	$2.0688 \cdot 10^{-5}$	$6.8425 \cdot 10^{-6}$
3	-	-	$5.5248 \cdot 10^{-5}$	$2.7699 \cdot 10^{-5}$	$2.5353 \cdot 10^{-5}$
4	$3.8457 \cdot 10^{-4}$	$1.6820 \cdot 10^{-4}$	$1.2141 \cdot 10^{-4}$	$4.4682 \cdot 10^{-1}$	$1.5638 \cdot 10^{-4}$
5	-	-	$1.6033 \cdot 10^{-5}$	$1.0019 \cdot 10^{-5}$	$9.2320 \cdot 10^{-6}$
6	-	-	$4.1119 \cdot 10^{-5}$	$2.3447 \cdot 10^{-5}$	$5.3133 \cdot 10^{-5}$

Table 1: Table of mean squared errors for Example 1

respectively: 0.0022, 0.00125, 0.001, 0.0078, 0.00125 and 0.0022. Thus, the numerical results obtained Table 1 and Fig. 2 are according with the limit previously developed.

Example 2

Let us consider the equation

$$\frac{\partial U}{\partial t} = U(\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2}) \tag{46}$$

with the exact solution:

$$U(x, y, t) = \frac{1}{1-t}(\frac{x^2 + y^2 + 1}{4} + xy + x + y) \tag{47}$$

This case corresponds to a heat transmission problem where the conductivity K depends on the temperature U.
This example corresponds to a quasilinear whose convergence has been studied in previous section.

$\triangle t$ has been calculated by using the rate of convergence for each cloud of points

 ISBN: 978-84-617-8694-7

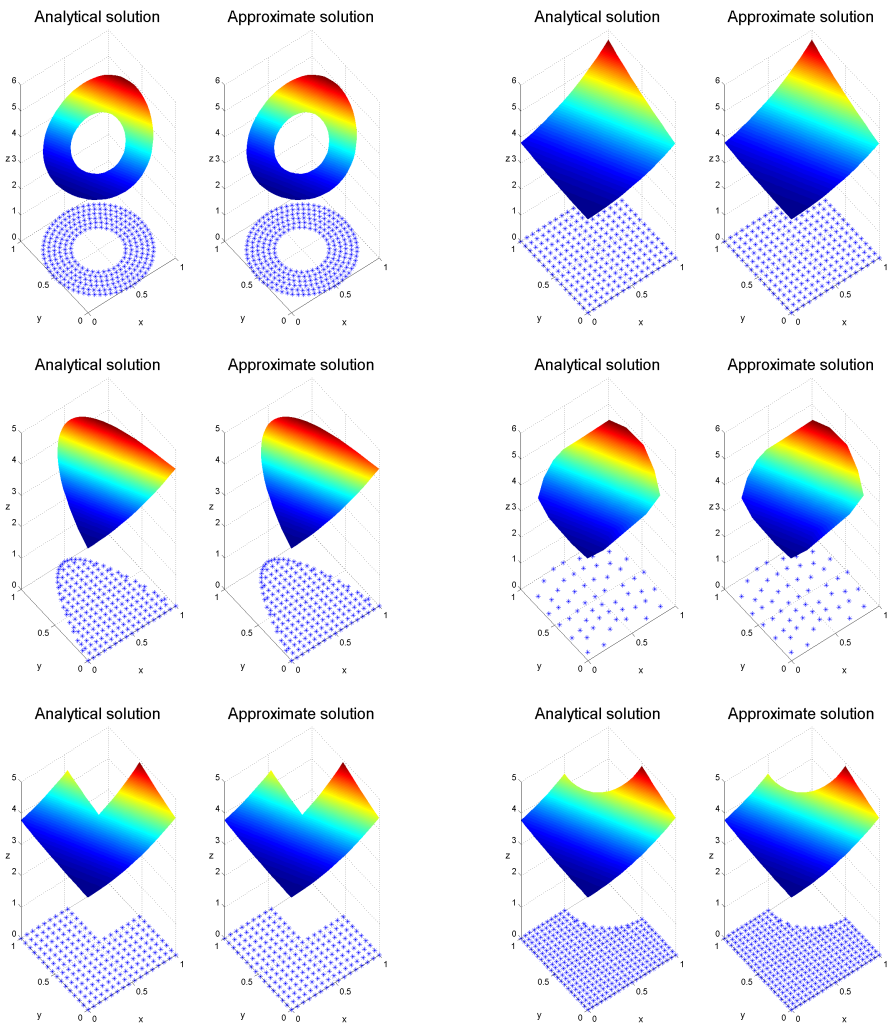

Figure 2: Exact and approximated solutions of the example 1 on meshes 1, 2, 3, 4 5 and 6

being, respectively: 0.00088, 0.00035, 0.00067, 0.0038, 0.00076 and 0.00088. Thus, the numerical results obtained Table 2 and Fig. 3 are according with the convergence theory, previously developed.

Example 3

 ISBN: 978-84-617-8694-7

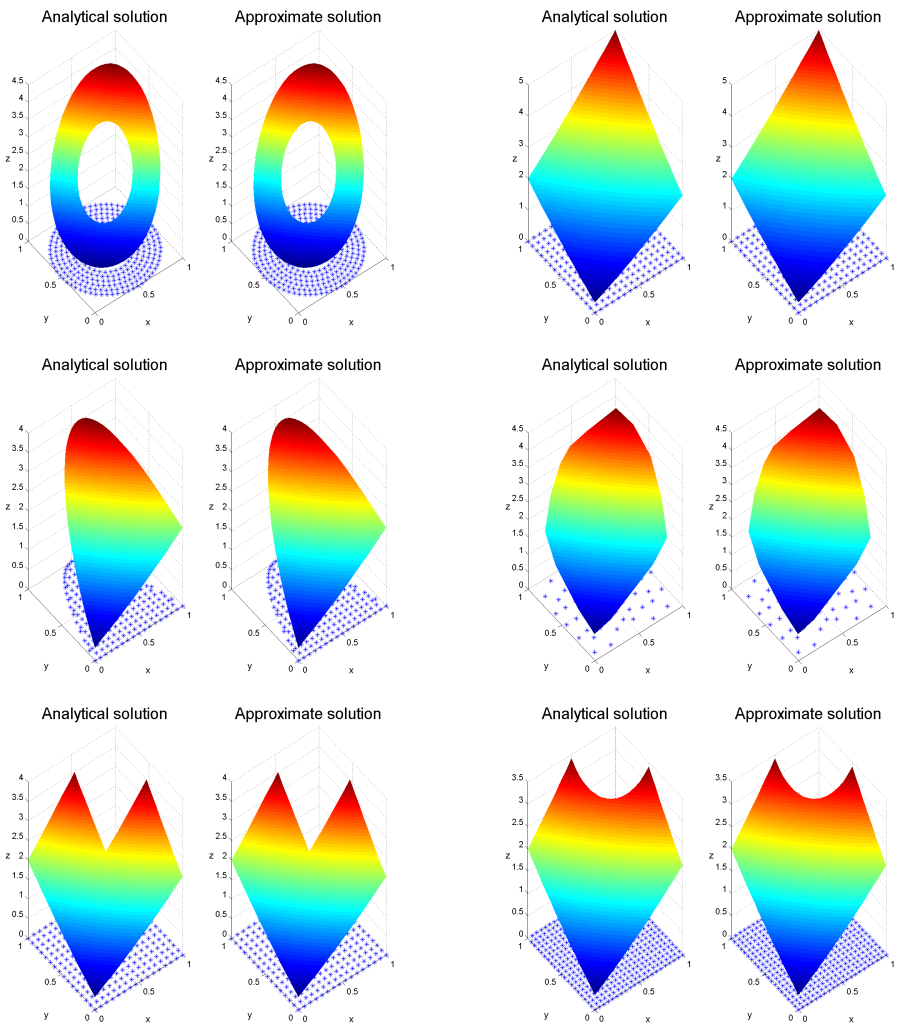

Figure 3: Exact and approximated solutions of the example 2 on clouds of points 1, 2, 3, 4, 5 and 6

Let us consider the equation

$$\frac{\partial U}{\partial t} = U(\frac{\partial^2 U}{\partial^2 x} + \frac{\partial^2 U}{\partial^2 y}) + U \tag{48}$$

with the exact solution:

$$U(x, y, t) = e^t(1 + e^x \sin(y)) \tag{49}$$

 ISBN: 978-84-617-8694-7

2	-	-	-	$1.497 \cdot 10^{-1}$	$1.3643 \cdot 10^{-5}$
3	-	-	-	$4.9862 \cdot 10^{-5}$	$4.7147 \cdot 10^{-5}$
4	-	$2.1002 \cdot 10^{-4}$	$1.9940 \cdot 10^{-4}$	$1.9655 \cdot 10^{-4}$	$1.9527 \cdot 10^{-4}$
5	-	-	-	$3.8149 \cdot 10^{-1}$	$2.1619 \cdot 10^{-5}$
6	-	-	$5.2962 \cdot 10^{-1}$	$2.838 \cdot 10^{-5}$	$2.2815 \cdot 10^{-5}$

Table 3: Table of mean squared errors for Example 3

$\triangle t$ computed by using the rate of convergence for each mesh are, respectively: 0.0017, 0.00065, 0.00062, 0.0031, 0.00072 and 0.0017. Thus, the numerical results obtained Table 3 and Fig 4 are according with the convergence, previously developed.

5 Conclusions

In this paper explicit and implicit methods using GFDM for solving different non-linear parabolic PDEs, have been considered.
Convergence has been studied, for semilinear and quasilinear equations, and limits of convergence have been developed and implemented in different examples.
The examples provided illustrates the viability of the application of GFDM for solving parabolic non-linear PDEs in 2D. The efficiency of the developed methods is clearly shown.
The accuracy of the GFDM has been tested in different non-linear PDEs, including different cases related with acoustics, heat transfer, mass transfer, heat extinction, combustion.
Numerical results for several non-linear problems validate the use of GFDM to solve this type of practical problems.

Rational Interpolation, Newton Correction and Zero-Finding Methods

Luca Gemignani[1]

[1] *Dipartimento di Informatica, Università di Pisa, Pisa, Italy*

emails: luca.gemignani@unipi.it

Abstract

In this talk we discuss the numerical properties of structured linearizations formed by Bezoutian-like matrices as well as of their rank structured counterparts generated from the values of the Newton correction applied for the solution of a nonlinear equation. Numerical results are presented and some open questions are listed.

1 Introduction

We consider the problem of estimating zeros of an analytic function $f:\Omega \subset \mathbb{C} \to \mathbb{C}$ from the values of a related rational function at sample points. Approaches based on interpolation techniques are known for this problem [11]. Recently, the interest on these methods has been renewed in [1], where approximations of the zeros of $f(z)$ inside the unit circle are computed by solving certain structured generalized eigenvalue problems directly constructed from the values attained by $f(z)$ at the roots of unity. Efficient eigensolvers based on rank-structured matrix algorithms are presented in [7, 5, 4]. Differently, the associated linearized eigenvalue problems might be solved using the Ehrlich-Aberth method [3, 8] for simultaneous polynomial root-finding. Numerical experiments carried out in [7, 6] show that the weakness of the resulting procedure lies in the evaluation of $f(z)$ at the interpolation points which can be prone to round-off errors. Approximation schemes based on computing the ratio $f(z)/f'(z)$ –generally referred as the Newton correction of $f(z)$– are numerically more reliable. It is an immediate observation that the function value and the derivative might overflow/underflow while the ratio may still be a reasonable machine number. In this talk we elaborate upon the construction of structured linearizations of the zerofinding problem using the values of the Newton correction.

ISBN: 978-84-617-8694-7

More precisely, for a given fixed $n \in \mathbb{N}$ let $\mathcal{Z}^{(1)} = \{z_j\}_{j=1}^n$ and $\mathcal{Z}^{(2)} = \{w_j\}_{j=1}^n$ be two disjoint sets of pairwise distinct points. Let us consider rational approximations of the meromorphic function $N(z) = f'(z)/f(z)$, which gives the reciprocal of the Newton correction applied to $f(z)$. The rational interpolant $r(z) = p(z)/q(z)$ of of type $(n-1, n)$ on $\mathcal{Z} = \mathcal{Z}^{(1)} \cup \mathcal{Z}^{(2)}$ is defined by the conditions

$$\frac{p(t_j)}{q(t_j)} = N(t_j) = \frac{f'(t_j)}{f(t_j)}, \quad t_j \in \mathcal{Z}; \quad p(z) \in \mathcal{P}_{n-1},\ q(z) \in \mathcal{P}_n,\ q(0) = 1,$$

where $\mathcal{P}_\ell$ denotes the set of univariate polynomials of degree at most ℓ.

Let us introduce the two matrices $B_1 = (b_{i,j}^{(1)}), B_2 = (b_{i,j}^{(2)}) \in \mathbb{C}^{n\times n}$ given by

$$b_{i,j}^{(1)} = \frac{N(z_i) - N(w_j)}{z_i - w_j}, \quad z_i \in \mathcal{Z}^{(1)}, w_j \in \mathcal{Z}^{(2)}, \quad 1 \le i, j \le n,$$

and

$$b_{i,j}^{(2)} = \frac{z_i N(z_i) - w_j N(w_j)}{z_i - w_j}, \quad z_i \in \mathcal{Z}^{(1)}, w_j \in \mathcal{Z}^{(2)}, \quad 1 \le i, j \le n,$$

Pairs of matrices of the form (B_1, B_2) are considered in [9, 10]. Properties of these matrices can be enlightened by using some classical connections with other well known classes of displacement structured matrices. From

$$b_{i,j}^{(1)} = \frac{N(z_i) - N(w_j)}{z_i - w_j} = \frac{\frac{p(z_i)}{q(z_i)} - \frac{p(w_j)}{q(w_j)}}{z_i - w_j} = q(z_i)\frac{p(z_i)q(w_j) - p(w_j)q(z_i)}{z_i - w_j}q(w_j).$$

There follows that

$$B_1 = \operatorname{diag}\left[q(z_i)\right] \cdot \mathcal{B}_1 \cdot \operatorname{diag}\left[q(w_j)\right],$$

where

$$\mathcal{B}_1 = \left(\frac{p(z_i)q(w_j) - p(w_j)q(z_i)}{z_i - w_j}\right)_{1\le i,j\le n}.$$

Recall that the symmetric $n \times n$ matrix $\mathcal{B}_{p,q} = (f_{i,j})$ such that

$$\frac{p(x)q(y) - p(y)q(x)}{x - y} = \left[1, x, \ldots, x^{n-1}\right] \mathcal{B}_{p,q} \left[1, y, \ldots, y^{n-1}\right]^T = \sum_{i,j=0}^{n-1} f_{i+1,j+1} x^i y^j,$$

is called the *Bezoutian* associated with the polynomial pair $(p(z), q(z))$. Hence, it is found that

$$\mathcal{B}_1 = \mathcal{V}^T(z_1, \ldots, z_n) \cdot \mathcal{B}_{p,q} \cdot \mathcal{V}(w_1, \ldots, w_n),$$

where

$$\mathcal{V}(x_1, \ldots, x_n) = \begin{bmatrix} 1 & \ldots & \ldots & 1 \\ x_1 & \ldots & \ldots & x_n \\ \vdots & \vdots & \vdots & \vdots \\ x_1^{n-1} & \ldots & \ldots & x_n^{n-1} \end{bmatrix},$$

 ISBN: 978-84-617-8694-7

is the classical Vandermonde matrix generated from the nodes $x_1, \ldots, x_n$. The matrix $\mathcal{B}_{p,q}$ can further be decomposed by using the properties of Vandermonde matrices [12]. For the sake of simplicity, let us assume that the zeros $\xi_1^{(n)}, \ldots, \xi_n^{(n)}$ are pairwise distinct. Then we have

$$\mathcal{B}_{p,q} = \mathcal{V}^{-T}(\xi_1^{(n)}, \ldots, \xi_n^{(n)}) \cdot \mathrm{diag}\left[\varepsilon_{1,i}^{(n)}\right] \cdot \mathcal{V}^{-1}(\xi_1^{(n)}, \ldots, \xi_n^{(n)}),$$

where

$$\varepsilon_{1,i}^{(n)} = p(\xi_i^{(n)})q'(\xi_i^{(n)}), \quad 1 \le i \le n.$$

A similar analysis relates the matrix B_2 with $\mathcal{B}_{zp,q}$ such that

$$\mathcal{B}_{zp,q} = \mathcal{V}^{-T}(\xi_1^{(n)}, \ldots, \xi_n^{(n)}) \cdot \mathrm{diag}\left[\varepsilon_{2,i}^{(n)}\right] \cdot \mathcal{V}^{-1}(\xi_1^{(n)}, \ldots, \xi_n^{(n)}),$$

where

$$\varepsilon_{2,i}^{(n)} = \xi_i^{(n)} p(\xi_i^{(n)})q'(\xi_i^{(n)}), \quad 1 \le i \le n.$$

In this way, we arrive at the following two-step procedure for approximating the zeros of $q(z)$ and therefore, hopefully, the zeros of $f(z)$:

1. for two given set of points $\mathcal{Z}^{(1)} = \{z_j\}_{j=1}^n$ and $\mathcal{Z}^{(2)} = \{w_j\}_{j=1}^n$, evaluate $N(z_i)$ and $N(w_i)$, $1 \le i \le n$, and then form the matrices B_1 and B_2;

2. compute the generalized eigenvalues of the matrix pair (B_2, B_1).

A rank structured linearization can also be defined starting from the matrix pair (B_1, B_2). If we set $D_2 = \mathrm{diag}([w_1, \ldots, w_n])$ then we have

$$B_2 - B_1 D_2 = \boldsymbol{e}\,[N(z_1), \ldots, N(z_n)]\,, \quad \boldsymbol{e}^T = [1, \ldots, 1]\,.$$

The resulting representation of $B_1^{-1}B_2$ as a diagonal plus a rank-one matrix corresponds with the linearization provided in [2] based on Lagrange interpolation.

In this talk we analyze the role of structured linearizations formed by Bezoutian-like matrices as well as of their rank structured counterparts generated from the values of the Newton correction applied for the solution of a nonlinear equation. Numerical results are presented and some open questions are listed.

Abstract

The power unit is the key element of heavy machinery. Its actual technological complexity makes it difficult either for constructors or engineers to predict properly its failure. The main contribution of this work is, firstly, to provide a suitable model to obtain the probability distribution that better reflects the fault occurrence on the power unit for mining excavators from a work management approach. Secondly, an optimum maintenance strategy is modelled through an influence diagram in terms of repair costs and production losses, representing the direct and indirect costs engineers have to face when a machine breaks down. Results show Weibull distribution as the best probabilistic model for the estimation of prior fault probabilities of the power unit elements. Indirect costs are demonstrated to be about 4.5 times bigger than direct costs, reflecting the necessity for a maintenance strategy capable to reduce faults in the early stages avoiding costs to become expansive over time. This approach tries to minimize production losses at the same time engineers gain knowledge in the management of risks involved with the severity and time of appearance of certain types of faults.

Key words: model selection, reliability and life testing, decision making, maintenance

1 Introduction

Excavators (Hydraulic Excavators) are heavy construction equipment decisive for earth-moving operations both in mining and civil works. The engine consists of three parts. The engine block, the engine head and the lower engine. Each part is constituted respectively for a large number of components which are assembled in order to obtain the intended part. When talking about failures, from the set of faults that can be recorded during the machine operating life, according to their prevalence, those that can be associated with the power unit can be classified as: direct engine faults, injection system faults and starter engine faults.

During the past 20 years there has been a heightened improvement in the manufacture of heavy machinery engines. They are more powerful and fuel efficient with a minimized impact of emissions. The reliability has also been significantly enhanced with the inclusion of sophisticated electronic settings able to detect and predict nearby faults, but with a high price. Commonality and simplicity of design has turned now into complex structures with multiple sensors and an increased number of components. On many occasions, when faults occur time to repair takes a considerable time due to disassembly process which has to be carried out by qualified technical staff.

However, from a management perspective when a fault occurs the problem for engineers is not so much which component has failed, rather than how long the machine is going to be stopped or how much is the reparation cost. This situation, creates the necessity to define maintenance strategies oriented toward a wider scale represented by the set of power unit elements failure instead of power unit components failure. This new approach provides a great simplification of the domain problem, although is widely known that the decision-model results and conclusions are reliable as the probability model is well specified.

The motivation behind this work comes from trying to figure out whether different distributions change maintenance decisions in a considerably way. In this context, this paper evaluates exponential and Weibull distributions due to its extensive use in data analysis and reliability engineering [1]. The exponential distribution excels by its simplicity in calculation, but might not be appropriate to model the overall lifetime power unit elements, because the failure rates are not constant, and a constant failure rate approximation could not be representative enough. Alternatively, an important aspect of the Weibull distribution is how the values of the shape parameter k and the scale parameter λ affect the probability density function (PDF) and how they properly represent the power unit reliability [2]. For this latter issue, a suitable estimation of Weibull parameters is needed in order to obtain a reliable analysis of the occurrence of faults in the power unit.

The rest of the paper is structured in the following way. Section 2 presents the mathematical methods used to determine Weibull parameters and obtain the cumulative distribution function (CDF), both for Weibull and exponential distribution. Section 3 explains the influence diagram design. Section 4 shows the decision model results and discusses

the findings obtained about how these distributions may influence maintenance decisions. Section 5 concludes the paper and provides future work.

2 Model selection

The Weibull distribution is a suitable probability distribution for modelling survival analysis and has been widely used in reliability engineering and failure analysis due to its versatility. The density function of a Weibull distribution is given by the following expression:

$$f\left(x|\theta\right)=\frac{k}{\lambda}\left(\frac{x}{k}\right)^{k-1}e^{-(x/\lambda)^{k}},\ \ \text{if } x\geq 0,$$

where $\theta=(k,\lambda)^{t}$, $k>0$ is the shape parameter, $\lambda>0$ the scale parameter and t denotes transposed. On the other hand, the exponential distribution is a particular case with $k=1$ indicating a constant failure rate $\eta=\frac{1}{\lambda}>0$ over time and therefore that random external events are causing the components failure.

2.1 Estimation methods

In order to select the probabilistic model that better determines the fault of the power unit in mining excavators, several methods have been implemented for the estimation of the parameter θ. Given a sample $\{x_1,x_2,,x_n\}$ of size n drawn from a random variable X, the following estimation methods can be defined:

Method 1. Maximum likelihood estimation. Under i.i.d. assumptions, θ is estimated by maximizing the likelihood function defined as:

$$L\left(\theta\right)=\prod_{i=1}^{n}f\left(x_i|\theta\right).$$

Method 2. Moment matching estimation. This technique is based on matching the sample moments with the corresponding distribution moments:

$$E\left(X^{r}\right)=\frac{1}{n}\sum_{i=1}^{n}x_i^{r},\ r=1,2.$$

Method 3. Quantile matching estimation. Based on matching the sample quantiles, Q_{n,p_r}, with the corresponding distribution moments:

$$F^{-1}\left(p_r|\theta\right)=Q_{n,p_r},\ 0<p_r<1.$$

Method 4. Maximum goodness-of-fit estimation with the Cramer-von Mises goodness-of-fit distance. Assuming that an ordered sample, $x_1\leq x_2\leq\ldots\leq x_n$, θ is estimated by minimizing:

 ISBN: 978-84-617-8694-7

$$\frac{1}{12n}+\sum_{i=1}^{n}\left[F\left(x_i|\theta\right)-\frac{2i-1}{n}\right]^2. \tag{1}$$

Method 5. Maximum goodness-of-fit estimation with the Kolmogorov-Smirnov goodness-of-fit distance. Assuming that an ordered sample , $x_1 \leq x_2 \leq \ldots \leq x_n$, θ is estimated by minimizing:

$$max\left\{max_{i=1,\ldots,n}\left[\frac{1}{n}-F\left(x_i|\theta\right)\right], max_{i=1,\ldots,n}\left[F\left(x_i|\theta\right)-\frac{1-1}{n}\right]\right\}. \tag{2}$$

2.2 Goodness-of-fit statistics

Different goodness-of-fit statistics were calculated to measure the distance between the adjusted parametric distribution and the empirical distribution. Firstly, three goodness-of-fit statistics which are classically considered when fitting continuous distributions: Cramer-von Mises, based on (1), Kolmogorov-Smirnov, whose distance was given in (2), and Anderson-Darling with the following goodness-of-fit distance, assuming an ordered sample:

$$-n-\frac{1}{n}\sum_{i=1}^{n}\left(2i-1\right)\log\left\{F\left(x_i|\theta\right)\left[1-F\left(x_{n+1-i}|\theta\right)\right]\right\}.$$

Secondly, Akaike information criterion or the Bayesian information criterion were calculated. These loglikehood criteria are often appropriate to avoid overfitting when small samples are available:

$$\begin{aligned} AIC &= 2r-2\ln\left[L\left(\hat{\theta}\right)\right], \\ BIC &= \ln\left(n\right)r-2\ln\left[L\left(\hat{\theta}\right)\right], \end{aligned}$$

with $r=2$, number of estimated parameters.

Finally, root mean square error:

$$RMSE=\left\{\frac{1}{n}\sum_{i=1}^{n}\left[f\left(x_i|\hat{\theta}\right)-\frac{1}{n}\right]^2\right\}^{1/2}$$

and Chi-squared distance:

$$\chi^2=\frac{\sum_{i=1}^{n}\left[f\left(x_i|\hat{\theta}\right)-\frac{1}{n}\right]^2}{n-r}$$

were also calculated.

 ISBN: 978-84-617-8694-7

2.3 Estimated parameters and selected probability distributions

All calculations were obtained using the open source programming language R [3]. The results obtained with the different goodness-of-fit statistics allowed to identify Method 5 for the engine, Method 1 for the starter engine and Method 3 for the injection system as the best estimation methods for the obtainment of Weibull parameters. The values of the parameters required for the representation of the cumulative distribution function for each power unit element with the winning methods are shown in Table 1.

Table 1: Parameters values for Weibull and exponential distributions representation

Distribution	Parameters	Engine	Starter Engine	Injection System
Weibull	Shape (k)	0.91290	1.44447	1.94212
	Scale (λ)	1222.22	3244.58	3658.132
Exponential	Failure Rate (η)	0.00027586	0.00015517	0.00012069

Note that the cumulative distribution function for the Weibull distribution is:

$$F(x) = 1 - e^{-(x/\lambda)^k},\ x \geq 0,$$

whose representation requires the estimation of the scale λ and shape k parameters. Whereas, the exponential distribution only needs the failure rate η, being its cumulative distribution function:

$$F(x) = 1 - e^{-\eta x},\ \eta = \frac{1}{\lambda}, x \geq 0.$$

Table 1 showns the constant failure rate for each power unit element estimated by means of the average of faults in the machine operating life. It is interesting to analyse the payoff between its simplicity of calculation and the magnitude of the difference in the results, Figure 1, especially when they are transferred to an influence diagram affecting strategic decisions.

In view of Figure 1, it can be seen how the Weibull distribution gives higher probabilities to the failure of the units during the first years of its operating time.

3 Influence diagram for maintenance strategy evaluation

The maintenance strategy is modelled through an influence diagram (ID). An ID is a directed acyclic graph representing a generalization of a Bayesian network, in which probabilistic inference can be applied to solve decision making problems [4]. In this case, the ID was created using the decision modelling software BayesFusion, LLC [5]. The problem design depicted in Figure 2 involves 4 variable types for notation:

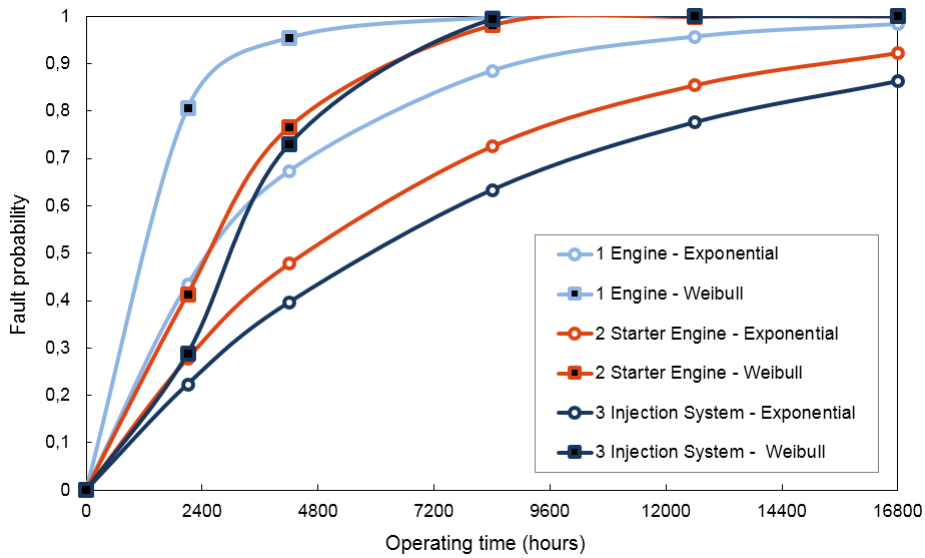

Figure 1: Cumulative distribution functions comparison for the power unit elements

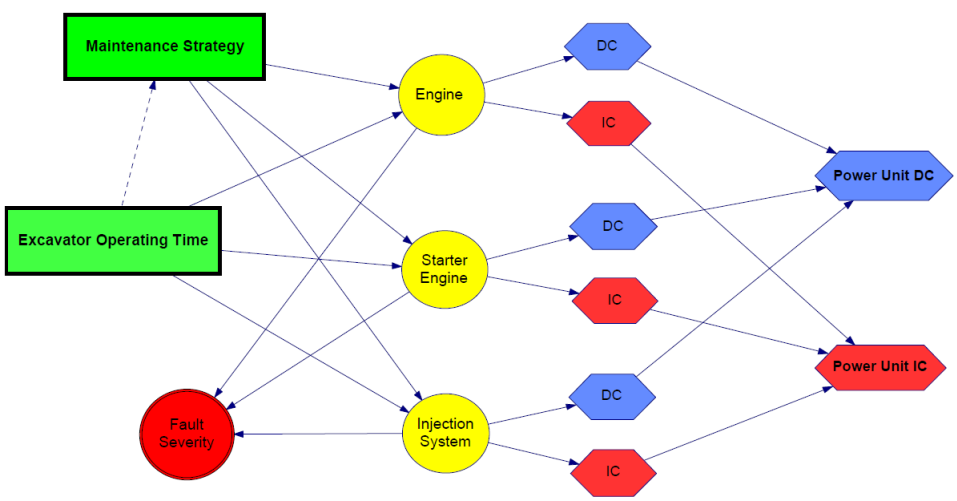

Figure 2: Influence diagram (ID) for power unit maintenance evaluation

 ISBN: 978-84-617-8694-7

Table 2: Deterministic node definition. Fault occurrences (yes or no) determining power unit fault severity (very high, high, medium or low)

Engine	Yes	Yes	Yes	Yes	No	No	No
Starter Engine	Yes	Yes	No	No	Yes	Yes	No
Injection System	Yes	No	Yes	No	Yes	No	Yes
Very high	✓		✓				
High		✓		✓	✓		
Moderate							✓
Low						✓	

- 2 decision nodes (green rectangles). The *excavator operating time* is evaluated in hours. Every operation year the excavator works 4800 hours, considering a service life at full performance up to 16800 hours. The *maintenance strategy* node offers the possibility to assess the maintenance strategy according to the fault probabilities for each element of the power unit obtained with exponential and Weibull distributions (Figure 1).

- 3 chance nodes (yellow circles). The *engine* itself, the *starter engine* and the *injection system*. They are quantified by the probabilities (Figure1) which integrate the uncertainty associated to the failure of the power unit.

- 1 deterministic node (red double circle). It represents the *fault severity* of the power unit. Once all their parents are known, there is no uncertainty about the outcome. The quantification is similar to chance nodes. The only difference now is that when a fault event takes place, the outcome is known with certainty. The definition is done with a probability table (Table 2) that contains the fault severity depending on the combination of fault elements in the power unit, according to the criteria of mining engineers consulted.

- 8 value nodes (blue and red hexagons). Blue hexagons represent the direct cost (DC) and red hexagons the indirect cost (IC) for each power unit element fault. DCs refer to the economic cost of fault repair. On the other hand, ICs imply a broader concept. They compute the economic cost associated with the loss of production due to the failure of the machine. The loss of production depends on the repair time, which is in turn dependent on the severity of the fault. For this reason, the utility costs for every element fault are computed independently. Moreover, for a generalized analysis it is usually easier for the decision maker to combine them in a single multi-attribute utility function (MAU) [6]. Thus, the influence diagram has two final MAUs, the

Power Unit DC and the Power Unit IC, summarizing the direct and indirect costs expected for the power unit elements failure over time.

In accordance with the expected utility theory, the goal of an influence diagram is to choose a decision alternative that has the highest expected gain or utility [7]. Utility is, however, by assumption subjective. In this particular case, the influence diagram enables engineers and decision makers assess the expected costs of suffering a failure over time. This approach means that direct and indirect costs need now to be minimized knowing that utility has not a meaningful zero point because maintenance has always an associated cost and it is very rare the case, not to say impossible, that an excavator has no faults during its operating time.

Various decision makers facing the same problem and even sharing the same set of beliefs may choose differently because of their preference structure and different utility functions. This can be especially noticed in a field such as engineering. Taking this into account, the utility elicitation of fault costs was made through an extensive review of repair invoices from power units of several mining excavators in the last 5 years.

4 Decision model results

The results obtained offer two main contributions. Firstly, how the estimations of prior probabilities can affect decision making for maintenance policy in this new approach based on the power unit segmentation into three main failure elements. Secondly, how the risk for fault severity changes depending on the model selected.

4.1 Distribution influence on decision making

The expected direct and indirect costs associated with the failure of the power unit modelled either with exponential or Weibull distribution show a significant growth in the first two years (see iceberg chart in Figures 3 and 4). After the second year, when the machine has been operating more than 9600 hours, the expected costs present a certain stabilization.

Comparing the results obtained with each model, a big difference lies within the first 3 years. The influence diagram, when is modelled with exponential distribution, gives rise to lower direct and indirect costs for that period. These differences reduce over time, from 48% less for the first year to 20% less the second and just 10% less the third. This highlights that even if both models present a good similarity from the third year onwards, Weibull distribution, more mathematically appropriate, can better respond to the expected costs during the initial stages. Therefore, even though for some real life scenarios a constant failure rate can represent a good approximation, a Weibull distribution has proven to be a worthwhile distribution for modelling power unit faults, although the estimations of its parameters may be more time-consuming in terms of calculation.

 ISBN: 978-84-617-8694-7

This last point is also supported by the fact that Weibull distribution enables a better understanding of power unit elements. The shape parameter k represents the failure rate behaviour. A value of $k < 1$ indicates that the failure rate decreases over time. This is the case of the engine block k=0.91290 (Table 1). When $k > 1$ the failure rate increases with the passing of time. The starter engine k=1.44447 and the injection system k= 1.94212 (Table 1) present this condition reflecting the existence of an aging process. It is noticeable that the engine itself is the one with the most similar behaviour to an exponential distribution (k=1), while the injection system gets closer to a Rayleigh distribution (k=2) with the starter engine in the middle of these two.

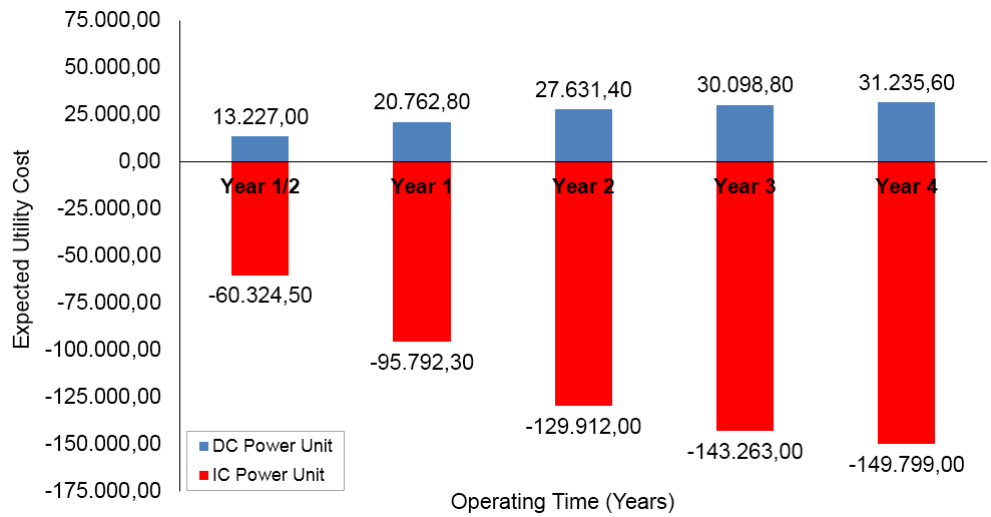

Figure 3: Direct and indirect expected fault costs for the exponential probabilistic model

When designing an optimum maintenance policy this knowledge is crucial. The engine is known now as more sensitive to suffer initial faults, while the starter engine and the injection system present the inverse condition. A right balance could be found with an extensive maintenance that pays special attention to the machine in its initial stage moving toward a less exhaustive maintenance when the machine have reached its half-life. This could ensure a good adaptation of the engine to the work environment whilst promoting a healthy aging for the starter engine and the injection system.

From a management perspective, a fault minimization at the beginning of the excavator operating life not only involves a reduction in direct costs associated with repair, but also would contribute to quickly reach the required hours to complete the amortization of the machine. Indirect costs show up in a ratio of 4.5 to 1 compared with direct cost. They are larger from what many engineers can imagine, often hidden behind the shadow of the faults having a huge role in the whole system performance.

 ISBN: 978-84-617-8694-7

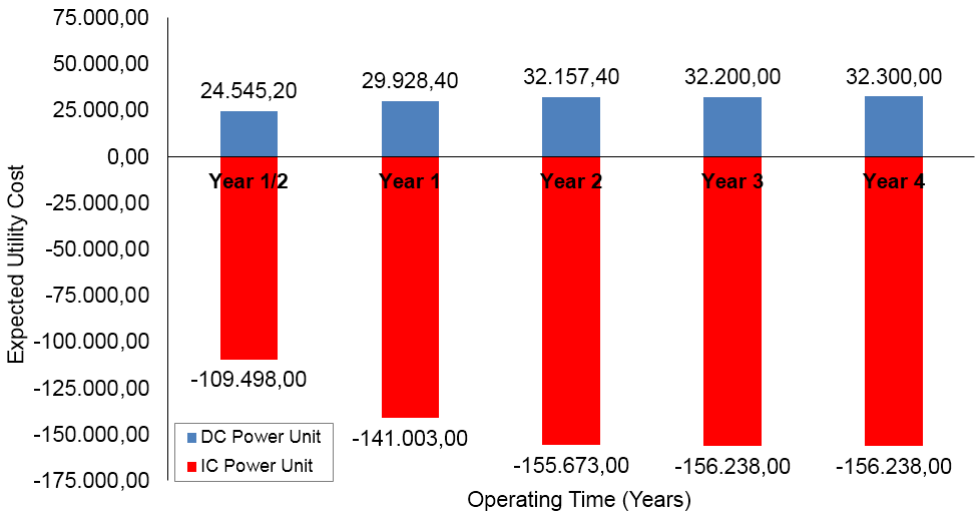

Figure 4: Direct and indirect expected fault cost for the Weibull probabilistic model

4.2 Fault severity

Aleatory or stochastic uncertainty due to the faults randomness is always at some point inherent to the variability of the system regardless of how good the maintenance strategy is. However, epistemic or subjective uncertainty arising from the lack of knowledge about the system and its behaviour can be certainly reduced by acquiring knowledge through probability and decision models like the one shown here. One aspect that holds special importance is the risk of suffering a fault with a high degree of severity, because of its huge cost and long time to repair.

The deterministic node incorporated in the influence diagram (Figure 2) with engineers' criteria for the fault degree of severity regarding the particular damaged elements in the power unit (Table 2) makes it possible to calculate the risk profile for the machine operating time (Figure 5). The risk profile is important for identifying the acceptable level of risk an individual or corporation is able to accept. It is expressed in terms of risk probability including the results of using in the influence diagram the prior probabilities for both the exponential and Weibull model.

As it can be seen in Figure 5, from year 2 the likelihood of having a fault with a very high severity exceeds the 50%. Year 2 can, therefore, set the point for which the risk level determines the maintenance strategy. During the two first years could be implemented an extensive maintenance based on a predictive approach that tries to minimize fault risk levels for the later years. From the third year a preventive maintenance, less exhaustive, can be applied. The aging effect is already present and expensive maintenance approaches could

 ISBN: 978-84-617-8694-7

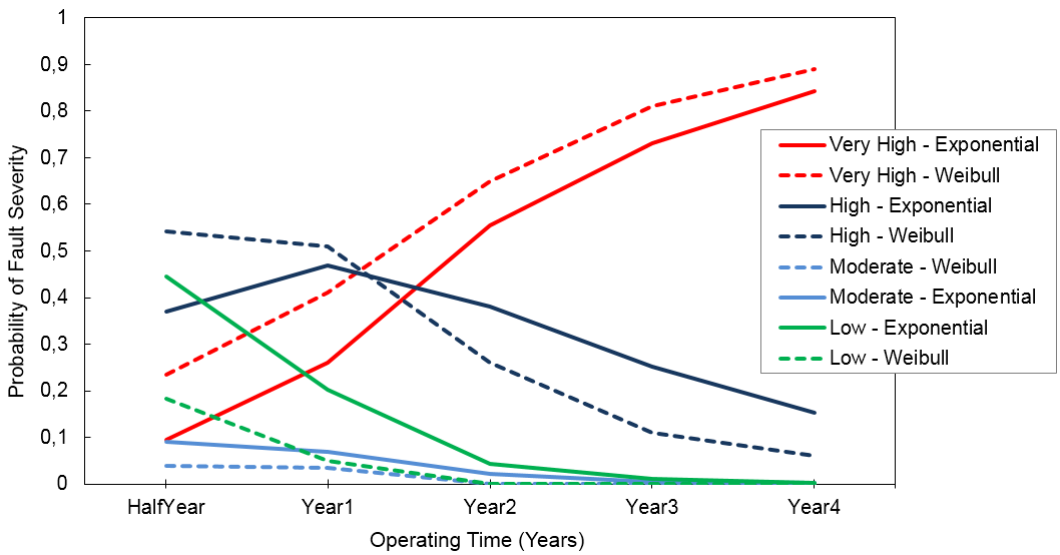

Figure 5: Probability risk profile for the power unit fault severity

not really stop faults appearance.

5 Conclusions and future work

In this paper, it was tried to develop a new process for the estimation of the power unit failure in mining excavators using an innovative management perspective. The power unit was divided in three main fault elements and from data of faults collected the last years in different mining excavators throughout its operation life, exponential and Weibull probabilistic models were used in order to obtain the prior fault probabilities for each element. The analysis of the prior probabilities into an influence diagram showed that the Weibull model offers a more accurate representation of the expected direct and indirect costs for the power unit.

A risk profile for the faults severity was calculated proposing an optimized maintenance solution for this machinery. Maintenance strategies should be designed under the assumption of a certain probability model that does not influence decisions. Since the selection of the probability model is carried out at an early stage of the design, one might expect a low impact on the final selection of the best strategy. This paper shows how a misspecification of the probability model can lead to erroneous conclusions since early stages causing expansive economic losses. Future work is required to analyse and optimize maintenance strategies in other crucial parts of excavators and other mining and civil machinery, especially those

exposed to a high level of wear.

Abstract

We investigate some simple models to describe prevention measures for mosquito borne diseases like dengue fever. We introduce the concepts of optimal control in very simple models which can in most aspects be treated analytically, namely the linear infection model, which has been used previously to describe for example vaccine trial data and could be as well applied to other control measures. We then relax the conditions of the linear infection model, and have to perform now most steps numerically, until we reach realistic models for mosquito borne diseases, namely the SISUV model as a simplest model with susceptible and infected humans, S and I, and susceptible and infected mosquitoes, U and V.

The SISUV model has already sufficient nonlinearities to not only apply quadratic cost functions for optimization but also linear cost functions, which have nontrivial optimal control equations due to the nonlinearities in the disease model. The classically used quadratic cost functions to be optimized are compared to linear cost functions, which are more realistical from the health economics point of view than the quadratic cost functions, but tend to the occasional occurence of bang-bang control signals. However, we can give examples of non-linear models, like the SISUV model, in which qudratic and linear cost functions give qualitatively very similar control signals, avoiding any

 ISBN: 978-84-617-8694-7

complications of the optimum reaching any unreasonable boundaries, which could lead to bang-bang controls. The small numerical differences are due to different scalings in quadratic and linear cost functions, and could eventually be removed. But these numerical differences are of little practical relevance.

Key words: optimal control theory, dengue fever, vaccination, mosquito repellents, linear infection model, SISUV model

1 Introduction

Zika infection, dengue fever, chikungunya and yellow fever are examples of vector-borne diseases transmitted by day-time active mosquitoes. In 128 countries, in particular in tropic and sub-tropic regions of Asia and Latin America these diseases are a major health risk and a negative economic factor.

In recent years, however, vector-borne diseases and especially dengue fever are occurring in Europe. Some reasons for this are the worldwide flow of trade and travelling tourism. Increasing urbanization, as well as regional warming due to global climate change, have amplified the spread of mosquitoes like *Aedes albopictus* in Europe. In 2010, infections with the dengue virus were registered in Croatia, France and Italy. In 2012 and 2013, more than 2000 autochtonous cases having dengue fever were found on the isle of Madeira/Portugal transmitted by *Aedes aegypti*. Chikungunya infections occurred in Italy (2007) and Spain/France (2015). Eggs, larvae, pupae and adult mosquitoes of *Aedes albopictus* were repeatedly detected in the south of Germany in autumn 2014 and in 2015. Researchers assume from these findings that Asian tiger mosquitoes can survive the winter and settle in Germany.

Over the past few decades, the incidences of dengue have grown dramatically. Recent studies indicate the existence of approximately 390 million dengue infections per year and that 3,9 billion people, in 128 countries including Thailand, Brazil, India and Pakistan, are at risk of being infected with the dengue virus. The WHO has set the goal to constrain and control the spreading of dengue fever by 2020, however there are major obstacles in achieving this goal. Some vaccines are in advanced trial stages, but not effective against all serotypes, with the Phase 3 results of the Sanofi Pasteur vaccine as front runner just concluded, and have negative effects in some age classes. WHO guidelines for vaccine trials are very detailed and specific in their requirements of scientific investigation before licensing, with phases 1, 2, 2b and 3, and finally phase 4 after licensing.

As already mentioned, for dengue fever first vaccine trials are running, but the results are not satisfactory. In general regarding mosquito vector-borne diseases vaccines are quite imperfect like DengVaxia for dengue fever, recently licenced by Sanofi-Pasteur, or vaccines do not yet exist as is the case for the Zika virus. In relation to yellow fever the vaccine is even in some cases lethal. Classical mosquito control measures, like bed-nets and municipal spraying in the streets, have proven to be of little effectiveness in combating disease cases. In

 ISBN: 978-84-617-8694-7

mosquito control, some activities in demonstration of efficacy using bed-nets via the WHO are performed. However bed nets are not very efficient against the disease. One reason is that vectors of dengue, the species *Aedes aegypti* and *Aedes albopictus* are active in the morning and evening, but not very active at night. Another important aspect in eliminating mosquitoes by classical pesticides and insecticides, beside the danger to human health, is that the elimination of mosquitoes, would also deprive many fish, birds, and reptiles of a food source and even destroy critical pollinator for plants.

In future research we will investigate SIR-type models with repellency and vaccination and analyse with optimal control theory. Here we first study a toy model which can in many aspects be treated analytically, and can already capture some simplest aspects of repellents respectively vaccination. Then numerical methods are studied to relax the need for analyticity in the models. In order to calculate numerically the influence of repellency and vaccination in the model we will use the gradient method. For some aspects see also [1, 2]. Ones the effectiveness of different control measures in known, like e.g. in the case of the dengue vaccine [3] using the experimental data obtained during the phase 3 trial, e.g. [4] or like new generations of mosquito repellent applications (including nano-particles in textiles, wall paints etc.) the next step, of course, is the suggestion of optimal strategies to combat vector-borne diseases like dengue fever, and it would be a matter of optimal control as a mathematical field.

2 The mathematical model for dengue fever

2.1 The general SIRUV-model for coupling mosquito to human epidemiology including repellency and vaccination

For pure human disease epidemiology, we assume the usual SIR model given by the ODEs

$$\begin{aligned} \frac{d}{dt}S &= \mu(N-S) - \frac{\beta}{N}SI \\ \frac{d}{dt}I &= \frac{\beta}{N}SI - (\gamma+\mu)I \\ \frac{d}{dt}R &= \gamma I - \mu R \end{aligned} \tag{1}$$

with state variables S for susceptible humans, I for infected and R for recovered humans. The population of humans $N = S + I + R$ is assumed constant. The infection rate is given by β, recovery rate γ and birth and death rate for humans by μ.

The stationary states are easily otained. For the human infection we obtain the trivial disease-free equilibrium stationary state $I_1^* = 0$ and the non-trivial case $I_2^* = (\mu/(\gamma+\mu)(1-(\gamma+\mu)/\beta)N$. Respectly we have the two stationary states for the susceptibles $S_1^* = N$ and $S_2^* = ((\gamma+\mu)/\beta)N$ and for the recovered in both cases $R^* = N - S^* - I^*$.

 ISBN: 978-84-617-8694-7

Now we add to the ODEs (1) the susceptible mosquito population U and the infected mosquitos as disease vectors V. In the easiest case the total population size M adds up to $M = U + V$. We assume, since mosquitoes do not have an immune system, they cannot recover from the infection. So the resulting ordinary differential equations give the following system

$$\begin{aligned} \frac{d}{dt}S &= \mu(N-S) - \frac{\beta}{M}SV - \upsilon S \\ \frac{d}{dt}I &= \frac{\beta}{M}SV - (\gamma+\mu)I \\ \frac{d}{dt}R &= \gamma I - \mu R + \upsilon S \\ \frac{d}{dt}U &= \psi - \nu U - \frac{\vartheta}{N}UI \\ \frac{d}{dt}V &= \frac{\vartheta}{N}UI - \nu V \end{aligned} \tag{2}$$

with mosquito birth rate ψ, infection rate from human to mosquito ϑ and mosquito mortality ν, mosquito population size $M = U(t) + V(t)$ assumed constant, hence for now $\psi := \nu \cdot M$. We also included in the above equations (2) the vaccination factor υ. Here the repellent acts as reducing contact rates between humans and mosquitoes, hence β and ϑ, where in time scale separation or center manifold analysis the simplest version already gives $\beta \cdot \vartheta$ as contact parameter in the effective SIR model [5].

2.2 The simple case of linear infection model and optimal control

Using the described model in the last section we use the simple case of the linear infection model to understand the application of the optimal control method in these above mentioned models. The linear infection model with reaction scheme

$$S + I^* \quad \stackrel{\beta}{\longrightarrow} \quad I + I^* \tag{3}$$

with susceptibles S meeting outside infected I^* assumed in equilibrium with infection rate β brings the different aspects of modelling and analysing disease control measures together, since

$$\begin{array}{lcl} S_c + I^* & \stackrel{\beta}{\longrightarrow} & I_c + I^* \\ S_v + I^* & \stackrel{(1-k_v)\beta}{\longrightarrow} & I_v + I^* \end{array}$$

is used in its stochastic version to describe vaccine trials [3]. Here k_v is the vaccine efficacy which can be estimated e.g. in a Bayesian framework from empirically given numbers of

 ISBN: 978-84-617-8694-7

infected in the vaccine group I_v, ones β is estimated from the number of infected in the control group I_c. And S_c and S_v are given by the group sizes of control group and vaccine group. Vaccines, however, are not always completely effective or even in some age groups like the dengue vaccine dangerous with occasionally negative vaccine efficacy $k_v < 0$, giving quite interesting effects in more complex multi-strain models including such imperfect vaccines in itself [7, 8].

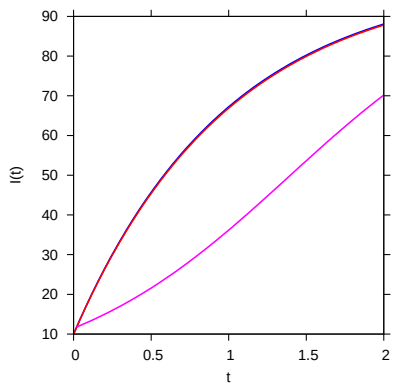

Figure 1: *Number of infected with time for the linear infection model, blue and red on top of each other for the uncontroled system, blue with the direct integration of the ODE, red with the discretized solution. The controlled system gives the number of infected with time as shown by the pink curve.*

Hence, other control measures like mosquito repellents, modelled as

$$\begin{array}{ccc} S_c + I^* & \xrightarrow{\beta} & I_c + I^* \\ S_M + I^* & \xrightarrow{(1-k_M)\beta} & I_M + I^* \end{array}$$

should be studied, with an as yet to investigate mosquito repellent efficacy k_M.

The reaction scheme Eq. (3) gives the rate equation

$$\frac{d}{dt}I = \frac{\beta}{N}SI^* = \beta^* S \tag{4}$$

with $\beta^* = (\beta/N)I^*$ and then omiting the star, but keeping conservation of population size N constant, hence

$$\frac{d}{dt}I = \beta S = \beta(N - I) \tag{5}$$

defining the linear infection model [6]. For the optimal control problem the linear infection model is given by

$$\frac{d}{dt}I = \beta_0(N - I) \tag{6}$$

 ISBN: 978-84-617-8694-7

with natural infection rate β_0, as for example measured from a control group study. For any control measure, vaccination or mosquito control, we obtain then

$$\frac{d}{dt}I = (1-k)\beta_0(N-I) = (\beta_0 - k\beta_0)(N-I) \tag{7}$$

with a maximally possible control $u_0 := k\beta_0$ for a vaccination of mosquito repellency group with all members vaccinated (hence 100% coverage). Any actual control strategy $u(t)$ then should be larger zero and smaller than the maximum, hence $0 < u(t) < u_0$.

We introduce the control signal $u(t)$ in $\beta(t) = (\beta_0 - u(t))$ in the above optimal control problem (7) with the simple solution of the ODE $\dot{I} = (\beta_0 - u(t))(N-I)$ given by

$$\begin{aligned} I(t) &= N - (N-I_0)e^{-\int_{t_0}^{t}\beta(\tilde{t})d\tilde{t}} \\ &= N - (N-I_0)e^{-\int_{t_0}^{t}\{\beta_0 - u(\tilde{t})\}d\tilde{t}} \qquad (8) \\ &=: I[u(\tilde{t})] \qquad (9) \end{aligned}$$

and then the optimal control problem minimizes the cost function

$$\mathcal{J} = \int_{t_0}^{T}\{\frac{1}{2}kI^2 + \frac{1}{2}\ell u^2\}\,dt \quad . \tag{10}$$

By using the variation of the cost function to obtain the optimal control signal $u(t)$

$$\frac{\delta\mathcal{J}[u(t)]}{\delta u(t)} = 0 \tag{11}$$

and for numerical analysis discretisation we can then solve the above problem. For the solution we discretize the total time T into n steps with size Δt

$$T = n\Delta t \tag{12}$$

and hence the continuous $I(t)$ becomes time discretisized using Eq. (8)

$$I_i = N - (N-I_0)e^{-\sum_{k=0}^{i-1}\{\beta_0 - u_k\}\,\Delta t} \tag{13}$$

and for convenience $B_i := e^{-\sum_{k=0}^{i-1}\{\beta_0 - u_k\}\,\Delta t}$. Note that we run the sum from $k=0$ to $k = i-1$. The cost function becomes plugging the above into Eq. (10), and using $m := \ell/k$ with unimportant factor k in the cost function

$$\begin{aligned} \mathcal{J}(T) &= \sum_{i=1}^{n}\{\frac{1}{2}I_i^2 + \frac{1}{2}mu_i^2\}\,\Delta t \\ &= \mathcal{J}\underbrace{(u_0, u_1, \cdots, u_{n-1})}_{=:\underline{u}} = \mathcal{J}(\Big\{u_k\Big\}_{k=0}^{n-1}) \qquad (14) \end{aligned}$$

 ISBN: 978-84-617-8694-7

hence

$$\mathcal{J}(\underline{u}) = \sum_{i=1}^{n} \{\frac{1}{2} I_i^2(\underline{u}) + \frac{1}{2} m u_i^2\} \, \Delta t \tag{15}$$

so the optimization problem reduces to optimizing $\mathcal{J}$ in respect to $\underline{u}$, i.e.

$$\frac{\partial \mathcal{J}(\underline{u})}{\partial u_j} = 0 \tag{16}$$

for all u_j.

After some calculations one finds the following expressions for the partial derivatives for the cost function $\mathcal{J}$

$$\frac{\partial \mathcal{J}(\underline{u})}{\partial u_j} = m u_j \cdot \Delta t + \sum_{i=j+1}^{n+1} I_i(\underline{u}) \cdot (-(N - I_0) B_i) \, (\Delta t)^2 \tag{17}$$

with $I_i(\underline{u}) = N - (N - I_0)B_i$ and the B_i being functions of the control signal $\underline{u}$. These partial derivatives either could be analyzed to be zero, but no solution is easily visible, or they can be used for a gradient method numerically, the way we went finally. Hence for the update of the $(\nu + 1)$ step of the control signal u_j from the ν step with initially zero control $u_j^{(0)} := 0$ is given by

$$u_j^{(\nu+1)} = u_j^{(\nu)} + h_j \tag{18}$$

with $h_j = c \cdot (-\partial \mathcal{J} / \partial u_j)$, i.e. maximizing $G := -\mathcal{J}$, and a step size c initially quite large, and then halfening every time it overshoots the minimization process. Numerical results are given in Figs. 1 and 2.

2.3 Generalization to not directly solvable disease dynamics

In cases when the disease dynamics $\dot{I} = f(I, u)$ cannot be solved analytically, we can use Lagrange multipliers $\lambda(t)$ for the optimization of the cost function, taking the disease dynamics as constraint into account, hence

$$\mathcal{L}[I(t), u(t), \lambda(t)] = \int_{t_0}^{T} \{\frac{1}{2} I^2 + \frac{1}{2} m u^2 + \lambda(\dot{I} - f(I, u))\} \, dt \tag{19}$$

to be minimized.

Now the discretization, done in the same way as before, reveals some interesting insights, namely the variation in respect to the Lagrange multipiers $\partial \mathcal{L} / \partial \lambda_j = 0$ gives back the constraint of the disease dynamcis

$$\frac{1}{\Delta t}(I_{j+1} - I_j) = f(I_j, u_j) \tag{20}$$

 ISBN: 978-84-617-8694-7

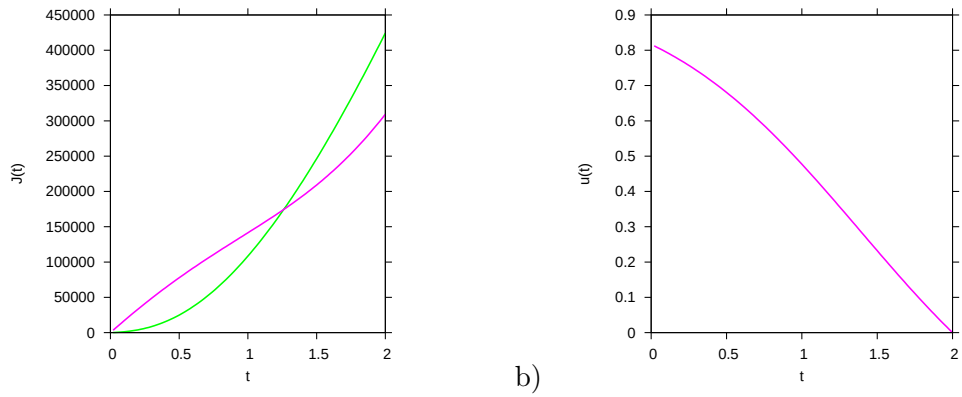

Figure 2: *In a) we show the cost function of the uncontrolled system in green, and the result after optimization in pink, reducing the cost significantly at the end of the target time, while initially the costs were increased due to control costs and not yet achieved reduction in disease cases. In b) we show the optimal control signal itself. The main effect has a control at the beginning of the controling time, and then relaxing, since the initial increase of infected has been successfully dampened.*

and then variation in respect to the infecteds $\partial\mathcal{L}/\partial I_j = 0$ gives a backward in time dynamics for the Lagrange multipliers

$$\frac{1}{\Delta t}(\lambda_{j-1} - \lambda_j) = \lambda_j \frac{\partial f}{\partial I_j} - I_j \tag{21}$$

with the upper boundary condition $\lambda_n = -I_{n+1} \cdot \Delta t \to 0$ for small time steps $\Delta t \to 0$. Finally the variation in respect to the control signal $\partial\mathcal{L}/\partial u_j = 0$ gives an algebraic equation system

$$mu_j - \lambda_j \frac{\partial f}{\partial u_j} = 0 \tag{22}$$

which in the case of a linear control in f, like we have here in the linear infection model, gives the control signal u_j as a function of λ_j and I_j only, due to $\partial f/\partial u_j$ is then only a function of I_j, and not of u_j any more. Hence then the forward dynamics for the infected and the backward dynamics for the Lagrange multipliers are sufficient to solve the optimal control problem, and

$$u_j = \frac{1}{m}\lambda_j \frac{\partial f}{\partial u_j} \tag{23}$$

determins the new updated control signal.

We implemented this method and in this case of the linear infection method we obtain exactly the same result as with the known analytic solution $I(\underline{u})$. Numerically, the results are indistinguishable from Figs. 1 and 2.

2.4 Optimal control for the SIS system

Now we use the resulting method for general disease models $\dot{I} = f(I, u)$ and generalize to the next simplest model of the SIS system, susceptibles becoming infected with rate β and recovering with rate α, hence

$$\dot{I} = f(I, u) = (\beta_0 - u(t)) \cdot \frac{I}{N}(N - I) - \alpha I \tag{24}$$

which is nonlinear in the disease variable I. In principal the direct method with

$$u_j = \frac{1}{m}\lambda_j \frac{\partial f}{\partial u_j} \tag{25}$$

could still be used, but this gives not converging cost functions, but oscillations between different values of the cost function, hence no clear minimum can be found.

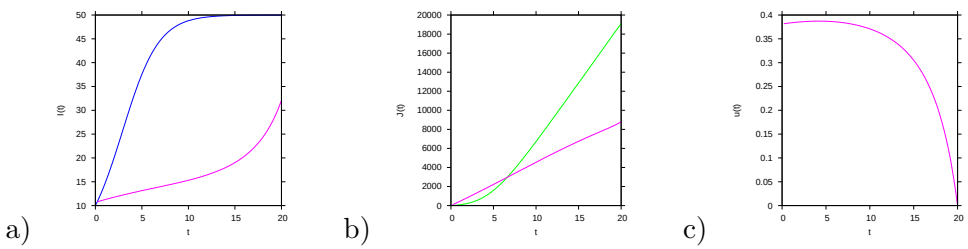

Figure 3: *Optimal control of the SIS system for cost function weight* $m = 5000$.

However, the constraint of the disease function has to be fulfilled always, so we keep the disease dynamics with given control signal in an Euler-forward scheme. Then, we also use the optimal solution of the backward dynamics for the Lagrange multipliers, and only replace the optimization of the control signal, which is most likely causing oscillations between minimal and maximal solutions of the cost function, by an explicit gradient method, as described before, i.e. with large initial step size and on rejection halfening this step size.

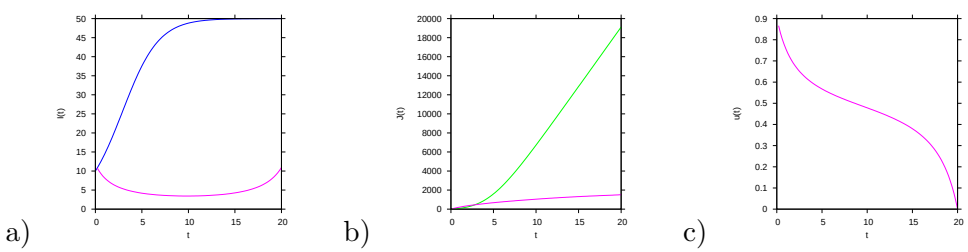

Figure 4: *Optimal control of the SIS system for reduced cost function weight* $m = 500$.

 ISBN: 978-84-617-8694-7

In this way we found a valid optimal solution also for the nonlinear SIS system, as given in Fig. 3 for the cost function weight of $m = 5000$, as before used for the linear infection model, and Fig. 4 for reduced costs of the control with weight $m = 500$.

2.5 Optimal control for the SISUV system: non-linear dynamics and non-linear control allow quadratic and also linear cost-functions with similar results

We now give some first preliminar results on the optimal control of the SISUV model [5], with percentual control in the contact parameters β and ϑ. Due to the non-linearities not only in the disease dynamics but also in the control signal, we can obtain similar optimal control results for the above given quadratic cost function and for a more economically reasonable linear cost function.

The SISUV model, describing in a simple way the time scale separation of mosquito dynamics versus the human disease dynamics and serving as a simplified version of the SIRUV model described above [5], is in its result given by the differential equation

$$\dot{I} = (\beta \cdot \vartheta) \cdot \frac{I}{N}(N - I) \cdot \frac{1}{\nu + \vartheta \frac{I}{N}} - \alpha I \tag{26}$$

with all notations also used and described in more detail in [5]. Now we will control the two contact rates, β of human susceptibles being infected by infected mosquitoes, and ϑ of susceprible mosquitoes being infected by infected humans, both in percentage of the rate in order to have comparable control signals in both parameters, hence

$$\beta(t) = \beta_0 \cdot (1 - u(t)) \tag{27}$$

and

$$\vartheta(t) = \vartheta_0 \cdot (1 - u(t)) \tag{28}$$

such that we have finally the controllable disease dynamics given by

$$\dot{I} = f(I, u) = (\beta_0 \cdot \vartheta_0) \cdot \frac{I}{N}(N - I) \cdot \frac{(1 - u)^2}{\nu + (1 - u) \cdot \vartheta_0 \frac{I}{N}} - \alpha I \tag{29}$$

hence a nonlinear dynamics $f(I, u)$ as well in the number of infected I as in the control signal u.

For the evaluation of the optimal control as described above in the section for the SIS model, we need the partial derivatives of $f(I, u)$, which can be calculated analytically as

$$\frac{\partial f}{\partial u} = (\beta_0 \cdot \vartheta_0) \cdot \frac{I}{N}(N - I) \cdot \frac{(u - 1)\left((1 - u)\vartheta_0 \frac{I}{N} + 2\nu\right)}{\left(\nu + (1 - u) \cdot \vartheta_0 \frac{I}{N}\right)^2} \tag{30}$$

 ISBN: 978-84-617-8694-7

and

$$\frac{\partial f}{\partial I} = (\beta_0 \cdot \vartheta_0) \cdot \frac{(1-u)^2}{N} \cdot \frac{(N-2I)\nu - (1-u)\vartheta_0 \frac{I^2}{N}}{\left(\nu + (1-u)\cdot \vartheta_0 \frac{I}{N}\right)^2} - \alpha \tag{31}$$

to be inserted in the conditions $\partial\mathcal{L}/\partial\lambda_j = 0$ for the disease forward dynamics, $\partial\mathcal{L}/\partial I_j = 0$ for the Langrange multiplier backward dynamics and for the gradient method of updating the control signal u the gradient $\partial\mathcal{L}/\partial u_j$, ones the cost function $\mathcal{J}$ and hence the Lagrangian $\mathcal{L}$ are specified.

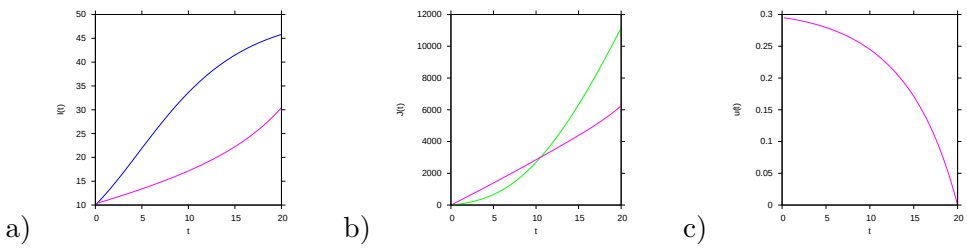

Figure 5: *Optimal control of the SISUV system for quadratic cost function with weight* $m_2 = 5000$.

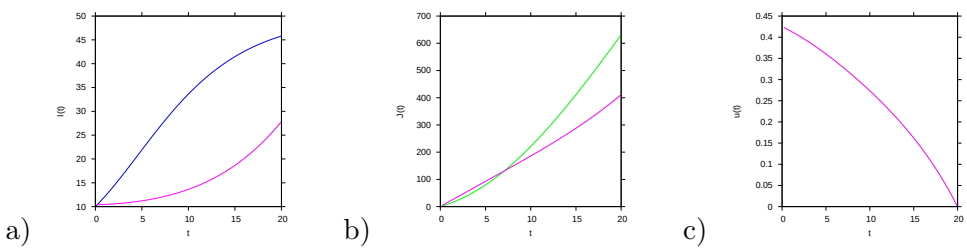

Figure 6: *Optimal control of the SISUV system for linar cost function with weight* $m_1 = 20$, *giving similar results to those using the quadratic cost function in the previous figure.*

Here we can now compare the results for the already above mentioned quadratic cost function

$$\mathcal{J}_2(\underline{u}) = \sum_{i=1}^{n} \left(\frac{1}{2} I_i^2(\underline{u}) + \frac{1}{2} m_2 u_i^2 \right) \Delta t \tag{32}$$

and an in economical terms better justifiable linear cost function, which however might be less convenient mathematically,

$$\mathcal{J}_1(\underline{u}) = \sum_{i=1}^{n} \left(I_i(\underline{u}) + m_1 u_i \right) \Delta t \tag{33}$$

both already given in their discretized version.

For the quadratic cost function and hence the Lagrangian function respectively we obtain the above mentioned results: The variation in respect to the Lagrange multipiers $\partial\mathcal{L}/\partial\lambda_j = 0$ gives back the constraint of the disease dynamcis

$$\frac{1}{\Delta t}(I_{j+1} - I_j) = f(I_j, u_j) \tag{34}$$

and then variation in respect to the infecteds $\partial\mathcal{L}/\partial I_j = 0$ gives the backward dynamics for the Lagrange multipliers

$$\frac{1}{\Delta t}(\lambda_{j-1} - \lambda_j) = \lambda_j \frac{\partial f}{\partial I_j} - I_j \tag{35}$$

while the variation in respect to the control signal $\partial\mathcal{L}/\partial u_j$ gives the gradient to be used in updating the control signal $\underline{u}$

$$\partial\mathcal{L}/\partial u_j = \left(m u_j - \lambda_j \frac{\partial f}{\partial u_j}\right) \cdot \Delta t \tag{36}$$

with the results after optimization given in Fig. 5 with a weight of the control signal in the quadratic cost function as $m_2 = 5000$.

For the linear cost function we obtain from the variation the following results: The variation in respect to the Lagrange multipiers $\partial\mathcal{L}/\partial\lambda_j = 0$ gives again the constraint of the disease dynamcis

$$\frac{1}{\Delta t}(I_{j+1} - I_j) = f(I_j, u_j) \tag{37}$$

and then variation in respect to the infecteds $\partial\mathcal{L}/\partial I_j = 0$ gives the backward dynamics for the Lagrange multipliers now in the slightly different form

$$\frac{1}{\Delta t}(\lambda_{j-1} - \lambda_j) = \lambda_j \frac{\partial f}{\partial I_j} - 1 \tag{38}$$

while the variation in respect to the control signal $\partial\mathcal{L}/\partial u_j$ gives the gradient to be used in updating the control signal $\underline{u}$ now also slightly different as

$$\partial\mathcal{L}/\partial u_j = \left(m - \lambda_j \frac{\partial f}{\partial u_j}\right) \cdot \Delta t \tag{39}$$

with the results after optimization given in Fig. 6, when using a weight of the control signal in the linear cost function as $m_1 = 20$ as a first guess to obtain similar control results as for the quadratic cost function given in Fig. 5 with $m_2 = 5000$. The results for both cost functions, the quadratic and the linear, are qualitatively in good agreement. No effort was given to find an m_1 for the linear cost function which could closer match the results obtained with m_2 in the case of the quadratic cost function.

On viable solutions of differential inclusions with fractional derivative without singular kernel

Ewa Girejko[1]

[1] *Faculty of Computer Science, Department of Mathematics, Bialystok University of Technology*

emails: e.girejko@pb.edu.pl

Abstract

In the paper we provide sufficient conditions assuring existence of viable solutions of differential inclusions with fractional derivative without singular kernel, namely Caputo–Fabrizio derivative of order $\alpha \in (0, 1)$. A modified condition of tangency, according to specifity of system with this new fractional derivative is given.

Key words: viability, differential inclusion, Caputo–Fabrizio derivative

1 Introduction and preliminaries

Viability theory as well as fractional calculus have a wide range of applications. And so, viablity theory designs and develops mathematical and algorithmic methods that can be found, for example, in biological evolution, economics, environmental sciences, financial markets or control theory and robotics (see [2] and the references within), while fractional calculus finds numerous applications in viscoelasticity, capacitor theory, electrical circuits (see for example [8, 9, 10, 11]). It was a motivation for the author to examine a combination of these two so applicative fields of mathematics. The goal of this research is to deliver conditions under which solutions of fractional differential inclusion are constrained to be in a given set (viable solutions). To the best of our knowledge, there are only few papers devoted to this subject [5, 6, 7, 12]. In the paper we give tangency conditions for the existence of viable solutions of differential inclusions with fractional derivative without singular kernel - Caputo–Fabrizio derivative.

 ISBN: 978-84-617-8694-7

We start with the definition of Caputo fractional derivative (for details see [9]). For given $b > 0$ and $\alpha \in (0,1)$ the Caputo fractional derivative is given by

$$ {}^{C}D^{\alpha} f(t) = \frac{1}{\Gamma(1-\alpha)} \int_{t_0}^{t} (t-s)^{-\alpha} f'(s) ds \,, \quad t > t_0. $$

Now changing the kernel $(t-s)^{-\alpha}$ by the function $\exp^{\frac{-\alpha(t-s)}{1-\alpha}}$ and $\frac{1}{\Gamma(1-\alpha)}$ by $\frac{1}{\sqrt{2\pi(1-\alpha^2)}}$ we obtain the new Caputo–Fabrizio fractional derivative of order $\alpha \in (0,1)$ introduced racently by Caputo and Fabrizio in [4] in the following form:

$$ {}^{CF}D^{\alpha} f(t) = \frac{(2-\alpha)M(\alpha)}{2(1-\alpha)} \int_{t_0}^{t} \exp\left(-\frac{\alpha}{1-\alpha}(t-s)\right) f'(s) ds \,, \quad t \geq t_0 \,, \tag{1} $$

where $M(\alpha)$ is a normalization constant depending on α.

Let F be a multifunction from $[t_0, T] \times \mathbb{R}^n$ into $\mathbb{R}^n$. We consider the differential inclusion with Caputo–Fabrizio derivative as follows:

$$ {}^{CF}D^{\alpha} y(t) \in F(t, y(t)) \,, \quad y(t_0) = y_0 \,, \quad t \in [t_0, T] \,. \tag{2} $$

Definition 1. An absolutely continuous function $y(\cdot)$ is said to be a solution to differential inclusion (2) if there exists a measurable selection $f_y(t) \in F(t, y(t))$ such that for all $t \in [t_0, T]$ one has

$$ y(t) = c + a_\alpha f_y(t) + b_\alpha \int_{t_0}^{t} f_y(s) ds \,, \tag{3} $$

where $c = -a_\alpha f(t_0, y_0) + y_0$, $a_\alpha = \frac{2(1-\alpha)}{(2-\alpha)M(\alpha)}$, $b_\alpha = \frac{2\alpha}{(2-\alpha)M(\alpha)}$ and $M(\alpha) = \frac{2}{2-\alpha}$, $0 \leq \alpha \leq 1$ and $y' \in L^{\infty}([t_0, T], \mathbb{R}^n)$.

2 Main results

The main result of the paper is theorem that delivers viability conditions for fractional differential inclusions with Caputo–Fabrizio derivative. Before we start with the assumptions on a set-valued map F and a function f, we define a multifunction $G(t,x) := \overline{co} F([t_0, T], x + \mathbb{B})$ (then G has convex closed values) and consider a differential inclusion with an initial condition as follows

$$ {}^{CF}D^{\alpha} y(t) \in G(t, y(t)) \,, \quad y(t_0) = y_0 \,, \quad t \in [t_0, T] \,. \tag{4} $$

Now we propose an assumption:

(A1) Assume that $F : [t_0, T] \times \mathbb{R}^n \rightsquigarrow \mathbb{R}^n$ is upper semi–conitnuous (short: u.s.c., for definition and details see [1, 2, 3]) set–valued map with nonempty convex and compact values. Moreover, let F be Lipschitz with the constant $k(t)$.

 ISBN: 978-84-617-8694-7

Next proposition is crucial for the main results.

Proposition 2. *Let us assume that* $(A1)$ *is fullfiled. Then there exists a constant* N_α *such that* $\|G(t,y(t))\| \leq N_\alpha$ *a.e. in* $[t_0,T]$ *for every solution* $y(\cdot)$ *to* (4) *and the solution set of* (4) *is equicontinuous.*

Now we introduce the notion of viability.

Definition 3. Let $K \subset \mathbb{R}^n$ be a closed set and let $y_0 \in K$. We say that K is *viable* with respect to (2) if there exists a solution $y(\cdot)$ to (2) such that $y(t) \in K$ for $t \in [t_0,T]$. This kind of solutions we call *viable*.

One of the main difficulties is to establish the tangency condition taking into account the specificity of the fractional system with Caputo–Fabrizio derivative. In order to deliver approximate solutions remaining close to the set K we propose the following tangency condition.

Definition 4. Suppose $t_0 \leq \bar{t} < T$. Let $E \in \mathbb{R}^n$ be bounded, $f(\cdot) \in L^\infty([t_0,T],\mathbb{R}^n)$ and let us define $y(t) = c + a_\alpha f(t) + b_\alpha \int_{t_0}^t f(s)ds$. The pair (f,E) is said to be tangent to $[t_0,T]\times K$ at $(\bar{t},\bar{y}) \in [t_0,T]\times K$ if $y(\bar{t}) = \bar{y}$ and

$$\liminf_{h\to 0^+} \frac{1}{h} d(\bar{y} + a_\alpha r(\bar{t},f(\cdot))(h) + h\cdot b_\alpha E, K) = 0\,, \tag{5}$$

where $r(\bar{t},f(\cdot))(h) = f(\bar{t}+h, y(\bar{t}+h)) - f(\bar{t},\bar{y})$.

Remark 5. Observe that the above tangency condition one can understand as follows. For $t_0 \leq \bar{t} < \bar{t}+h \leq T$ a solution to (2) is of the form $y(\bar{t}+h) = c + a_\alpha f_y^F(\bar{t}+h) + b_\alpha \int_{t_0}^{\bar{t}+h} f_y^F(s)ds$
$= c + a_\alpha f_y^F(\bar{t}) + b_\alpha \int_{t_0}^{\bar{t}} f^F(s,y(s))ds + a_\alpha r(\bar{t},f_y^F(\cdot))(h) + b_\alpha \int_{\bar{t}}^{\bar{t}+h} f^F(s,y(s))ds\,,$
where $r(\bar{t},f_y^F(\cdot))(h) = f_y^F(\bar{t}+h) - f_y^F(\bar{t})$ and $f_y^F(\cdot)$ is a measurable function such that $f_y^F(t) \in F(t,y(t))$, $t \in [t_0,T]$. Then having in mind that $F(\cdot,\cdot)$ is u.s.c. we get $\liminf_{h\to 0^+} \frac{1}{h} dist(\bar{y} + a_\alpha r(\bar{t},f_y^F(\cdot))(h) + h\cdot b_\alpha F(\bar{t},\bar{y}), K) = 0$ for $y(\bar{t}) = \bar{y}$. It clearly implies that for every viable solution $y(\cdot)$ to (2) the pair $\big({}^{CF}D^\alpha y, F(t,y(t))\big)$ is tangent to $[t_0,T]\times K$ at $(t,y(t))$ for almost all $t \in [t_0,T]$.

In order to prove existence of viable solution we need a suitable construction of approximate solutions.

Proposition 6. *Let assumption* $(A1)$ *be fullfiled and let* $y(\cdot)$ *be an absolutely continuous function on* $[t_0,\bar{t}]$ *with* $y(t_0) = y_0$ *and* $t_0 \leq \bar{t} < T$. *If the pair* $\big({}^{CF}D^\alpha y(\cdot), F(\bar{t},\bar{y})\big)$ *is tangent to* $[t_0,T]\times K$ *at* $(\bar{t},\bar{y}) \in [t_0,T]\times K$, *then for every* $\varepsilon > 0$ *there exist* $\delta > 0$ *and* ε*-solution* $z(\cdot)$ *to* (2) *on* $[\bar{t},\bar{t}+\delta]$, *which is an extension of* $y(\cdot)$, *such that* $z(\bar{t}+\delta) \in K$.

Finally we are in the position to present the main result of the paper.

Theorem 7. *Let us assume that* $(A1)$ *hold. If the tangency condition is fullfiled by system* (2) *at every* $(\bar{t},\bar{y}) \in [t_0,T]\times K$, *then there exists at least one viable solution to* (2).

Probabilistic evolution theory for explicit autonomous ordinary differential equations: recursion of squarified telescope matrices and optimal space extension

Coşar Gözükırmızı[1] and Metin Demiralp[2]

[1] *Computer Engineering Department, Beykent University*

[2] *Informatics Institute, Istanbul Technical University*

emails: cosargozukirmizi@beykent.edu.tr, metin.demiralp@gmail.com

Abstract

Probabilistic evolution theory facilitates the solution of initial value problem of explicit autonomous ordinary differential equations with second degree multinomial right hand side functions. Its formulation has components we call telescope matrices. The matrices grow in size very rapidly and has many zeroes and repeating structures. In order to avoid the computational complexity coming from telescope matrices, squarified telescope matrices are utilized. Their calculation is through a recursion. This recursion has been used in several works by the authors and their colleagues but its proof was not given. This work gives the proof of the recursion and all the surrounding details. A second purpose of this work is to provide a method for most facilitative (optimal) space extension: using probabilistic evolution theory when degree of multinomiality of the right hand side functions is more than two. For this purpose, an approach using method of exhaustion (brute-force) is proposed.

Key words: probabilistic evolution theory, squarification, Kronecker multiplication, telescope matrices, space extension

1 Probabilistic Evolution Theory

The problem under consideration is the initial value problem of explicit autonomous ODE set where the right hand side functions are second degree multinomials [1, 2]. It is in the compact form

$$\begin{aligned} \dot{\mathbf{x}}(t) &= \mathbf{F}_0 + \mathbf{F}_1\mathbf{x}(t) + \mathbf{F}_2\mathbf{x}(t)^{\otimes 2}, \\ &\quad \mathbf{x}(0) = \boldsymbol{\alpha} \end{aligned} \tag{1}$$

 ISBN: 978-84-617-8694-7

where $\otimes 2$ on the exponent represents taking the second Kronecker power: Kronecker product of a vector by itself. ODEs with a higher degree of multinomiality may be put in the form in (1) using space extension. Section 3 has information about space extension. In (1), $\mathbf{F}_0$ is a vector, $\mathbf{F}_1$ is a square matrix and $\mathbf{F}_2$ is a rectangular matrix. Considering that $\mathbf{x}(t)$ in (1) is a vector with n elements, then $\mathbf{F}_0$ is of type $n \times 1$, $\mathbf{F}_1$ is of type $n \times n$ and $\mathbf{F}_2$ is of type $n \times n^2$. $\mathbf{F}_0$, $\mathbf{F}_1$ and $\mathbf{F}_2$ have constants (independent of t) as elements. These constants represent the parameters of the dynamics of the system whose state at time t is represented by the vector $\mathbf{x}(t)$.

Constancy adding space extension (CASE) is utilized to eliminate $\mathbf{F}_0$ at the expense of incrementing each dimension of matrices and vectors by 1. It relies on appending a constant element to $\mathbf{x}(t)$. In addition, the new (augmented) $\mathbf{F}_1$ may be put in a form so that it is proportional to the identity matrix. Therefore, using CASE, (1) may be written in the form

$$\begin{aligned} &\overline{\mathbf{x}}(t) \equiv \begin{bmatrix} \mathbf{x}(t) \\ \alpha_{n+1} \end{bmatrix}, \\ &\dot{\overline{\mathbf{x}}}(t) = \beta\, \overline{\mathbf{x}}(t) + \mathbf{F}\, \overline{\mathbf{x}}(t)^{\otimes 2}, \\ &\overline{\mathbf{x}}(0) \equiv \mathbf{a} \end{aligned} \tag{2}$$

where α_{n+1} is any real nonzero constant. The value of α_{n+1} will not show itself in the final solution: norm minimization makes the result independent of α_{n+1}. β may also be calculated using norm minimization: unlike α_{n+1}, the value of β has an effect on the solution [2]. If a factor $\mathrm{e}^{\beta t}$ is pulled out from $\overline{\mathbf{x}}(t)$, then

$$\begin{aligned} &\overline{\mathbf{x}}(t) \equiv \mathrm{e}^{\beta t}\, \overline{\overline{\mathbf{x}}}(t) \\ &\dot{\overline{\overline{\mathbf{x}}}}(t) = \mathrm{e}^{\beta t}\, \mathbf{F}\, \overline{\overline{\mathbf{x}}}(t)^{\otimes 2}, \\ &\overline{\overline{\mathbf{x}}}(0) = \mathbf{a} \end{aligned} \tag{3}$$

appears. The initial value problem in (3) has only second degree terms. On the other hand, it is not autonomous. If the independent variable is taken as a certain function of t instead of t itself, autonomous behavior may be obtained. This may be shown as

$$\begin{aligned} &u \equiv \frac{\mathrm{e}^{\beta t} - 1}{\beta}, \qquad \mathbf{y}(u) \equiv \overline{\overline{\mathbf{x}}}(t), \\ &\frac{d\mathbf{y}}{du} = \mathbf{F}\, \mathbf{y}(u)^{\otimes 2}, \\ &\mathbf{y}(0) = \mathbf{a} \end{aligned} \tag{4}$$

where taking β as 0 is a special case in which u is equal to t. The initial value problem in (4) is autonomous. In order to form the solution, the derivative of Kronecker power of a

 ISBN: 978-84-617-8694-7

vector is necessary. This may be performed using Leibniz rule as follows

$$\begin{aligned}\frac{d}{du}\left(\mathbf{y}(u)^{\otimes m}\right) &= \sum_{j=0}^{m-1}\mathbf{y}(u)^{\otimes j}\otimes\frac{d\mathbf{y}(u)}{du}\otimes\mathbf{y}(u)^{\otimes m-j-1},\\ &= \left(\sum_{j=0}^{m-1}\mathbf{I}_n^{\otimes j}\otimes\mathbf{F}\otimes\mathbf{I}_n^{\otimes m-j-1}\right)\mathbf{y}(u)^{\otimes m+1},\\ &\qquad m=0,1,2,...\end{aligned}\tag{5}$$

where $\mathbf{I}_n$ is $n\times n$ identity matrix. In (5) and from here on, n shows the number of elements in the system vector after constancy adding space extension (CASE). (5) relies on distributive property of product over Kronecker product. There is also the distributive property of Kronecker product over product. The matrix coefficients in (5) are named "monocular matrices". They are defined as follows.

$$\begin{aligned}&\mathbf{M}_m\equiv\left(\sum_{j=0}^{m-1}\mathbf{I}_n^{\otimes j}\otimes\mathbf{F}\otimes\mathbf{I}_n^{\otimes m-j-1}\right),\qquad m=0,1,2,...\\ &\frac{d}{du}\left(\mathbf{y}(u)^{\otimes m}\right)=\mathbf{M}_m\mathbf{y}(u)^{\otimes m+1},\\ &\mathbf{y}(0)^{\otimes m}=\mathbf{a}^{\otimes m+1}\qquad m=0,1,2,...\end{aligned}\tag{6}$$

Integrating both sides of the ODE in (6),

$$\mathbf{y}(u)^{\otimes m}=\mathbf{a}^{\otimes m+1}+\mathbf{M}_m\int_0^u d\upsilon\mathbf{y}(\upsilon)^{\otimes m+1},\quad m=0,1,2,...\tag{7}$$

may be obtained. Proceeding in the same manner,

$$\begin{aligned}\mathbf{y}(u) &= \mathbf{a}+\mathbf{M}_1\int_0^u d\upsilon\mathbf{y}(\upsilon)^{\otimes 2}\\ &= \mathbf{T}_0\mathbf{a}+u\mathbf{T}_1\mathbf{a}^{\otimes 2}+\mathbf{T}_2\int_0^u d\upsilon_1\int_0^{\upsilon_1}d\upsilon_2\mathbf{y}\left(\upsilon_2\right)^{\otimes 3}\\ &= \sum_{j=0}^{2}\frac{u^j}{j!}\mathbf{T}_j\mathbf{a}^{\otimes j+1}+\mathbf{T}_3\int_0^u d\upsilon_1\int_0^{\upsilon_1}d\upsilon_2\int_0^{\upsilon_2}d\upsilon_3\mathbf{y}\left(\upsilon_3\right)^{\otimes 4}\end{aligned}\tag{8}$$

appears where $\mathbf{T}$ matrices are telescope matrices: they are ordered products of monocular matrices defined as follows.

$$\mathbf{M}_0\equiv\mathbf{I}_n,\qquad\mathbf{T}_m\equiv\mathbf{M}_0...\mathbf{M}_m,\qquad m=0,1,2,...\tag{9}$$

 ISBN: 978-84-617-8694-7

The generalization of (8) gives

$$\mathbf{y}(u)=\sum_{j=0}^{m}\frac{u^{j}}{j!}\mathbf{T}_{j}\mathbf{a}^{\otimes j+1}+\mathbf{T}_{m+1}\int_{0}^{u}dv_{1}...\int_{0}^{v_{m}}dv_{m+1}\mathbf{y}\left(v_{m+1}\right)^{\otimes m+2},\quad m=0,1,2,... \tag{10}$$

and taking m to infinity by taking into consideration that the integral in (10) approaches zero when m is increased,

$$\mathbf{y}(u)=\sum_{j=0}^{\infty}\frac{u^{j}}{j!}\mathbf{T}_{j}\mathbf{a}^{\otimes j+1} \tag{11}$$

appears. (11) may be used in order to calculate the solution of the ODE given in (1). The only drawback is the size of telescope matrices: $\mathbf{T}_j$ is an $n\times n^{j+1}$ matrix.

2 Recursion of Squarified Telescope Matrices

In previous works, recursion of squarified telescope matrices is given [3] and is applied to many different problems. On the other hand, proof of recursion of squarified telescope matrices is given in this paper. Squarification is utilized so that (11) is simplified. Assume that there is a matrix $\mathbf{S}_m(\mathbf{a})$ such that

$$\mathbf{T}_{m}\mathbf{a}^{\otimes m+1}\equiv\mathbf{S}_{m}\left(\mathbf{a}\right)\mathbf{a},\qquad m=0,1,2,... \tag{12}$$

holds. $\mathbf{S}_m(\mathbf{a})$ is named "squarified telescope matrix" (SquTelMat). The calculation of these matrices may be performed by the use of a recursion. This section shows the proof of the recursion between SquTelMats. Using (12) in (11),

$$\mathbf{y}(u)=\left\{\sum_{j=0}^{\infty}\frac{u^{j}}{j!}\mathbf{S}_{j}\left(\mathbf{a}\right)\right\}\mathbf{a} \tag{13}$$

is obtained. The derivative of $\mathbf{y}(u)$ may be found using (13). Differentiating (13), j comes down as a factor and forms $(j-1)!$ on the denominator. The exponent becomes $(j-1)$. The zeroth term of the sum is 0 since $(j-1)!$ goes to infinity when j is 0. Therefore, the infinite sum starts from 1. In order to make it start from 0, all instances of j may be replaced by $(j+1)$. Then,

$$\frac{d\mathbf{y}(u)}{du}=\left\{\sum_{j=0}^{\infty}\frac{u^{j}}{j!}\mathbf{S}_{j+1}\left(\mathbf{a}\right)\right\}\mathbf{a} \tag{14}$$

 ISBN: 978-84-617-8694-7

may be obtained. Therefore, differentiation corresponds to increasing the subindex of SquTelMats. The right hand side of the ODE is in the form

$$\mathbf{F}\mathbf{y}(u)^{\otimes 2} = \lfloor\, \mathbf{F}, \mathbf{y}(u) \,\rceil\, \mathbf{y}(u) \tag{15}$$

where the first factor on the right hand side of (15) is a squarification. A squarification takes two operands: a matrix and a vector. The result of a squarification is a vector which is a linear combination of the square blocks of the matrix where the elements of the vector are the linear combination coefficients. Squarification is a linear operation with respect to its vector operand. The squarification in (15) is

$$\lfloor\, \mathbf{F}, \mathbf{y}(u) \,\rceil = \sum_{j=0}^{\infty} \frac{u^j}{j!} \lfloor\, \mathbf{F}, \mathbf{S}_j(\mathbf{a})\, \mathbf{a} \,\rceil \tag{16}$$

by using (13) and linearity of squarification with respect to its vector operand. Multiplying both sides of (16) by $\mathbf{y}(u)$ from right and using Cauchy product of two infinite series,

$$\begin{aligned}
\lfloor\, \mathbf{F}, \mathbf{y}(u) \,\rceil\, \mathbf{y}(u) &= \left\{ \sum_{k=0}^{\infty} \frac{u^k}{k!} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\, \mathbf{a} \,\rceil \sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_j(\mathbf{a}) \right\} \mathbf{a} \\
&= \left\{ \sum_{k=0}^{\infty} \frac{u^k}{k!} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\, \mathbf{a} \,\rceil \sum_{j=k}^{\infty} \frac{u^{j-k}}{(j-k)!} \mathbf{S}_{j-k}(\mathbf{a}) \right\} \mathbf{a} \\
&= \left\{ \sum_{j=0}^{\infty} \frac{u^j}{j!} \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\, \mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a}) \right\} \mathbf{a}
\end{aligned} \tag{17}$$

is obtained. Substituting (17) in (15) and using (14) and (4),

$$\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_{j+1}(\mathbf{a})\, \mathbf{a} = \sum_{j=0}^{\infty} \frac{u^j}{j!} \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\, \mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\, \mathbf{a} \tag{18}$$

appears. (18) has the following consequence: for a certain power of u, the coefficient vector on the left side of (18) should be equal to the coefficient vector on the right side of (18). Therefore,

$$\begin{aligned}
\mathbf{S}_{j+1}(\mathbf{a})\, \mathbf{a} &= \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\, \mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\, \mathbf{a} \\
j = 0, 1, 2, \ldots \qquad & \mathbf{S}_0 = \mathbf{T}_0 = \mathbf{I}_n
\end{aligned} \tag{19}$$

should be the case in order for (18) to hold for any value of u. (19) is a recursion between vectors. The initial value of the recursion is $\mathbf{S}_0\mathbf{a}$. (19) has been used for the solution of

 ISBN: 978-84-617-8694-7

certain initial value problems in previous proceedings by the authors of this paper and their colleagues [4, 5]. The fact that it is possible to obtain (19) from the original ODE set and the definition of squarification is important: the direct proof for the recursion between the images of the (augmented) initial vectors under SquTelMats is complete. The recursion in (19) suffices for finding the solution of an initial value problem by probabilistic evolution theory. In fact, the use of the vector recursion in (19) is more efficient than the matrix recursion between the squarified telescope matrices. On the other hand, it is also necessary to show that the vector recursion in (19) may be used in order to prove the matrix recursion between the squarified telescope matrices. This is done by proof by contradiction. Assuming that the solution to the matrix recursion is not unique, thus adding an $\mathbf{R}_j(\mathbf{a})$ matrix to each $\mathbf{S}_j(\mathbf{a})$, it is possible to find that $\mathbf{R}_j(\mathbf{a})$ matrices should all be zero matrices.

$$\begin{aligned}
&\mathbf{S}_{j+1}(\mathbf{a}) = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a}) \\
&\mathbf{S}_j(\mathbf{a}) \equiv \overline{\mathbf{S}}_j(\mathbf{a}) + \mathbf{R}_j(\mathbf{a}), \qquad \mathbf{R}_j(\mathbf{a})\,\mathbf{a} = 0, \\
&\overline{\mathbf{S}}_{j+1}(\mathbf{a}) = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \overline{\mathbf{S}}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \overline{\mathbf{S}}_{j-k}(\mathbf{a}) \\
&\mathbf{R}_{j+1}(\mathbf{a}) = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \overline{\mathbf{S}}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{R}_{j-k}(\mathbf{a}) \\
&\qquad j = 0, 1, 2, ... \qquad \overline{\mathbf{S}}_0 = \mathbf{I}_n, \qquad \mathbf{R}_0(\mathbf{a}) = \mathbf{0}
\end{aligned} \tag{20}$$

The recursion at the end of (20) is a linear recursion. Its solution may be performed by the following steps. Creating infinite sums at both sides of the recursion in (20),

$$\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{R}_{j+1}(\mathbf{a}) = \sum_{j=0}^{\infty} \frac{u^j}{j!} \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \overline{\mathbf{S}}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{R}_{j-k}(\mathbf{a}) \tag{21}$$

and then considering that the left side is the derivative of a certain entity,

$$\begin{aligned}
\frac{d}{du}\left(\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{R}_j(\mathbf{a})\right) &= \sum_{k=0}^{\infty} \frac{u^k}{k!} \lfloor\, \mathbf{F}, \overline{\mathbf{S}}_k(\mathbf{a})\,\mathbf{a} \,\rceil \sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{R}_j(\mathbf{a}) \\
\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{R}_j(\mathbf{a}) &= \exp\left(\sum_{k=0}^{\infty} \frac{u^k}{k!} \lfloor\, \mathbf{F}, \overline{\mathbf{S}}_k(\mathbf{a})\,\mathbf{a} \,\rceil\right) \mathbf{R}_0(\mathbf{a}) \\
&\mathbf{R}_j(\mathbf{a}) = \mathbf{0}, \qquad j = 0, 1, 2, ...
\end{aligned} \tag{22}$$

 ISBN: 978-84-617-8694-7

appears. The last equality of (22) shows that all $\mathbf{R}_j(\mathbf{a})$ must be zero since $\mathbf{R}_0(\mathbf{a})$ is $\mathbf{0}$. Vector recursion yields the matrix recursion.

$$\mathbf{S}_{j+1}(\mathbf{a})\,\mathbf{a} = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\,\mathbf{a}$$

$$\mathbf{S}_{j+1}(\mathbf{a}) = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})$$

$$j = 0, 1, 2, ... \qquad \mathbf{S}_0 = \mathbf{T}_0 = \mathbf{I}_n \tag{23}$$

Therefore, the matrix recursion is

$$\mathbf{S}_{j+1}(\mathbf{a}) = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})$$

$$j = 0, 1, 2, ... \qquad \mathbf{S}_0 = \mathbf{I}_n \tag{24}$$

and it may be used to calculate all squarified telescope matrices.

Another way to see that the recursion is valid is to start with the recursion and come back to the ODE. Multiplying both sides of (24) by $\mathbf{a}$ from right

$$\mathbf{S}_{j+1}(\mathbf{a})\,\mathbf{a} = \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\,\mathbf{a}$$

$$j = 0, 1, 2, ... \qquad \mathbf{S}_0\mathbf{a} = \mathbf{a} \tag{25}$$

and forming an infinite sum in both sides of (25),

$$\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_{j+1}(\mathbf{a})\mathbf{a} = \sum_{j=0}^{\infty} \frac{u^j}{j!} \sum_{k=0}^{j} \binom{j}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\,\mathbf{a} \tag{26}$$

may be obtained. Simplifying the factorials and rewriting the summation in the triangular region

$$\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_{j+1}(\mathbf{a})\mathbf{a} = \sum_{k=0}^{\infty} \sum_{j=k}^{\infty} \frac{u^j}{k!(j-k)!} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \mathbf{S}_{j-k}(\mathbf{a})\,\mathbf{a} \tag{27}$$

appears. Using Cauchy product rule in (27),

$$\sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_{j+1}(\mathbf{a})\mathbf{a} = \sum_{k=0}^{\infty} \frac{u^k}{k!} \lfloor\, \mathbf{F}, \mathbf{S}_k(\mathbf{a})\,\mathbf{a} \,\rceil\, \sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{S}_j(\mathbf{a})\mathbf{a} \tag{28}$$

 ISBN: 978-84-617-8694-7

is obtained. Using the linearity of squarification

$$\sum_{j=0}^{\infty}\frac{u^j}{j!}\mathbf{S}_{j+1}(\mathbf{a})\mathbf{a}=\left\lfloor\ \mathbf{F},\sum_{k=0}^{\infty}\frac{u^k}{k!}\mathbf{S}_k\left(\mathbf{a}\right)\mathbf{a}\ \right\rceil\sum_{j=0}^{\infty}\frac{u^j}{j!}\mathbf{S}_j(\mathbf{a})\mathbf{a} \tag{29}$$

appears. The next step is to see that the left hand side of (29) is the derivative of a term having $\mathbf{S}_j(\mathbf{a})$. Therefore,

$$\frac{d}{du}\left(\sum_{j=0}^{\infty}\frac{u^j}{j!}\mathbf{S}_j(\mathbf{a})\mathbf{a}\right)=\left\lfloor\ \mathbf{F},\sum_{k=0}^{\infty}\frac{u^k}{k!}\mathbf{S}_k\left(\mathbf{a}\right)\mathbf{a}\ \right\rceil\sum_{j=0}^{\infty}\frac{u^j}{j!}\mathbf{S}_j(\mathbf{a})\mathbf{a} \tag{30}$$

which is a matrix ODE. Making the following definition

$$\mathbf{g}(u)\equiv\sum_{j=0}^{\infty}\frac{u^j}{j!}\mathbf{S}_j(\mathbf{a})\mathbf{a} \tag{31}$$

(30) may be written in the compact form

$$\frac{d}{du}(\mathbf{g}(u))=\lfloor\ \mathbf{F},\mathbf{g}(u)\ \rceil\,\mathbf{g}(u) \tag{32}$$

and using the definition of squarification

$$\frac{d\mathbf{g}(u)}{du}=\mathbf{F}\mathbf{g}(u)^{\otimes 2},\quad \mathbf{g}(0)=\mathbf{a} \tag{33}$$

may be obtained. This was the original ODE. Consequently, it is also possible to show that the recursion is valid by starting with the recursion and finding out that it is a recursion of the matrices in the solution of the ODE in (33). It is possible to replace u by t using (4), to obtain

$$\overline{\mathbf{g}}(t)\equiv \mathrm{e}^{\beta t}\sum_{j=0}^{\infty}\frac{(\mathrm{e}^{\beta t}-1)^j}{j!}\mathbf{T}_j\mathbf{a}^{\otimes j+1} \tag{34}$$

which is the solution via telescope matrices.

3 Optimal Space Extension

In the vector form of the ODE, the matrix coefficient corresponding to the first degree terms is forced to be proportional to the identity matrix. If the proportionality constant is chosen as 0, the exponential term does not appear in the probabilistic evolution theory solution. In that case, the distinction between space extension and constancy adding space extension (CASE) disappears; space extension by itself suffices to form purely second degree multinomial right hand side functions. This special case is worth studying, because it gives a lot of information about what the most facilitative space extension may be. This section focuses on finding the most facilitative space extension where the proportionality constant corresponding to first degree terms (β) is 0.

 ISBN: 978-84-617-8694-7

3.1 Basis Set Utilization

A multivariate basis set is used for showing the multinomial right hand side functions. It is given as follows

$$\begin{aligned} u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n) &= x_1^{\ell_1} x_2^{\ell_2} x_3^{\ell_3} \ldots x_n^{\ell_n} \\ \ell_1 &= 0,\ldots,m_1 \\ \vdots &\qquad \vdots \\ \ell_n &= 0,\ldots,m_n \end{aligned} \tag{35}$$

where each function has n upper indices. The functions are linearly independent. Then, the ODE set with n equations and n unknowns may be shown in the form

$$\begin{aligned} \dot{x}_1(t) &= \sum_{\ell_1,\ldots,\ell_n} a_1^{(\ell_1,\ldots,\ell_n)} u^{(\ell_1,\ldots,\ell_n)}(x_1(t),\ldots,x_n(t)) \\ \dot{x}_2(t) &= \sum_{\ell_1,\ldots,\ell_n} a_2^{(\ell_1,\ldots,\ell_n)} u^{(\ell_1,\ldots,\ell_n)}(x_1(t),\ldots,x_n(t)) \\ \vdots &\qquad\qquad \vdots \\ \dot{x}_n(t) &= \sum_{\ell_1,\ldots,\ell_n} a_n^{(\ell_1,\ldots,\ell_n)} u^{(\ell_1,\ldots,\ell_n)}(x_1(t),\ldots,x_n(t)) \end{aligned} \tag{36}$$

where the right hand sides have n summations. The coefficients also have n upper indices. The lower indices of the coefficients show which equation a certain coefficient belongs to. The idea here is to show the ODE set in terms of the basis set and then use space extension to form purely second degree structures. The sought functions, the derivatives of which appear on the left hand side of (36), may also be shown in terms of the basis set with basis functions having one upper index being 1 and all others 0. The temporal derivatives of the basis functions are

$$\dot{u}^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n) = \frac{\partial u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n)}{\partial x_1}\dot{x}_1(t) + \cdots + \frac{\partial u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n)}{\partial x_n}\dot{x}_n(t) \tag{37}$$

where the derivatives with respect to sought functions are

$$\begin{aligned} \frac{\partial u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n)}{\partial x_1} &= \ell_1 x_1^{\ell_1-1}\left(x_2^{\ell_2}\ldots x_n^{\ell_n}\right) \\ \frac{\partial u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n)}{\partial x_2} &= x_1^{\ell_1}\ell_2 x_2^{\ell_2-1}\left(x_3^{\ell_3}\ldots x_n^{\ell_n}\right) \\ \vdots &\qquad\qquad \vdots \\ \frac{\partial u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n)}{\partial x_n} &= \left(x_1^{\ell_1}\ldots x_{n-1}^{\ell_{n-1}}\right)\ell_n x_n^{\ell_n-1}. \end{aligned} \tag{38}$$

 ISBN: 978-84-617-8694-7

Using (38) in (37), temporal derivatives of the basis functions appear as

$$\begin{aligned}\dot{u}^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n) &= \ell_1 u^{(\ell_1-1,\ell_2,\ell_3,\ldots,\ell_n)}(x_1,\ldots,x_n)\sum_{j_1,\ldots,j_n} a_1^{(j_1,\ldots,j_n)} u^{(j_1,\ldots,j_n)}(x_1,\ldots,x_n)\\ &+ \ell_2 u^{(\ell_1,\ell_2-1,\ell_3,\ldots,\ell_n)}(x_1,\ldots,x_n)\sum_{j_1,\ldots,j_n} a_2^{(j_1,\ldots,j_n)} u^{(j_1,\ldots,j_n)}(x_1,\ldots,x_n)\\ &+ \cdots\\ &+ \ell_n u^{(\ell_1,\ell_2,\ell_3,\ldots,\ell_n-1)}(x_1,\ldots,x_n)\sum_{j_1,\ldots,j_n} a_n^{(j_1,\ldots,j_n)} u^{(j_1,\ldots,j_n)}(x_1,\ldots,x_n)\ .\end{aligned} \tag{39}$$

This representation will be utilized when introducing new equations in space extension.

3.2 Basis Set with a Singularity

The philosophy stays the same when working with singularities. Consider the case where the basis set is

$$\begin{gathered}u^{(\ell_1,\ldots,\ell_n)}(x_1,\ldots,x_n) = x_1^{\ell_1}x_2^{\ell_2}x_3^{\ell_3}\ldots x_n^{\ell_n}\\ \ell_1 = 0,\ldots,m_1\\ \vdots \qquad\qquad \vdots\\ \ell_{i-1} = 0,\ldots,m_{i-1}\\ \ell_i = -s,\ldots,m_i\\ \ell_{i+1} = 0,\ldots,m_{i+1}\\ \vdots \qquad\qquad \vdots\\ \ell_n = 0,\ldots,m_n\end{gathered} \tag{40}$$

Then, (37), (38) and (39) are still valid.

3.3 Applications

A brute-force method based on the formulation above is formed and it is used for the solution of classical quartic anharmonic oscillator and gravitational two body problem. A computer program using Maxima language is formed. The program finds the optimal space extension of classical quartic anharmonic oscillator and it is adaptable to other systems. The application details will be given in the conference presentation.

 ISBN: 978-84-617-8694-7

4 Concluding Remarks

Recursion of squarification is one of the primary reasons why probabilistic evolution theory is powerful. This recursion was conjectured in a previous work by the authors and it was applied to different problems with success. The step by step direct proof of the recursion is given in this paper.

Also, a brute-force approach for making ODE sets with multinomial right hand side functions (with a degree greater than two) into an ODE set with purely second degree multinomial right hand side functions is proposed. It relies on finding the number of equations in all the possible space extensions and choosing the one with the smallest number of equations: therefore minimal number of equations is guaranteed.

Abstract

In this paper, we focus on the recently developed decomposition method we have called "Tridiagonal Folmat Enhanced Multivariance Products Representation (TFEM PR)". This method uses recently defined mathematical objects called folded matrix (folmat) and folded vector (folvec), and, is designed to reduce the computation cost by avoiding the decomposition on each way (direction, dimension). This method has now been applied on digital image sequence data like digital videos in our recent works including the present one. The method mentioned here is applicable to many areas such as digital image, digital image sequence, signal processing and also compressing problems due to the convenience of its nature.

Key words: Tridiagonal Folmat Enhanced Multivariance Products Representation (TFEMPR), Folded Vectors, Folded Matrices, Folded Arrays, Multiway Arrays, Decomposition, Factorization, Digital Image Processing

MSC 2000: 94A08, 41Axx, 49M27

1 Introduction

Multiway array decomposition is a commonly focused issue in image processing, neuroscience (like on FMRI data), data science, mathematics etc. Tucker Decomposition [1, 2],Lathauwer's Multilinear Singular Value Decomposition [3–6], PARAFAC, SVD are amongst the well-known decomposition methods [7–10]. One of commonly used decomposition method is High Dimensional Model Representation (HDMR) which has been proposed by Sobol [11] and developed by Rabitz and Demiralp [12–15] beside some others whose works can be found in scientific literature. Enhanced Multivariance Products Representation (EMPR) is another decomposition method arisen from reinforcing HDMR with supports. This method is developed by Demiralp and his group [16–20] during HDMR implementations on the image reconstruction problem.

Basically EMPR of a matrix which is two way array is explicitly given as,

$$\mathbf{A} = a_0 \mathbf{u}\mathbf{v}^T + \mathbf{a_1}\mathbf{v}^T + \mathbf{u}\mathbf{a_2}^T + \mathbf{A_{1,2}}. \tag{1}$$

The representation includes $2^2 = 4$ components; respectively constant component (a_0), the univariate components respectively in direction of row and column ($\mathbf{a_1}$ and $\mathbf{a_2}$) and

 ISBN: 978-84-617-8694-7

bivariate component which is also called as remainder term($\mathbf{A_{1,2}}$). Here, $\mathbf{u}$ and $\mathbf{v}$ are known as the support vectors which enhance the multivariance of each term to 2th order multivariance. The representation turns out to be High Dimensional Model Representation (HDMR) of the matrix under consideration by taking each support equal to a normalized vector whose all elements are same. We do not intend to give details about the determination of EMPR components. Details can be found in papers [16–20].

Remainder term has gained more importance during the image reconstruction problems in consequence of being located major information of image in. To extract this information, EMPR is applied remainder term recursively. When whole information is extracted from remainder, a factorization is obtained. This factorization and decomposition method is developed by Demiralp and his group and called as Tridiagonal Matrix Enhanced Multivariance Products Representation (TMEMPR) [21–23].

The paper is organised as follows. In section 2 we give a short explanation about folded matrices proposed by Demiralp [24,25]. Tridiagonal Folmat Enhanced Multivariance Product Representation (TFEMPR), which is the main method of this work, will be given in third section [26–28]. Fourth section includes the implementations about the method for real data and Peak Signal to Noise Ratio (PSNR) concept which is commonly used and known in literature as a measurer of reconstruction quality. The concluding remarks will be summarized in the final section.

2 Folded Matrices (Folmats)

Vectors and matrices in ordinary linear algebra are respectively considered as one-way and two-way arrays in literature. Matrices have two spaces (row and column space) and also have mapping characters. Folded matrices (Folmats) are defined for making analogy between matrices and multiway arrays and adapt the features of a matrix such as inner product, norm, outer product etc. to multiway arrays. The folarr, folmat and folvec concepts have been proposed by Demiralp [24–28] to facilitate the multiway array analyses.

2.1 Certain Basic Issues in Folmat Definitions

A folmat is in fact a matrix whose rows and columns are folded. In its present format, it can be defined as follows

$$\mathbf{A}_{G_L;G_R} \equiv \left[A_{(i);(j)} \right]_{\forall(i)\in G_L\downarrow}^{\forall(j)\in G_R\rightarrow}, \qquad L \equiv I_1 \times \cdots \times I_m, \quad R \equiv J_1 \times \cdots \times J_n, \tag{2}$$

where (i) and (j) stand for the following tuples

$$(i) \equiv (i_1, ..., i_m), \quad m = 1, 2, 3, ... \qquad (j) \equiv (j_1, ..., j_n), \quad n = 1, 2, 3, ... \tag{3}$$

The general elements of these tuples, i_k and j_ℓ are assumed to take integer values between 1 and I_k inclusive, and, 1 and J_ℓ inclusive respectively. As long as all I_ks are independent of the elements of the m-tuple (i), this implies that the domain of (i) is an orthogonal multidimensional grid whose kth edge contains I_k number of nodes located at the integer values. Same thing also remains valid for the other tuple (j) whose domain is also an orthogonal grid and its ℓth edge contains J_ℓ number of nodes located at the integer values as long as J_ℓs are all independent of the elements of (j).

If we denote the abovementioned grids whose general nodes are (i) and (j) respectively by G_L and G_R then their definitions can be given as follows

$$G_L \equiv \mathbb{Z}_{I_1}^+ \times \cdots \times \mathbb{Z}_{I_m}^+, \qquad G_R \equiv \mathbb{Z}_{J_1}^+ \times \cdots \times \mathbb{Z}_{J_n}^+ \tag{4}$$

 ISBN: 978-84-617-8694-7

where, for a positive integer I, $\mathbb{Z}_I^+$ stands for the finite set composed of first I number of positive integers. These grids can also be introduced by using following open set representations.

$$G_L \equiv \left\{ (i_1, ..., i_m) | \, i_p \in \mathbb{Z}_{I_p}^+, p \in \mathbb{Z}_m^+ \right\}, \qquad G_R \equiv \left\{ (j_1, ..., j_n) | \, j_p \in \mathbb{Z}_{J_p}^+, p \in \mathbb{Z}_n^+ \right\}. \tag{5}$$

As can be noticed immediately, the grids G_L and G_R are sets of m-tuples and n-tuples respectively such that the number of their elements are $I_1 \cdots I_m$ and $J_1 \cdots J_n$ respectively. In these definitions, m and n denotes the dimensions of the Cartesian spaces where G_L and G_R lay respectively. These numbers somehow correspond to the folding orders of rows and columns of an ordinary linear algebraic matrix. Hence we call m and n "row folding level" and "column folding level" respectively. Since they are fundamental properties of a folmat, they should be explicitly or implicitly declared somewhere in the definition of a folmat. We prefer to use types of grids for these declarations. The type definition for a grid is analogue to the type definitions of ordinary linear algebraic matrices. In this connection, the types of the grids G_L and G_R are denoted by $I_1 \times \cdots \times I_m$ and $J_1 \times \cdots \times J_n$ respectively. The folding levels are hidden in these representations such that they are equal to the number of "times" symbol plus 1. Hence, the types define the grids uniquely without leaving any doubt.

There are two ways to declare the type of a grid: (i) to use it as the subscript of the grid symbol G, like $G_{I_1 \times \cdots \times I_m}$ or $G_{J_1 \times \cdots \times J_n}$; (ii) to declare it as the value of a variable like in G_L, $L \equiv I_1 \times \cdots \times I_m$ or in G_R, $R \equiv J_1 \times \cdots \times J_n$. The second option has been used in (2) for typographical reasons. The subscripts L and R in grid symbols have been used to recall the statements "left grid type" and "right grid type" respectively.

We can also now define a "Global Grid" as the ordered pair of these newly defined grids through $G \equiv (G_L, G_R)$

In ordinary linear algebra a matrix can be given by its general term in the form like $a_{i,j}$ where the comma is generally exchanged with the space character by many authors since comma symbols in indices of continuum mechanical objects can be used to denote some kind of derivatives (covariant, and/or contravariant). Continuum mechanics is a quite specific external area for our work, hence we can exclude the danger of confusion in the comma utilization. Beyond this, the comma utilization accentuates the fact that the indices are truely corresponding to separate entities. On the other hand comma separation fits very well to tuple representation. i and j in $a_{i,j}$ correspond to the row and column locations respectively in an ascending ordering starting from 1. Hence we may also call i and j "row locator" and "column locator" respectively. Analogously, the m-tuple (i) and the n-tuple (j) can be considered the row and column locators of the folmat defined in (2) since their values taken from G_L and G_R specify somehow rowwise and columnwise locations. However, the use of grids in the domains of the indices somehow brings a geometrical structuring, "folding" to the issue. Hence we respectively call (i) and (j) "Folded Row Locator" and "Folded Column Locator".

At the right hand side of (2) the left and right brackets have been used to imply that the encompassed entity is a two way array whose rows and columns are folded to more than one ways. The symbol encompassed by the brackets stands for the general element of the multiway array at the focus. This is somehow a matrix, however it is composed of folded rows and columns each of which is denoted by a tuple like m-tuple (i) and n-tuple (j). That is, (i) and (j) stand for pointing to the folded rows and columns of this generalized or geometrically structured matrix.

Since we have used comma as an element separator in tuples we have used semicolon to distinguish these so-called folded row and column locators. The down and right arrows

 ISBN: 978-84-617-8694-7

in the right hand side of (2) imply the downward positionings (folded rows) and rightward positionings (folded columns) respectively. The inclusions of the tuples in the relevant grids have also been explicitly shown in the notation of (2) as sub and super indices. Beyond these the "forall" symbol accentuates that the left and right brackets encompass an array for all elements the relevant grids.

We use these notations for simplicity. We use folmats to get rid of very high computational complexity of each-way-separation-style decomposition of multiway arrays. Semicolon enables binary decomposition by separating indices into two groups. As can be noticed immediately, the important components in the folmat definition are the row and column folding levels and the grids for locating a specific element of folmat. These are for positionings of course and the other but very important entities are the elements of the folmat.

2.2 Folvec Definition

If we specifically choose $n = 0$ in the above definitions then we obtain no grid for columns. In other word, the folmat under consideration becomes an entity which has just a single folded column. We call these entities "folvec"s within an analogy to the matrix-vector discrimination in ordinary linear algebra. Folvec is in fact a special form of folmat. The general term of a folded vector (folvec) can be represented by $a_{(i);}$ where (i) belongs to the grid G_t, $t \equiv I_1 \times \cdots \times I_m$ where t stands for a variable name as any variable name can be used as long as its value declares the type of the relevant grid and unless there appears any confusion matter. The shorthand notation for this is $\mathbf{a}_{G_t;}$, $t \equiv I_1 \times \cdots \times I_m$. The further specification $m = 1$ corresponds to the vector of ordinary linear algebra.

The explicit folvec definition can be given as follows

$$\mathbf{a}_{G_t;} = \left[a_{(i);} \right]_{\forall (i) \in G_t \downarrow}, \qquad t \equiv I_1 \times \cdots \times I_m \tag{6}$$

where the folding level of this folvec is m as we can deduce from the type of the relevant grid.

3 Tridiagonal Folmat Enhanced Multivariance Products Representation (TFEMPR)

Tridiagonal Folmat Enhanced Multivariance Products Representation (TFEMPR) which is one of the recently developed decomposition methods for multiway arrays has the all features of binary decompositions due to the usage of folmat concept [26–28] (also see Sect. 2). TFEMPR method can be considered as higher order analogues of matrix decomposition.

First we will apply EMPR to a general folmat. We can write EMPR of a folmat as,

$$\mathbf{A}_{G_L;G_R} \;=\; a_0 \mathbf{U}_{G_L;} \mathbf{V}^T_{G_R;} + \mathbf{a}^{(1)}_{G_L;} \mathbf{V}^T_{G_R;} + \mathbf{U}_{G_L;} {\mathbf{a}^{(2)}_{G_R;}}^T + \mathbf{A}^{(1,2)}_{G_L;G_R} \tag{7}$$

where $\mathbf{A}_{G_L;G_R}$ stands for a folmat and G_L is called left grid which includes row space indices, G_R is called right grid including column space indices. The subscript L and R stand for two type variables and take the values $I_1 \times \cdots \times I_m$ and $J_1 \times \cdots \times J_n$ respectively, and, Is and Js are the upper limits of the corresponding indices. Beyond these we denote the sizes of grids. G_L and G_R, by μ and ν respectively. These parameters are defined through the equalities, $\mu \equiv I_1 \cdots I_m$, $\nu \equiv J_1 \cdots J_n$. The representation in (7) consists of four terms respectively, the constant term, the term towards left grid, the term towards

 ISBN: 978-84-617-8694-7

right grid and the remainder term ($\mathbf{A}^{(1,2)}_{G_L;G_R}$). $\mathbf{U}_{G_L;}$ and $\mathbf{V}_{G_R;}$ are preselected support folded vectors (folvecs) respectively on left and right grids.

In (7) there are four components to be determined, a_0, $\mathbf{a}^{(1)}_{G_L;}$, $\mathbf{a}^{(2)}_{G_R;}$, $\mathbf{A}^{(1,2)}_{G_L;G_R}$. It is necessary to provide two preconditions for determining the components. First condition is the unit norm standardization and can be given as follows for the left and right grid support folvecs

$$\mathbf{U}^T_{G_L;}\mathbf{U}_{G_L;} = \sum_{(i)\in G_L} U^2_{(i)} = 1, \qquad \mathbf{V}^T_{G_R;}\mathbf{V}_{G_R;} = \sum_{(j)\in G_R} V^2_{(j)} = 1 \tag{8}$$

Support folded vectors should satisfy these unit norm standardization. The second constraints on the components are the vanishing conditions:

$$\mathbf{U}^T_{G_L;}\mathbf{a}^{(1)}_{G_L;} = 0, \qquad {\mathbf{a}^{(2)}_{G_R;}}^T\mathbf{V}_{G_R;} = 0 \tag{9}$$

These conditions point out the orthogonality of support folvec and the relevant component through the same grid. And also $\mathbf{U}_{G_L;}$ should be in the left null space of $\mathbf{A}^{(1,2)}_{G_L;G_R}$ and $\mathbf{V}_{G_R;}$ is in the right null space of $\mathbf{A}^{(1,2)}_{G_L;G_R}$, that is,

$$\mathbf{U}^T_{G_L;}\mathbf{A}^{(1,2)}_{G_L;G_R} = \mathbf{0}_{;G_R}, \qquad \mathbf{A}^{(1,2)}_{G_L;G_R}\mathbf{V}_{G_R;} = \mathbf{0}_{G_L;} \tag{10}$$

Under these conditions we obtain components as follows.

$$a_0 = \mathbf{U}^T_{G_L;}\mathbf{A}_{G_L;G_R}\mathbf{V}_{G_R;} \tag{11}$$

$$\mathbf{a}^{(1)}_{G_L;} = \left(\mathbf{I}_{G_L;G_L} - \mathbf{U}_{G_L;}\mathbf{U}^T_{G_L;}\right)\mathbf{A}_{G_L;G_R}\mathbf{V}_{G_R;} \tag{12}$$

$$\mathbf{a}^{(2)}_{G_R;} = \left(\mathbf{I}_{G_R;G_R} - \mathbf{V}_{G_R;}\mathbf{V}^T_{G_L;}\right)\mathbf{A}^T_{G_L;G_R}\mathbf{U}_{G_L;} \tag{13}$$

$$\mathbf{A}^{(1,2)}_{G_L;G_R} = \left(\mathbf{I}_{G_L;G_L} - \mathbf{U}_{G_L;}\mathbf{U}^T_{G_L;}\right)\mathbf{A}_{G_L;G_R}\left(\mathbf{I}_{G_R;G_R} - \mathbf{V}_{G_R;}\mathbf{V}^T_{G_L;}\right) \tag{14}$$

Details about determination components of the representation (7) can be seen in [26–28]. From now on operations to be taken is for building recursive structure to give TFEMPR.

We use the following definitions to get the first step of the recursion we desire to construct

$$\mathbf{A}^{(0)}_{G_L;G_R} \equiv \mathbf{A}_{G_L;G_R}, \qquad \mathbf{A}^{(1)}_{G_L;G_R} \equiv \mathbf{A}^{(1,2)}_{G_L;G_R}, \qquad \mathbf{U}^{(1)}_{G_L;} = \mathbf{U}_{G_L;}, \qquad \mathbf{V}^{(1)}_{G_R;} = \mathbf{V}_{G_R;}. \tag{15}$$

For each recursion step we can get rid of the folvec components by defining new two support folvecs for rowwise and columnwise directioning such that each of which are orthogonal to its initially given counterpart

$$\mathbf{U}^{(2)}_{G_L;} = \frac{1}{\left\|\mathbf{a}^{(1)}_{G_L;}\right\|}\mathbf{a}^{(1)}_{G_L;}, \qquad \mathbf{V}^{(2)}_{G_R;} = \frac{1}{\left\|\mathbf{a}^{(2)}_{G_R;}\right\|}\mathbf{a}^{(2)}_{G_R;} \tag{16}$$

We also use the following definitions for simplicty

$$\alpha_1 = a_0, \qquad \beta_1 = \left\|\mathbf{a}^{(1)}_{G_L;}\right\|, \qquad \gamma_1 = \left\|\mathbf{a}^{(2)}_{G_R;}\right\| \tag{17}$$

Now, (7) is rewritten by using these definitions

$$\mathbf{A}^{(0)}_{G_L;G_R} = \alpha_1\mathbf{U}_{G_L;}{}^{(1)}{\mathbf{V}^{(1)}_{G_R;}}^T + \beta_1\mathbf{U}_{G_L;}{}^{(2)}{\mathbf{V}^{(1)}_{G_R;}}^T + \gamma_1\mathbf{U}_{G_L;}{}^{(1)}{\mathbf{V}^{(2)}_{G_R;}}^T + \mathbf{A}^{(1)}_{G_L;G_R} \tag{18}$$

 ISBN: 978-84-617-8694-7

which can be considered as the first step of a recursion.

The goal of the recursion we want to construct is to get rid of remainder term. To this end, in each step, we apply EMPR to the remainder term under the support folarrs which have been obtained one step before. This leads us to the following general recursion

$$\mathbf{A}^{(\ell)}_{G_L;G_R} = \alpha_{\ell+1}\mathbf{U}^{(\ell+1)}_{G_L;}\mathbf{V}^{(\ell+1)^T}_{G_R;} + \beta_{\ell+1}\mathbf{U}^{(\ell+2)}_{G_L;}\mathbf{V}^{(\ell+1)^T}_{G_R;} + \gamma_{\ell+1}\mathbf{U}^{(\ell+1)}_{G_L;}\mathbf{V}^{(\ell+2)^T}_{G_R;} + \mathbf{A}^{(\ell+1)}_{G_L;G_R} \tag{19}$$

The rank of the remainder term decreases by 1 in each step as ℓ increases. So this recursion stops when ℓ takes (at most) the value of $\min\{\mu,\nu\} = \min\{IJ, K\}$ where, in that specific case, remainder identically vanishes. Hence, this is a finite recursion. So we can write the following exact relation

$$\begin{aligned}\mathbf{A}_{G_L;G_R} &= \sum_{\ell=1}^{n_\alpha}\alpha_\ell \mathbf{U}_{G_L;}{}^{(\ell)}\mathbf{V}^{(\ell)}_{G_R;}{}^{T} + \sum_{\ell=1}^{n_\beta}\beta_\ell \mathbf{U}_{G_L;}{}^{(\ell+1)}\mathbf{V}^{(\ell)}_{G_R;}{}^{T} \\ &\quad + \sum_{\ell=1}^{n_\gamma}\gamma_\ell \mathbf{U}_{G_L;}{}^{(\ell)}\mathbf{V}^{(\ell+1)^T}_{G_R;} = \overline{\mathbf{U}}_{G_L;G_L}\boldsymbol{\Sigma}_{\mathbf{G_L};\mathbf{G_R}}\overline{\mathbf{V}}_{G_R;G_R}{}^{T}.\end{aligned} \tag{20}$$

where

$$\begin{aligned} &n_\alpha \equiv \min\{\mu,\nu\} \equiv \min\{IJ, K\}, \\ &n_\beta \equiv \begin{cases} n_\alpha & \mu < \nu \\ n_\alpha - 1 & \mu \geq \nu \end{cases} \qquad n_\gamma \equiv \begin{cases} n_\alpha & \mu > \nu \\ n_\alpha - 1 & \mu \leq \nu \end{cases} \end{aligned} \tag{21}$$

Here the entities of $\overline{\mathbf{U}}_{G_L;G_L}$ and $\overline{\mathbf{V}}_{G_R;G_R}$ are orthonormal folmats. Because the entities of these folmats are normalized support folvecs and orthogonal to each other we can write

$$\overline{\mathbf{U}}_{G_L;G_L} \equiv \left[\begin{array}{ccc}\mathbf{U}^{(1)}_{G_L;} & \ldots & \mathbf{U}^{(\mu)}_{G_L;}\end{array}\right], \qquad \overline{\mathbf{V}}_{G_R;G_R} \equiv \left[\begin{array}{ccc}\mathbf{V}^{(1)}_{G_R;} & \ldots & \mathbf{V}^{(\nu)}_{G_R;}\end{array}\right] \tag{22}$$

where the superscripts(μ) and (ν) respectively represents the sizes of the left and right grids and therefore equal to IJ and K respectively. We have used capital letters for denoting the left and right supports since the left one is folded vector hence has somehow a hidden matrix nature even though the right one is in fact a truly ordinary vector.

$\boldsymbol{\Sigma}_{\mu;\nu}$ consists of αs, βs and γs calculated at each step of recursion. These parameters represent the contribution of outer products. Under assumption of $\mu < \nu$ we can write

$$\boldsymbol{\Sigma}_{\mu;\nu} = \left[\begin{array}{ccccccccc} \alpha_1 & \gamma_1 & 0 & \cdots & \cdots & 0 & 0 & \cdots & 0 \\ \beta_1 & \alpha_2 & \gamma_2 & \cdots & \cdots & 0 & 0 & \cdots & 0 \\ 0 & \beta_2 & \alpha_3 & \ddots & \vdots & \vdots & \vdots & \cdots & \vdots \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots & \vdots & \cdots & \vdots \\ \vdots & \vdots & \vdots & \ddots & \ddots & \gamma_{\mu-1} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & \cdots & \beta_{\mu-1} & \alpha_\mu & \gamma_\mu & \cdots & 0 \end{array}\right] \tag{23}$$

By using α, β and γ parameters we can define quality measurers at each recursion step to measure how good the approximation is. Quality measurer definition is given as follows for the ℓth step of the recursion

$$\sigma_\ell = \sum_{i=1}^{\ell}\frac{\alpha_i^2 + \beta_i^2 + \gamma_i^2}{\|\mathbf{A}\|^2} \tag{24}$$

 ISBN: 978-84-617-8694-7

4 Numerical Implementations

In this section TFEMPR is applied on a digital image sequence and results given by quality measurer of the method which comes from method's nature and by PSNR which is commonly used in literature as a measurer on these issues. Illustrative numerical examples given previous works, you can see in [27].

4.1 Peak Signal to Noise Ratio (PSNR)

PSNR is a widely used parameter to measure how efficient the approximation to a signal sequence is. It is defined as follows

$$PSNR \equiv 10 \log_{10} \left(\frac{\max_{(G_L,G_R)} \left(\chi^2_{i,j;k} \right)}{MSE} \right), \quad MSE \equiv \frac{1}{\mu\nu} \left\| \mathbf{A}_{G_L;G_R} - \mathbf{A}^{TFEMPR}_{G_L;G_R} \right\|^2 \quad (25)$$

where μ and ν stand for the number of elements in G_L and G_R respectively while $\mathbf{A}_{G_L;G_R}$ and $\mathbf{A}^{TFEMPR}_{G_L;G_R}$ denote the target folmat and its TFEMPR approximant under consideration.

If we assume that $\mu < \nu$ then we can use (20) and its truncated form for N recursive step truncation and write the following equality

$$\mathbf{A}_{G_L;G_R} - \mathbf{A}^{TFEMPR}_{G_L;G_R} = \sum_{\ell=N+1}^{n_\alpha} \alpha_\ell \mathbf{U}^{(\ell)}_{G_L;} \mathbf{V}^{(\ell)\ T}_{G_R;} + \sum_{\ell=N+1}^{n_\beta} \beta_\ell \mathbf{U}^{(\ell+1)}_{G_L;} \mathbf{V}^{(\ell)\ T}_{G_R;} + \sum_{\ell=N+1}^{n_\gamma} \gamma_\ell \mathbf{U}^{(\ell)}_{G_L;} \mathbf{V}^{(\ell+1)T}_{G_R;} \quad (26)$$

which implies

$$\left\| \mathbf{A}_{G_L;G_R} - \mathbf{A}^{TFEMPR}_{G_L;G_R} \right\| = \sum_{\ell=N+1}^{n_\alpha} \alpha^2_\ell + \sum_{\ell=N+1}^{n_\beta} \beta^2_\ell + \sum_{\ell=N+1}^{n_\gamma} \gamma^2_\ell \quad (27)$$

and therefore

$$MSE = \frac{1}{mn} \left(\sum_{\ell=N+1}^{n_\alpha} \alpha^2_\ell + \sum_{\ell=N+1}^{n_\beta} \beta^2_\ell + \sum_{\ell=N+1}^{n_\gamma} \gamma^2_\ell \right). \quad (28)$$

where n_α, n_β, n_γ are defined as before. As we can see the number of the additive terms decreases as N grows such that MSE vanishes at the limit where none of the α, β, γ appears in the sums.

4.2 Real Data Implementations: Digital Video

In this part we will present application of TFEMPR on the real data obtained from digital videos. Grayscale video data will be taken into consideration as implementation in this part and the results will be provided numerically in table and visually in figures.

Grayscale video is basically taken into consideration as a three-way array. Two of these ways represent respectively the horizontal and vertical positions of each pixel in frames and the third way represents the location of the frame in the frame sequence. We can imagine video as a rectangular prism which is obtained by aligning the images consecutively. Despite the highly many components of digital video data, we consider only these three ways; height, width and the location of frame in these implementations. We will work on the grayscale video data first for simplicity.

 ISBN: 978-84-617-8694-7

The grayscale video data taken for TFEMPR implementation here is a $240 \times 320 \times 36$ type multiway array. We use the video file under the name "xylophone.mp4" which is a default image file in Matlab. Movement of a mallet during playing xylophone is tapen in this video. The results are given for the 18th frame, which produces the middle instantaneous display of video, to compare approximation and exact digital video in this paper. The resulting frames are illustrated such that the left frame represents approximation while the right frame characterizes the exact frame.

Figure 1 depicts the 18th approximation and exact frame of digital video for the 5 recursion steps under the use of Normalised Directional Average Support (NDAS). For 5 steps of TFEMPR, background is almost clear, but the mallet and hand are fuzzy due to their moving object characters.

Figure 2 presents the result for 10 recursion steps under the same conditions. Background is sharper, mallet and hand are still unsharp, but much sharper than Figure 1. The moving objects obtained for 20 recursion steps are visibly clear in Figure 3, and, as the last comparison in Figure 4, moving objects become clear and also background is sharp as in the exact frame. These results indicate that TFEMPR works pretty good on background reconstruction and video processing problems.

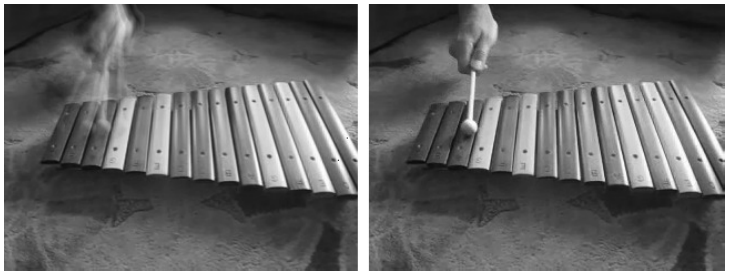

Figure 1: The result of 18th frame for 5 Recursion Step with NDAS

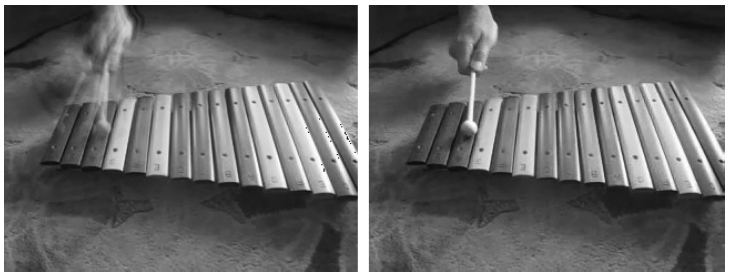

Figure 2: The result of 18th frame for 10 Recursion Step with NDAS

 ISBN: 978-84-617-8694-7

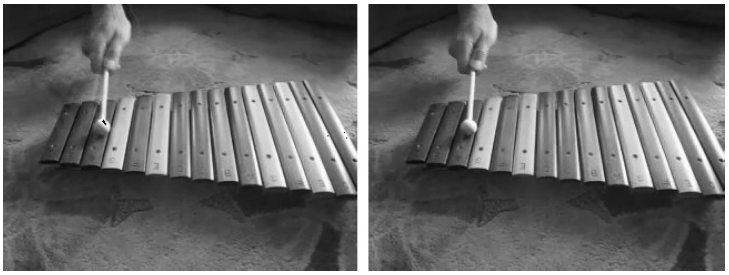

Figure 3: The result of 18th frame for 20 Recursion Step with NDAS

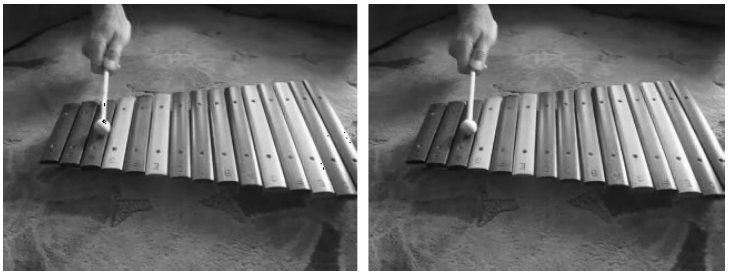

Figure 4: The result of 18th frame for 30 Recursion Step with NDAS

Quality measurers and PSNR results of TFEMPR method is tabulated in Table 1. It is clearly seen in Table 1 that approximation quality and PSNR get better as long as the number of recursion step increases.

Table 1: TFEMPR Quality Measurers and PSNR values for Grayscale Video Implementation

RecSN	5	10	20	30
σ	0,9949	0,9972	0,9990	0,9998
PSNR	30,2559	32,9384	37,5787	43,8265

TFEMPR is also applicable to multilinear arrays having more-than-three ways. Especially for digital video data we can increase dimension via some parameters. One of these is the color parameters which is well-known as RGB. RGB is abbreviation for the names of its main color components, Red, Green and Blue, each of which takes values from nonnegative integers in $\mathbb{Z}_{255}$ (the subset of integers composed of first natural numbers between 0 and 255 inclusive). All possible colors obtained from the mixtures of these colors and a color is represented by three values, for example red is $[255, 0, 0]$

We can increase the number of ways or dimensions by adding the audio, brightness, opaqueness components and so on. Audio data can be represented in 8 bit or 16 bit format and the data range is the interval $[-1, 1]$. Audio data is a sequence of digital signals in fact, as long as digital audio devices and relevant processors can be used. According to today's technology analog sound signals can also be processed as if they are digital data. However to this end a widely-used-in-computers method Pulse Code Modulation (PCM)

 ISBN: 978-84-617-8694-7

is utilized. Due to finite bit formats these parameters take also discrete and limited values too. So these may be the source of error accumulations for the TFEMPR at small level truncations. This can be cured perhaps by using modular arithmetic even though we have not attempted to do so yet.

5 Concluding Remarks

In this work we have focused on the decomposition of multiway arrays to outer products lower multivariance multiway arrays. To this end we have used the folmat and folvec concepts we have recently developed. The scheme has been designed in such a way that the additive components of decompositions are binary (two-factor) outer products. We have given illustrative and also confirmative implementations. We are planning to publish a more comprehensive report on these types digital image sequence decompositions pretty soon.

Abstract

This work takes into consideration a single variable function to be approximated. Then making a series of transformations it is represented as a contour integral where the kernel fuction is expressed in terms of two variables. This new representation allows us to apply Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR) method onto it and provides us with a good approximation of the kernel function which then is integrated to obtain an approximation for the initial function in question. Because of the overall conceptual approach to the problem through this article, applications which are done are intended to be given during the oral representation.

Key words: Univariate Approximation, multivariate approximation, EMPR, TKEMPR, Contour integrals
MSC 2000: 00A69, 15A12, 65D15

1 Introduction

The intended work uses the TKEMPR method which decomposes a linear integral operator on univariate functions by using high dimensional modelling with the basic idea to use Enhanced Multivariance Products Representation (EMPR) technique created and conjectured by Demiralp. The representation used here is not based on the general EMPR and is a specific EMPR construction for bivariate function decomposition. We call this decomposition Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR). It

 ISBN: 978-84-617-8694-7

uses EMPR [1-18] bivariate function decomposition consecutively such that in each step the remainder term is expanded to again a bivariate EMPR but with different support functions. To make a function approximation using TKEMPR, first we represent our function in terms of contour integration, then following a procedure which allows us to obtain the kernel to be used in TKEMPR [19-24], we obtain a two variable form and finally use it to approximate our function.

2 Basics of EMPR

Enhanced Multivariance Products Representation (EMPR) is a decomposition method recently developed by M. Demiralp. For a given multivariate function $f(x_1, ..., x_N)$ it can be written as

$$\begin{aligned} f(x_1, ..., x_N) \;=\; & f_0 \prod_{i=1}^{N} s_i(x_i) + \sum_{j=1}^{N} f_j(x_j) \prod_{i=1, i\neq j}^{N} s_i(x_i) \\ & + \sum_{\substack{j_1, j_2 = 1 \\ j_1 < j_2}}^{N} f_{j_1, j_2}(x_{j_1}, x_{j_2}) \prod_{i=1, i\neq j_1, j_2}^{N} s_i(x_i) \\ & + \sum_{\substack{j_1, j_2, j_3 = 1 \\ j_1 < j_2 < j_3}}^{N} f_{j_1, j_2, j_3}(x_{j_1}, x_{j_2}, x_{j_3}) \prod_{i=1, i\neq j_1, j_2, j_3}^{N} s_i(x_i) \\ & + \cdots \end{aligned} \tag{1}$$

where f_js stand for the EMPR components ordered in ascending multivariance. The univariate functions denoted by s are called support functions and finally

$$x_i \in [\, a_i, b_i \,], \qquad i = 1, ..., N \tag{2}$$

where the interval may or may not be a finite one. There are 2^N unknown components given in a single equation. Hence some constraints apply to uniquely determine EMPR components. These constraints are constructed via vanishing integrals over the EMPR components except f_0. To define these integrals univariate weight functions the product of which defines a single multivariate weight function, are used. These univariate weight function integrals over the relevant intervals given above are set equal to 1 to facilitate further analysis; these constraints are not necessary but provide the averaging property to the weight function.

$$\int_{a_i}^{b_i} dx_i W_i(x_i) = 1, \qquad i = 1, ..., N \tag{3}$$

 ISBN: 978-84-617-8694-7

$$W(x_1, ..., x_N) \equiv \prod_{i=1}^{N} W_i(x_i). \tag{4}$$

nd the vanishing conditions can be written as follows

$$\int_{a_i}^{b_i} dx_i W_i(x_i) f_{j_1,...,j_k}(x_{j_1}, ..., x_{j_k}) = 0,$$
$$i \in \{j_1, ..., j_k\}, \qquad k = 1, ..., N \tag{5}$$

By using them after integrating both sides of the EMPR definitions over certain chosen x independent variables over their intervals and under the product of the corresponding univariate weight factors produces the unique values of the EMPR components.

EMPR is an extended form of the High Dimensional Model Representation (HDMR) first proposed by Sobol with all unit intervals $[0, 1]$ and unit constant weight functions whose values are all one throughout the relevant intervals. This form can be called Sobol's plain HDMR. A lot of new extensions have been developed in Demiralp's group studies. Amongst them, the most important one is the extension to EMPR which becomes HDMR when all univariate support functions are taken equal to just unit constant function over the relevant interval.

3 EMPR for Bivariate Functions

When matrices have been taken as target entities a new decomposition method called "Tridiagonal Matrix Enhanced Multivariance Products Representation ", has been developed. The elements of a matrix being located via two indices which take positive integer values, independently from the other index values, this allows us to construct, so-called "Discrete Bivariate EMPR, over the matrices. Following this step we have to search for a method to apply this construction to corresponding bivariate functions. To this end we can write the following equality for a given bivariate function $f(x, y)$

$$f(x, y) = f_0 u(x) v(y) + f_1(x) v(y) + f_2(y) u(x) + f_{1,2}(x, y) \tag{6}$$

where u and v are the support functions. In this construction we will use the unit interval $[0, 1]$ for both independent variables, x and y without any loss of generality Beyond that the weight factors are defined as follows

$$W_1(x) \equiv 1, \quad W_2(y) \equiv 1, \qquad x, y \in [0, 1]. \tag{7}$$

The support functions are assumed to have unit norms over the above intervals and under the above weights

$$\int_0^1 dx u(x)^2 = 1, \qquad \int_0^1 dy v(y)^2 = 1 \tag{8}$$

 ISBN: 978-84-617-8694-7

For this case the vanishing conditions should be taken as constraints imposed on $f_1(x)$, $f_2(y)$ and, $f_{1,2}(x,y)$. They can be written as follows

$$\int_0^1 dx f_1(x)u(x) = 0 \tag{9}$$

$$\int_0^1 dy f_2(y)v(y) = 0 \tag{10}$$

$$\int_0^1 dx f_{1,2}(x,y)u(x) = 0 \tag{11}$$

$$\int_0^1 dy f_{1,2}(x,y)v(y) = 0 \tag{12}$$

These equations allow us to evaluate the EMPR terms uniquely as

$$f_0 = \int_0^1 dx \int_0^1 dy f(x,y)\, u(x)\, v(y) \tag{13}$$

$$f_1(x) = \int_0^1 dy f(x,y)\, v(y) - f_0 u(x) \tag{14}$$

$$f_2(y) = \int_0^1 dx f(x,y)\, u(x) - f_0 v(y) \tag{15}$$

$$\begin{aligned} f_{1,2}(x,y) &= f(x,y) - f_0 u(x)\, v(y) \\ &\quad -f_1(x)\, v(y) - f_2(y)\, u(x). \end{aligned} \tag{16}$$

These four equations can be used to obtain more concise expressions for EMPR terms and EMPR's itself. To this end we can define the following integral operators through their actions on a given arbitrary function g which may be taken depending on x and y as we need

$$\begin{aligned} \widehat{P}g(x) &\equiv u(x) \int_0^1 d\xi u(\xi)\, g(\xi) \\ \widehat{Q}g(y) &\equiv v(y) \int_0^1 d\eta v(\eta)\, g(\eta) \end{aligned} \tag{17}$$

 ISBN: 978-84-617-8694-7

This enables us to write the following equalities

$$f_0 u(x)v(y) = \widehat{P}\widehat{Q}f(x,y) \tag{18a}$$

$$f_1(x)v(y) = \left(\widehat{I}_x - \widehat{P}\right)\widehat{Q}f(x,y) \tag{18b}$$

$$f_2(y)u(x) = \widehat{P}\left(\widehat{I}_y - \widehat{Q}\right)f(x,y) \tag{18c}$$

$$f_{1,2}(x,y) = \left(\widehat{I}_x - \widehat{P}\right)\left(\widehat{I}_y - \widehat{Q}\right)f(x,y) \tag{18d}$$

and finally

$$\begin{aligned} f(x,y) &= \widehat{P}\widehat{Q}f(x,y) + \left(\widehat{I}_x - \widehat{P}\right)\widehat{Q}f(x,y) + \widehat{P}\left(\widehat{I}_y - \widehat{Q}\right)f(x,y) \\ &\quad + \left(\widehat{I}_x - \widehat{P}\right)\left(\widehat{I}_y - \widehat{Q}\right)f(x,y) \end{aligned} \tag{19}$$

where $\widehat{I}_x$ and $\widehat{I}_y$ stand for the unit operators in the spaces of univariate functions depending on x and y respectively.

From (19) the EMPR is an orthogonal decomposition of the target function into two components laying in the space spanned by $u(x)$ and in its complementary space and another two components laying in the space spanned by $v(y)$ and in its complementary space. Therefore "EMPR is a projective decomposition projecting onto the spaces spanned by support functions and their complementary spaces.

Finally to reach (TKEMPR) construct which consists of using EMPR bivariate function decomposition consecutively such that in each step the remainder term is expanded to again a bivariate EMPR but with different support functions.

4 Contour Integration

A function $f(x)$ can be represented in terms of a contour integration over an interval $[0,1]$ which may in fact easily be converted to any finite interval $[a,b]$ without loss of generality

$$f(x) = \frac{1}{2\pi i}\oint_C d\xi \frac{f(\xi)}{\xi - x}, \quad x \in [0,1] \tag{20}$$

$$C \to \xi = x + e^{i\theta}$$
$$r > 0, \quad \theta \in [0, 2\pi)$$

 ISBN: 978-84-617-8694-7

The corresponding integration interval $[0, 2\pi]$ can be divided into two halves.

$$\begin{aligned} f(x) &= \frac{1}{2\pi}\int_0^{2\pi} d\theta f\left(x + re^{i\theta}\right) \\ &= \frac{1}{2\pi}\int_0^{\pi} d\theta f\left(x + re^{i\theta}\right) + \frac{1}{2\pi}\int_{\pi}^{2\pi} d\theta f\left(x + re^{i\theta}\right) \end{aligned} \tag{21}$$

Via a simple change of variable, the second half can be written in terms of the first one and the overall expression is expressed in a more compact manner.

$$f(x) = \int_{\pi}^{2\pi} d\theta f\left(x + re^{i\theta}\right) \overset{2\pi-\theta}{\rightarrow} \int_0^{\pi} d\theta f\left(x + re^{-i\theta}\right) \tag{22}$$

$$f(x) = \frac{1}{\pi}\int_0^{\pi} d\theta \frac{1}{2}\left[f\left(x + re^{i\theta}\right) + f\left(x + re^{-i\theta}\right)\right] \tag{23}$$

The function with two different arguments can be written as below, by representing their real and imaginary components separately.

$$\begin{aligned} f\left(x + re^{i\theta}\right) &= f_g + if_s \\ f\left(x + re^{-i\theta}\right) &= f_g - if_s \end{aligned} \tag{24}$$

Thus f_g can be written as

$$f_g = \frac{1}{2}\left[f\left(x + re^{i\theta}\right) + f\left(x + re^{-i\theta}\right)\right] \tag{25}$$

By making a change of variable $\theta \rightarrow \pi\theta$ we obtain

$$f(x) = \int_0^{1} d\theta \frac{1}{2}\left[f\left(x + re^{i\pi\theta}\right) + f\left(x + re^{-i\pi\theta}\right)\right] \tag{26}$$

Now, let us make a definition which corresponds to Heaviside step function

$$1_f \equiv \begin{cases} 1 & 0 \leq \theta \leq 1 \\ 0 & other \end{cases} \tag{27}$$

Correspondingly we obtain the expression below.

$$\mathcal{I}1_f = \int_0^{1} d\theta K(\theta, x) 1_f \tag{28}$$

The final form of the kernel to be used in TKEMPR can be written as follows:

$$K(\theta, x) = \frac{1}{2}\left[f\left(x + re^{i\theta}\right) + f\left(x + re^{-i\theta}\right)\right] \tag{29}$$

 ISBN: 978-84-617-8694-7

5 Method

Now that we have constructed a bivariate form for a function $f(x)$ needed to be used it in (TKEMPR), we have to adapt it to the proper form mentioned in bivariate (EMPR)

$$K(\theta, x) = K_0 u(\theta) v(x) + K_1(\theta) v(x) + K_2(x) u(\theta) + K_{1,2}(\theta, x) \tag{30}$$

where u and v are support functions which will be chosen as 1 for the initial step. θ and x are taken on the unit interval as mentioned before. The same will be valid for the weight functions also. Now when we proceed for the (EMPR) we will obtain

$$K_{1,2}(\theta, x) = K(\theta, x) - K_0 u(\theta) v(x) - K_1(\theta) v(x) - K_2(x) u(\theta). \tag{31}$$

At this stage, this is again a bivariate function which needs our attention in terms of (EMPR). This process can be repeated as many times as we need and each time we add a new step a better approximation will be obtained.

A final step after making sufficient number of iterations to approximate the bivariate function $K_{1,2}(\theta, x)$ is to integrate this latter over the interval $[0, 1]$ to obtain back the intended approximation of our original function $f(x)$

$$f(x) = \int_0^1 d\theta K(\theta, x) \tag{32}$$

6 Conclusion

The decomposition obtained by applying (TKEMPR) to a univariate function after having obtained a bivariate counterpart of it via contour integration provides us with a good approximation to the bivariate kernel. Finally if we integrate this kernel over the unit interval we obtain an approximation to the original function. An intended future work consists of applying the same method to the remainder term of a Taylor expansion of a function, expressed in integral form and obtain a better approximation enforced by the Taylor expansion itself, after necessary transformations

Abstract

This paper analyzes how optimal therapies are affected when the time evolution of cancer is envisaged as an additional element determining malignancy. We introduce a time valuation factor that measures the increase of malignancy associated to the quick development of the disease and the persistent negative effects of initial drug doses. Taking as reference a mathematical model of Chronic Myeloid Leukemia (CML), we solve and simulate the model with and without the new time valuation factor. We conclude that the consideration of this factor allows more efficient optimal therapies to be designed.

1 Introduction

The design of optimal therapies to fight cancer is an important research field in today's Biomathematics (see [5] and [7]). Basically, an optimal therapy problem is a control problem consisting of: first, a set of difference/differential equations describing the biological dynamics of the disease under the specified treatment; and, second, an objective function measuring the malignancy of the treated cancer. By solving this optimal control problem it is possible to find the optimal therapy, i.e, the drug doses that minimize the malignancy of the treated disease. Until now, the mathematical formulation adopted to measure the

 ISBN: 978-84-617-8694-7

malignancy of cancer exclusively considers as malignancy elements the tumor size (given by the number of cancer cells) and the administered drug concentration measured in a given instant. From this assumption, a given number of cancer cells and a given drug dosage always cause the same malignancy, independently of the moment of time in which these magnitudes have been observed/administered. However, from the biomedical perspective, it is a well established fact that the faster the cancer grows the worse the cancer is. To take into account this malignancy factor, ignored by the literature, would entail assigning higher malignancy to cancer cells at the beginning of the cancer and lower malignancy to those appeared afterwards, that is, a time valuation factor weighting cancer size. On the other hand, it is also widely accepted by biomedical researchers and practitioners that drugs are not totally eliminated by patients and remain in their bodies, and that, additionally, the apparition of drug resistance is a direct consequence of early and persistent treatments. Subsequently, a given drug dose involves more negative effects if it is administered at the beginning of treatment than at the end, and then, to evaluate malignancy associated to drug doses, it would also be necessary to consider a time valuation factor assigning higher malignancy to the initial drug doses. We will study these questions for a standard optimal therapy problem. To do so, after formulating a discrete version of the model of Chronic Myeloid Leukemia (CML) proposed in [1], we introduce a time valuation factor that allows the malignancy elements associated to time and commented on above to be considered. We analyze its consequences with the purpose of clarifying whether or not this time dependent malignancy factor modifies the optimal therapies and the population of normal and cancer cells, and quantifying these modifications.

2 A Mathematical Model of Treated CML

In [1] a continuous time model was introduced to analyze the global dynamics of CML. This model incorporates the existence of nonlinear effects of imatinib treatment over a fixed period of time. Here, in order to gain consistency in the analysis, comparisons with real data and simulations, we propose a discrete time version of that model incorporating a daily schedule in the dynamics, since in the empirical literature on CML and in clinical practice the parameters and variables involved in the model are measured in per day values. We start by considering two different populations: that of hematopoietic stem cells (HSC), and that of differentiated cells (DC). In addition, each of these populations is divided into normal cells and cancer cells. Then, at time instant t, it is possible to distinguish between four different populations: Normal HSC, denoted by $x_0(t)$; cancer HSC, denoted by $y_0(t)$; normal DC, represented by $x_1(t)$; and cancer DC, denoted by $y_1(t)$. The evolution over time of CML is described by a system of difference equations which incorporates the most relevant biomedical facts. First, the populations of all the considered types of cells naturally decrease at fairly constant rates. Upon this fact, let d_0, g_0, d and g be, respectively, the per

 ISBN: 978-84-617-8694-7

day decrease rates of normal HSC, cancer HSC, normal DC, and cancer DC. In addition, since DC are produced not only by proliferation of DC but also by HSC, it is necessary to distinguish between these two mechanisms of increase in the number of DC for both normal and cancer cells. In particular, let d_2 and g_2 be the per day rates at which normal and cancer DC proliferate and originate, respectively, normal and cancer DC; and let r and q denote the rates at which normal and cancer HSC produce normal and cancer DC, in this order. Finally, through the self-renewal process, normal and cancer HSC produce similar cells by division. Then, we let normal and cancer HSC divide at rates n and m per day, respectively. In this self-renewing activity, there underlies a homeostatic process that controls the proliferation of HSC. In this respect, the division of normal HSC x_0 is directed by homeostasis, depending on the total level of HSC $(x_0 + y_0)$, and given by

$$\Phi(x_0 + y_0) = 1 - \frac{x_0 + y_0}{K},$$

where K represents the carrying capacity of bone marrow. In the same way, homeostasis for cancer cells y_0 is governed by the function

$$\Psi(x_0 + \alpha y_0) = 1 - \frac{x_0 + \alpha y_0}{K},$$

where $\alpha \in (0, 1]$ measures the fall in the homeostatic efficiency due to the disease (see [5], chapter 9, for an analysis of this fall).

Drug treatment is described by a positive time-dependent function $u(t)$. This function $u(t)$ captures the drug dose, and given that there is a dosage limitation due to the drug's toxicity, $u(t)$ is supposed to be bounded in $[0, u_{max}]$ for all t in $[0, T]$, where T denotes the treatment duration, measured in days. The effects of imatinib treatment are introduced through nonlinear functions, which affect the lifetime of cancer cells, and imply their maximum effect only for an intolerable dosage. In [1], different scenarios were studied depending on the distinct effects of imatinib on the dynamics. That work concluded that the disease completely remits only when imatinib causes an additional mortality of cancer HSC, represented by the function $h(u)$, which is a nonlinear increasing function satisfying $h(0) = 0$ (this means that cancer HSC decline at rate g_0 without treatment), and h attains the maximum value 1 for an intolerable dosage. Since this is the case with highest plausibility from the biomedical point of view, we limit our study to this situation. The behavior under treatment of CML is therefore described by the following system of difference equations:

$$\left.\begin{array}{l} x_0(t+1) = x_0(t) + n\Phi(x_0(t) + y_0(t))x_0(t) - d_0 x_0(t) \\ x_1(t+1) = x_1(t) + r x_0(t) - (d - d_2)x_1(t) \\ y_0(t+1) = y_0(t) + m\Psi(x_0(t) + \alpha y_0(t))y_0 - g_0 y_0(t) - \beta h(u(t))y_0(t) \\ y_1(t+1) = y_1(t) + q y_0(t) - (g - g_2)y_1(t) \\ t = 0, 1, \ldots, T \end{array}\right\},$$

where $\beta \in [0, 1]$ is a parameters measuring the proportion for additional decline in cancer HSC.

 ISBN: 978-84-617-8694-7

3 The Optimal Therapy Problem

As in any optimal therapy problem, the objective is to find the therapy $u^*(t)$ minimizing the malignancy of the disease under treatment. Concerning the objective function measuring malignancy, [1] considers quadratic terms representing the nonlinear costs of the treatment and the malignancy of the cancer HSC and DC levels; however, it does not entail any valuation of time. Here we formulate the objective function

$$N(u) = \sum_{t=0}^{T} \rho^t [u^2(t) + y_0^2(t) + y_1^2(t)] + \rho^{T+1}[y_0^2(T+1) + y_1^2(T+1)],$$

where $\rho \in (0, 1]$ is a parameter measuring the increase of malignancy of early cancer development and drug administration. More specifically, we consider an objective function which incorporates a final addend measuring the malignancy at the end of the treatment, and that implies lower malignancy as time passes. In this respect, and given that a higher malignancy is associated with both early cancer growth and early drug administration, we introduce a time valuation malignancy factor, decreasing over time, that affects the objective function in the optimal therapy problem as a whole. This is consistent with the observed evidence for treated CML, obviously the only existing situation of the disease for which data exist. Indeed, most empirical survival analyses show decreasing rates of mortality as treated cancer persists, i.e., higher mortality rates at the beginning of the disease than in subsequent dates. This decreasing rate of mortality over time would also suggest introducing a time valuation factor weighting cancer malignancy, and implying decreasing malignancy as cancer persists. Summing up, we propose to solve and simulate the optimal therapy problem

$$\min \sum_{t=0}^{T} \rho^t [u^2(t) + y_0^2(t) + y_1^2(t)] + \rho^{T+1}[y_0^2(T+1) + y_1^2(T+1)]$$

$$s.t. \begin{cases} x_0(t+1) = x_0(t) + n(1 - \frac{x_0(t)+y_0(t)}{K})x_0(t) - d_0 x_0(t) \\ x_1(t+1) = x_1(t) + r x_0(t) - (d - d_2)x_1(t) \\ y_0(t+1) = y_0(t) + m(1 - \frac{x_0(t)+\alpha y_0(t)}{K})y_0 - g_0 y_0(t) - \beta h(u(t))y_0(t) \\ y_1(t+1) = y_1(t) + q y_0(t) - (g - g_2)y_1(t) \\ x_0(t) \geq 0, x_1(t) \geq 0, y_0(t) \geq 0, y_1(t) \geq 0, u_{max} \geq u(t) \geq 0 \\ t = 0, 1, \ldots, T \\ x_0(0), x_1(0), y_0(0), y_1(0) \quad \text{initially given} \end{cases} \tag{1}$$

 ISBN: 978-84-617-8694-7

4 Solving and Calibrating the Model

We investigate the role played by the malignancy parameter ρ in the control problem. As usually happens with optimal control problems in Biomedicine, the optimal therapy problem (1) does not have an explicit algebraic solution. We therefore numerically solve the problem taking account of the necessary conditions that the variables must satisfy. These necessary conditions involve the system of difference equations for the state variables describing the dynamics of CML and with the associated initial conditions, the system of difference equations for the Lagrange multipliers with the corresponding final conditions, and the nonlinear equation for the control variable (see [4]).

The numerical solution is obtained running an iterative procedure: we start with an initial guess for $u(t)$ at $0 \leq t \leq T$; with this initial iterant, we compute the corresponding values of the state and Lagrange multiplier variables; finally, from these approximations, we compute a new control variable. We iterate this procedure until convergence to the optimal control $u^*(t)$.

We implement this numerical method for a practical case. To this end, it is previously necessary to calibrate the parameters, i.e., to assign a value to the parameters in the system of difference equations providing the solution. This calibration is carried out on the basis of the available recent biomedical data ([2], [3], [6], [8], [9]). After the calibration, the optimal therapy is simulated for two referential situations, namely with and without the proposed time valuation factor.

5 Results and Conclusions

Regarding the consequences of the consideration of a time valuation factor capturing the higher malignancy associated to early growth of cancer and drug administration, our results are unequivocal: *this consideration allows more efficient therapies to be designed.* More specifically, when this time valuation factor is considered, the optimal drug doses are considerably lower, and do not entail significant increases in the number of cancer cells or in the disease duration.

Abstract

In this work we study some numerical properties of the continuous Newton's method, the continuous version of the classical Newton's method for solving nonlinear equations $p(z) = 0$. In fact, continuous Newton's method is an initial value problem whose solutions flow to a root of the equation. We show the influence of the multiplicity of the roots of the considered equation in the Jacobian matrix related to the problem. In addition we study some modifications of the continuous Newton's method that allow us to increase the velocity of the convergence of the solutions towards the roots of $p(z) = 0$.

Key words: Continuous Newton's method; nonlinear equations; fixed points.
MSC 2000: 65J15

1 Introduction

In this work we are concerned with some numerical properties of the initial value problem

$$z(0) = z_0, \quad z'(t) = -\frac{p(z(t))}{p'(z(t))}, \tag{1}$$

where $z : \mathbb{R} \to \mathbb{C}$ and $p(z)$ is a given complex function. This problem is called continuous Newton's method and it was initially posed in the late 1980s (see [4], [6], [7]). Later, the method was popularized by Neuberger [5].

Note that the classical Newton's method for solving a nonlinear equation $p(z) = 0$, can be seen as an Euler step to the differential equation (1). Even more, a general Euler approximation of the differential equation (1) with step size $h > 0$ gives rise to the damped Newton's method

$$z_{n+1} = z_n - h\frac{p(z_n)}{p'(z_n)}. \tag{2}$$

 ISBN: 978-84-617-8694-7

This relationship between the continuous and discrete Newton's method has been analyzed by Jacobsen et al. ([3]). Actually, they have studied the basins of attraction of the roots for methods (2) and they have realized that their fractal structure shrinks away when $h \to 0$. This fact has been also pointed out by Epureanu and Greenside ([1]). In addition, in [3] other ODE solvers, like Runge-Kutta methods or Adams-Bashforth methods have been considered. The influence of the step size in the fractal dimension of the basin boundaries is the same than in the Euler's case. However, higher-order approximations for solving ODEs did not necessarily produce root-finding methods with a good numerical efficiency. In [2] the relationship between the step size and the order of convergence is particularly considered. For a constant step size, these iterative root-finding methods have a low order of convergence (linear) but a high computational cost. For a non-constant step size, a plethora of root-finding methods can be constructed. In particular, the famous Chebyshev-Halley family of methods can be constructed in this way.

2 Modified continuous Newton's method

Neuberger ([5]) used the following improved version of continuous Newton's method for obtaining roots of a nonconstant complex polynomial p. For a given $z_0 \in \mathbb{C}$, the target is to get a continuous function $z : \mathbb{R} \to \mathbb{C}$ such that

$$z(0) = z_0, \quad p(z)'(t) = -p(z(t)),\ t \in \mathbb{R}. \tag{3}$$

Neuberger characterized the convergence of continuous Newton's method to the roots of p.

In this paper we consider the modified continuous Newton's method

$$\omega(0) = \omega_0, \quad p(\omega)'(t) = -kp(\omega(t)), \quad k > 0. \tag{4}$$

Our aim is to extend the results given by Neuberger and to analyze the influence of the parameter k in the velocity of convergence of the flow to the solutions. In fact, we can state that if ω is a solution of (4), then $p(\omega(t)) = p(\omega_0)e^{-kt}$.

For each $k > 0$, let us introduce the set $\mathcal{Q}_k$ of functions $\omega : \mathbb{R} \to \mathbb{C}$ which solve the differential equation (4). If $\omega \in \mathcal{Q}_k$, then $u = \lim_{t\to\infty} \omega(t)$ exists and $p(u) = 0$. In addition, we can deduce that the modified continuous Newton's method has the same properties than the classical Neuberger's problem (3).

3 Fixed points and equilibrium solutions

The fixed points (x^*, y^*) of a system of differential equations

$$\begin{cases} x'(t) &= f(x(t), y(t)), \\ y'(t) &= g(x(t), y(t)), \end{cases} \tag{5}$$

 ISBN: 978-84-617-8694-7

represent equilibrium solutions of the problem, since if $x(t) = x^*$ and $y(t) = y^*$ initially, then $x(t) = x^*$ and $y(t) = y^*$ for all time. We are interested in the study of the equilibria of the modified continuous Newton's method (4). Actually, if we make $z = x + iy$ we obtain a system of differential equations (5) where

$$f(x,y) = \mathbb{R}e\left(-\frac{p(x+iy)}{p'(x+iy)}\right), \quad g(x,y) = \mathbb{I}m\left(-\frac{p(x+iy)}{p'(x+iy)}\right). \tag{6}$$

Our first result characterizes the equilibria of (5) and establishes their local dynamical behavior in terms of the corresponding Jacobian matrices.

Theorem 1 *Let $z^* = x^* + iy^*$ be a zero with multiplicity m of a differentiable enough function $p(z)$. Then (x^*, y^*) is an asymptotically stable fixed point of the system (5) with f and g given by (6). In addition, if we denote $F(x,y)$ to the vector field $F(x,y) = (f(x,y), g(x,y))$, we have that the Jacobian matrix of $F(x,y)$ at (x^*, y^*) is*

$$\operatorname{Jac} F(x^*, y^*) = \begin{pmatrix} -k/m & 0 \\ 0 & -k/m \end{pmatrix}. \tag{7}$$

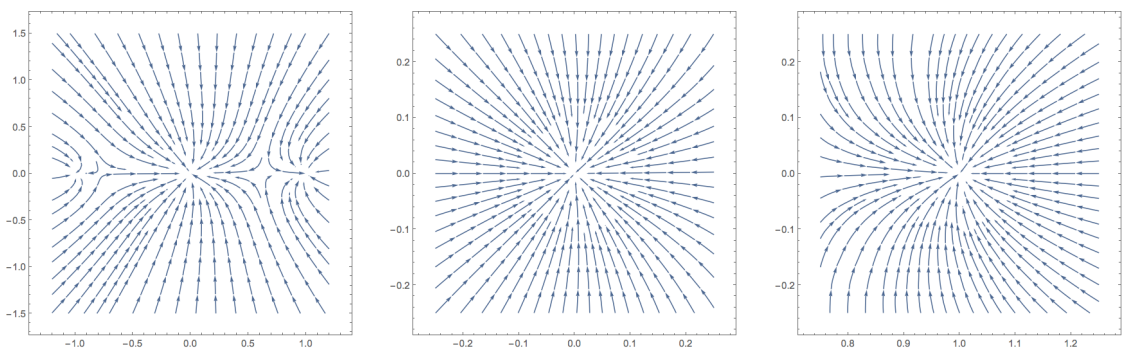

Figure 1: On the left, phase portrait of the continuous Newton's method applied to the polynomial $p(z) = z^3(z-1)^2(z+1)$. The other two figures are details around the points $(0,0)$ and $(1,0)$ respectively.

Remark 1 *Note that* $\operatorname{Jac} F(x^*, y^*)$ *is a diagonal matrix with a double eigenvalue of $\lambda = -k/m$. So from a local point of view, (x^*, y^*) behaves as a shrink star node whose typical phase portrait is shown in Figure 1. In fact, when the trajectories $(x(t), y(t))$ are close enough to the equilibrium point (x^*, y^*), these trajectories behaves as the functions*

$$\begin{cases} x(t) &= x^* + C_1 e^{-kt/m} \\ y(t) &= y^* + C_2 e^{-kt/m}. \end{cases}$$

 ISBN: 978-84-617-8694-7

So the convergence of the trajectories to the equilibrium point is slower when the multiplicity m increases. However the convergence of the trajectories to the equilibrium point is faster when the parameter k increases.

Abstract

The aim of this paper is to study evolution of transmembrane potencial on the cardiac cell under different rates of stimulation. For modeling this potential, the Fenton-Karma model was applied. It is a phenomenological model with three degree of freedom that corresponds to nondimensional transmembrane potencial and gating variables for regulation of inward and outward ion currents. Moreover, as a novelty, the model was forced by stimulus with shape of half sinus period. For solving the equations the explicit Runge-Kutta method was used. As the main aim of the paper it is shown that that the Fenton-Karma model is showing regular as well as irregular motion; periodic and also chaotic patterns are detected using bifurcation diagrams and 0-1 test for chaos.

1 Introduction

The cardiac electrophysiology is the result of complex processes occurring on the heart cell membranes, which aim to ensure the proper progression of cardiac action potential inherent in heart muscle. Understanding of this process is very important for prevention of heart failure, incompatible with life, such as ventricular fibrillation.

The Fenton-Karma model (FK3V) is commonly used to describe a simplified model of the heart and electrophysiology. Studies that uses this model can be generally divided into several groups. Studies dealing with the determination of model parameters to better replicate the outputs obtained by using physiological models or experimental data, studies

 ISBN: 978-84-617-8694-7

that uses FK3V model to study the electrophysiology of the heart and studies that examine the characteristics of the model FK3V itself.

The first group can include for example the study [7], which describes a procedure for finding such parameters FK3V model to its restitution characteristics correspond restitution characteristics of Courtemanche-Ramirez Nattel model of atrial tissue. In [6], the authors then edited the parameters of detailed and simplified (FK3V) model to fit for five clinical data of patients undergoing ablation therapy.

Termination of fibrillation is studied in [9]. Their objective was to numerical validation the experimental techniques for terminating fibrillation presented in [8]. In his work, they found that synchronized defibrillation can create a low-energy alternative to traditional defibrillation. In [1] the authors studied electrophysiological and dynamic mechanism of spiral waves break up. The authors found several alternans unstable modes with different growth rates, frequencies and spatial structures. In a study [2], the authors examined the behavior of fibers in a computing FK3V monodomain anisotropic model of re-entrant ventricular fibrillation.

The main aim of this paper is the research of dynamical properties of the FK3V model in dependence of the stimulation frequency; moreover regular as well as chaotic moments were observed.

2 FK3V model

FK3V model is ionic model of cardiac action potencial which is based on the Luo-Rudy I model. For reproducing action potencial it uses three variables u, v and w. Variable u represent nondimensional transmembrane potential (so that $u = 0$ and $u = 1$ are the rest and peak voltages, respectively) Transmembrane potential changing depending on ionic currents according to equation:

$$\dot{u} = J_{stim} - J_{fi} - J_{so} - J_{si}$$

where J_{fi} (accountable for depolarization of the membrane), J_{so} (accountable for repolarization of the membrane) and J_{si} (balances J_{so} during the plateau phase) are cross-membrane currents named fast inward (fi), slow outward (so) and slow inward (si) that roughly corresponds to sodium, potassium and calcium ion currents respectively. But because they do not represent quantitatively measured currents, but only their activation, inactivation, and reactivation it is preferred to call these currents as fast and slow inward, and slow outward, rather than Na, Ca, and K as a reminder of these simplification. J_{stim} indicates externally applied current. In this study is external current composition of pulses created by first half period of sinus function followed by zero function. J_{stim} is therefore defined by equation:

$$J_{stim} = \begin{cases} 0.48\sin(t - n(c+1)) & t \in < n(c+1), n(c+1)+1 > \quad n \in \mathbb{N} \cup \{0\} \\ 0 & t \notin < n(c+1), n(c+1)+1 > \quad n \in \mathbb{N} \cup \{0\}. \end{cases}$$

 ISBN: 978-84-617-8694-7

Where c denotes length of time interval between pulses. Dot over a variable denotes derivative with respect to time.
Cross membrane currents are given by

$$J_{fi}(u;v) = \Theta(u-u_c)(1-u)(u-u_c)\frac{-v}{\tau_d},$$

$$J_{so}(u) = \Theta(u_c-u)\frac{u}{\tau_0} + \Theta(u-u_c)\frac{1}{\tau_r},$$

$$J_{si}(u;w) = \frac{(1+\tanh\left[k(u-u_c^{si})\right])}{2}\frac{-w}{\tau_{si}},$$

where $\Theta(x)$ is the Heaviside function which replaced the gating functions $h_\infty(V)$, $m_\infty(V)$, $j_\infty(V)$, and $f_\infty(V)$, in the Beeler-Reuter or Luo-Rudy-I models. Function

$$\frac{(1+\tanh\left[k(u-u_c^{si})\right])}{2}$$

is than smooth function that replaced $d_\infty(V)$. to provide good fit of APD restitution curves.
Another two variables v and w used in the model are gating variables which regulates inactivation of J_{fi} and J_{so} takes the following form:

$$\dot{v} = \Theta(u_c-u)(1-v)\frac{1}{\tau_v^-(u)} - \Theta(u-u_c)v\frac{1}{\tau_v^+},$$

$$\dot{w} = \Theta(u_c-u)(1-w)\frac{1}{\tau_w^-} - \Theta(u-u_c)w\frac{1}{\tau_w^+},$$

$\tau_v(u)$ is function for defining time constants for two voltage ranges ($u_v < u < u_c$ and $u < u_v$) and is introduced for proper reproducing CV restitution curve. It controls reactivation of J_{fi} and is given by equation

$$\tau_v^-(u) = \Theta(u-u_v)\tau_{v_1}^- + \Theta(u_v-u)\tau_{v_2}^-$$

The model contains several constants, which are used for fitting the output curves into requested shape, time constants τ_r, τ_{si}, τ_0 ... and threshold potentials u_c, u_c^{si} and u_v.
The original paper [3] describes four different sets of parameters to fit for different dataset.

- BR: obtained by stimuli of Beeler-Reuter model with standard parameter values.
- MBR: obtained by stimuli of modified Beeler-Reuter model with speeded up calcium kinetic.
- MLBR-I: stimuli of Luo-Ruby-I model with speeded up calcium kinetic.

 ISBN: 978-84-617-8694-7

- GP: experimental data extracted by Girouard et al. from measuring membrane potentials on the epicardial surface of left Ventricle of a guinea pig.

Table 1: Original published parameters of FK3V model [3] for BR parameters set, $k = 10$

Parameter	**Description**	**unit**	**value**
τ_d	setting influence J_{fi} for $u > u_c$	ms	0.25
τ_r	setting influence J_{so} for $u > u_c$	ms	33
τ_{si}	setting influence $J_s i$ on $\dot{u}$	ms	30
τ_0	setting decrease u to 0 for $u < u_c$	ms	12.5
τ_v^+	setting decrease v to 0 for $u > u_c$	ms	3.33
$\tau_{v_1}^-$	setting value for $\tau_v^-(u)$ for $u > u_v$	ms	1250
$\tau_{v_2}^-$	setting value for $\tau_v^-(u)$ for $u < u_v$	ms	19.6
τ_w^+	setting decrease w to 0 for $u > u_c$	ms	870
τ_w^-	setting increase w to 1 for $u < u_c$	ms	41
u_c	depolarization threshold	-	0.13
u_v	threshold for activation $\tau_{v_1}^-$ or $\tau_{v_2}^-$	-	0.04
u_c^{si}	threshold for opening J_{si}	-	0.85

3 Main results

In this work, the BR parameter set was used. In individual simulations, the heart cell was irritated with the half-sinus shaped current pulses with amplitude 0.48 (twice as needed to cause irritation) and duration 1 ms. The individual stimulation pulses were separated by the delay c (see equation defining J_{stim} current). Computations was done for stimulation delays from 10 to 300 ms with step of 5 ms. Each simulation was done for time from 0 to 5×10^5 ms. From the last 20 % of results was consequently created a phase diagram for each simulated frequency and bifurcation diagram from the entire simulated frequency spectrum.

Chaotic behavior of the model was observed on stimulation delays from 10 to 85 ms (see Figures 1 and 2). This behavior can also be seen in bifurcation diagrams in Figures 4 and 5. Next, regular responses to stimulation impulses are observable on delays from 85 to 300 ms and this model output is shown in Figure 3 and also in bifurcation diagrams in Figures 4 and 5.

 ISBN: 978-84-617-8694-7

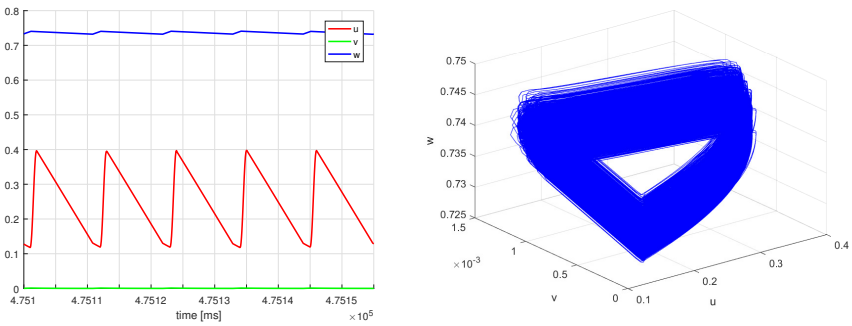

Figure 1: Time responses of u, v, w (left) and phase diagram (right) of the FK3V model for $c = 10$ ms.

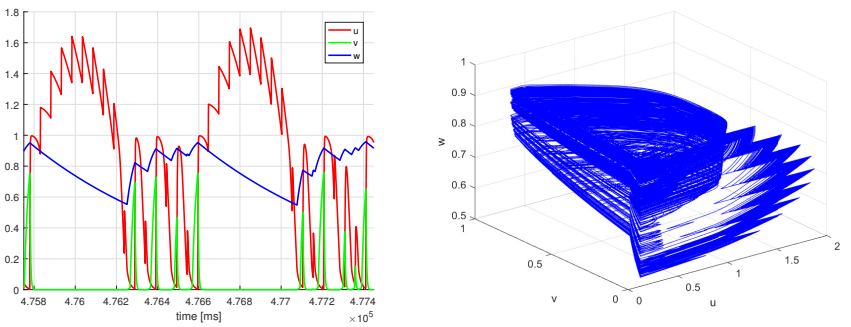

Figure 2: Time responses of u, v, w (left) and phase diagram (right) of the FK3V model for $c = 50$ ms.

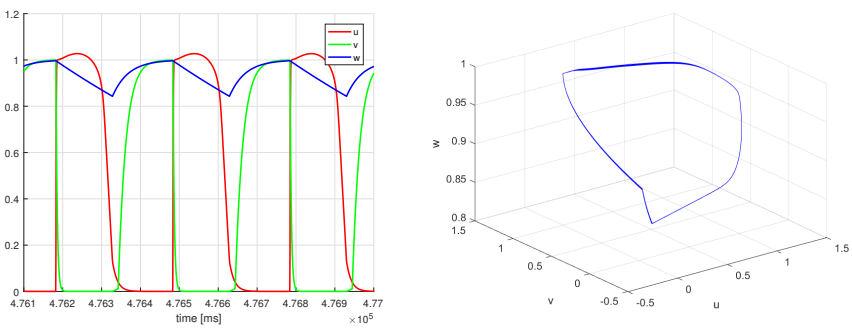

Figure 3: Time responses of u, v, w (left) and phase diagram (right) of the FK3V model for $c = 300$ ms

 ISBN: 978-84-617-8694-7

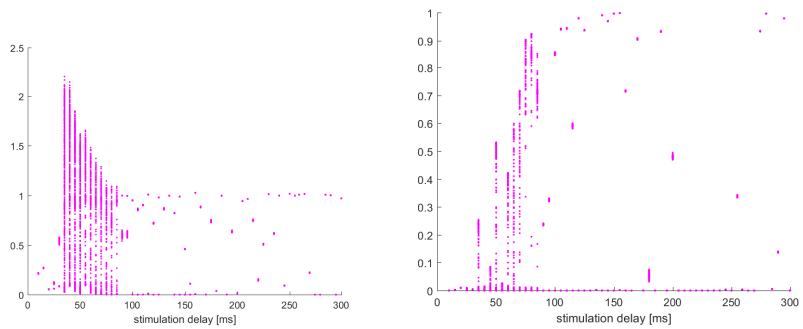

Figure 4: FK model bifurcation of variable u (lef) and v (right).

Figures 4, and 5 shows bifurcation diagrams of FK3V model. Values for diagrams was collected witch period of stimulation frequency (recorded was every fifth stimulus). In Figures can be seen that for stimulation delays from 35 to 85 ms is is response of the model chaotic.

Finally, 0-1 test for chaos was performed. This test, introduced in [4] (see also [5]), is used to distinguish regular and chaotic dynamic. It works with the time series and does not need any phase space reconstruction. The resulting value of this test can only be 0 (regular behavior) or 1 (chaos). The results of this test can bee seen in Figure 6. This test coincides just for variable w.

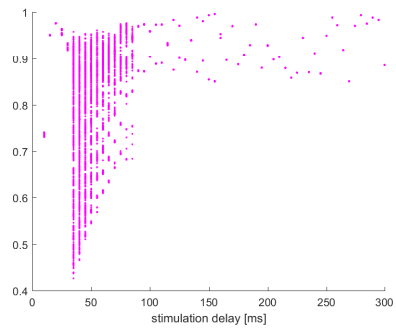

Figure 5: Bifurcation diagram of variable w.

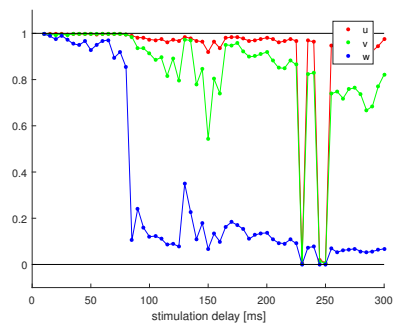

Figure 6: Results of the 0-1 test for chaos of variables u, v and u.

 ISBN: 978-84-617-8694-7

4 Conclusions

In this paper, responses of Fenton-Karma model of cardiac cell to various rates of stimulation frequencies were analyzed. Newly, the model was forced by stimulus with shape of half sinus period. The equations of potentials were solved numerically using Runge-Kutta method of the fourth order as *ode45* solver in Matlab.

It was observed that model is showing regular and also chaotic pattern for different range of stimulation delay. Chaotic behavior of variables u, v and w were confirmed by 0-1 test for chaos for suitable choices of stimulation delays.

Abstract

Classification of remotely sensed hyperspectral images is a challenging task due the enormous amount of information comprised in these images, that contain hundreds of continuous spectral bands. This creates a need to develop new techniques for hyperspectral classification using high performance computing architectures. Despite the availability of multiple algorithms adapted to parallel environments (such as multicore computers or accelerators like field programmable gate arrays or graphics processing units, the application of cloud computing techniques has not been as widespread, although there are many potential advantages in exploiting cloud computing architectures for distributed hyperspectral image analysis. In this paper, we present a cloud implementation (developed using Apache Spark) of a successful technique for hyperspectral image classification: the multinomial logistic regression probabilistic classifier. Our experimental results suggest that cloud computing architectures allow for the efficient classification of large hyperspectral image data sets.

Key words: Hyperspectral imaging, multinomial logistic regression, cloud computing, Apache Spark.

 ISBN: 978-84-617-8694-7

1 Introduction

Remotely sensed hyperspectral imaging is a popular technique for Earth observation (EO) [1], which allows for the simultaneous collection of images (at different wavelength channels) for the same area on the surface of the Earth. A characteristic of hyperspectral imagers is that they can collect data in thousands of narrow, contiguous spectral bands [2], providing so-called hyperspectral image data cubes [3].

An important property of hyperspectral instruments is their ability to acquire a complete reflectance spectrum for each pixel in the image (called contiguous spectral curves or spectral signatures). These signatures allow us to accurately distinguish different physical materials. For instance, the NASA's Jet Propulsion Laboratory's Airbone Visible/Infrared Imaging Spectrometer (AVIRIS) [4] measures the solar reflected spectrum from 0.4μm to 2.5μm at intervals of 0.01μm. The EO-1 Hyperion imaging spectrometer also collects bands in the range of 0.4μm to 2.5μm (more than 200 bands in both cases) [5, 6]. Several new satellite mission that will be soon operative and ready to collect data in a very similar spectral range. For instance, the German Environmental Mapping and Analysis Program (EnMAP [7]) is expected to collect data in the range 0.42μm to 2.45μm, as well as the Italian PRISMA program [8]. Other spectrometers acquire hyperspectral images in other regions of the spectrum, for instance the Reflective Optics System Imaging Spectrometer (ROSIS) takes images with a spectral range from 0.43μm to 0.96μm [9].[2].

Hyperspectral imaging has proved to be useful over a wide range of applications, such as agriculture, forestry, geology, ecological monitoring and disaster monitoring [10, 6]. However, due to the great dimensionality of hyperspectral data cubes, analysis techniques exhibit significant requirements in terms of storage and data processing [11, 12]. Therefore, the development of techniques that are computationally efficient becomes critical [6, 13, 14, 15].

Many efforts have been made within the field of hyperspectral image classification, both supervised and unsupervised [16]. Supervised techniques have been generally more popular due to their higher classification accuracy, but they require sufficient training information in order to perform properly. One of the supervised classifiers that can perform more accurately in the presence of limited training samples is the multinomial logistic regression (MLR) [17]. However, this classifier is computationally expensive, and available implementations have not considered the possibility of using cloud computing architectures [18]. These platforms can be greatly beneficial for hyperspectral image classification due to their advanced capabilities for internet-scale, service-oriented and high-performance computing. Specifically, the use of cloud computing for the classification of large hyperspectral data repositories can be considered a natural solution and an evolution of previously developed techniques for other kinds of computing platforms [19]. Still, there are few efforts in the recent literature oriented to the exploitation of cloud computing infrastructure for hyperspectral imaging techniques.

 ISBN: 978-84-617-8694-7

This work explores the possibility of using a distributed framework for classification of massive hyperspectral images based on cloud computing architectures. In particular we have focused on the discriminative MLR classifier [17] to demonstrate the applicability of utilizing cloud computing technologies to efficiently perform distributed classification of hyperspectral data.

The remainder of the paper is organized as follows. Section 2 first presents the theoretical principles of the MLR method (section2.1). Then, it describes our distributed framework design for this classifier (section 2.2). Finally, it describes our cloud implementation in detail (section 2.3). Section 3 validates the proposed cloud MLR algorithm by comparing it with other implementations. Finally, section 4 concludes with some remarks and hints at plausible future research lines.

2 Methodology

2.1 Multinomial Logistic Regression

To understand the operations of the MLR, we first we need to describe how logistic regression (LR) works. Given a collection of n linear-separable numeric samples $X = \{x_1, ..., x_n\}$ where each $x_i \in \mathbb{R}^d$, $x_i = [x_{i,1}, ..., x_{i,d}]$, the goal of classification methods is to categorize each x_i into a class or category y_i of those available in $Y = \{y_1, ..., y_k\}$, with $k < n$. But, in contrast to other classification methods, LR does not try to predict the value of a x_i given a set of inputs. Instead, the output is a probability that the input x_i belongs to a certain class y_i. It would be 0 when x_i does not belong to y_i and 1 if x_i belongs to y_i. Suppose that $x_i = [x_{i,1}, ..., x_{i,d}]$ and $Y = \{-, +\}$, LR assumes that the input d-space can be separated into two regions by a linear boundary: $\beta_0 + \beta_1 x_{i,1} + ... + \beta_d x_{i,d}$. This function outputs a value in $(-\infty, \infty)$ given an input data point, x_i[1]. To map the label probabilities with boundary values, LR applies log-odds functions[2] and calculates the predicted probabilities as $P(y_i = +|x_i, \beta) = \frac{\exp(\beta_0 + \sum_{j=1}^{d} \beta_j x_{i,j})}{1+\exp(\beta_0 + \sum_{j=1}^{d} \beta_j x_{i,j})}$. The goal of LR is to estimate the coefficients $\beta = \{\beta_0, \beta_1, ..., \beta_d\}$ through *maximum likelihood estimation* (MLE), that optimizes β in order to maximize the *log likelihood* (LL, i.e. the log odds).

MLR extends the binary problem of LR to any number of classes, $k > 2$. Specifically,

[1] If x_i lies in the region defined by the + class, the function's value is positive in the range $(0, +\infty)$ and its probability $P(y_i = +|x_i, \beta)$ is in $(0.5, 1]$. If x_i lies in the region defined by the − class, the function's value is negative in the range $(-\infty, 0)$ and its probability $P(y_i = -|x_i, \beta) = 1 - P(y_i = +|x_i, \beta)$ is in $[0, 0.5)$. Finally if we do not know whats x_i is, the function's value is 0, and probabilities of being + or − are exactly 0.5

[2] Given a probability function $P(x) \in [0, 1]$, the odds ratio is defined as $OR(x) = \frac{P(x)}{1-P(x)} \in [0, +\infty)$. Applying the logarithm to $OR(x)$ we obtain $\log(OR(x)) \in (-\infty, \infty)$. If the log-odds is $\log(\frac{P(x)}{1-P(x)}) = a + bx$, we can transform it into $\frac{P(x)}{1-P(x)} = \exp(a + bx) \rightarrow P(x) = \frac{\exp(a+bx)}{1+\exp(a+bx)}$, i.e the logistic function

 ISBN: 978-84-617-8694-7

MLR selects one category as the baseline, e.g. the k-th class, and calculates the regression coefficients for the $l = 1, ..., k-1$ non-baseline categories $(\beta^{(1)}, ..., \beta^{(k-1)}$ with $\beta^{(l)} = \{\beta_0^{(l)}, ..., \beta_d^{(l)}\})$ against the baseline class. The predicted probabilities are extended to $P(y_i = l|x_i, B) = \frac{\exp\left(\beta_0^{(l)} + \sum_{j=1}^{d} \beta_j^{(l)} x_{i,j}\right)}{1 + \sum_{l'=1}^{k-1} \left(\exp\left(\beta_0^{(l')} + \sum_{j=1}^{d} \beta_j^{(l')} x_{i,j}\right)\right)}$, where B is the $(d+1) \times (k-1)$ matrix of all the regression coefficients. The goal of MLR is then to estimate B given the samples dataset X and the categories Y, by minimizing the optimization function:

$$f(B; X, Y) = -\sum_{i=1}^{n} \log P(y_i|x_i B) + \frac{\lambda}{2} \sum_{j=1}^{d} \sum_{l=1}^{k-1} |\beta_j^{(l)}|^2, \tag{1}$$

where λ is a regularization term added in order to mitigate the overfitting problem.

2.2 Distributed framework design

To create our distributed environment, two frameworks have been used: 1) *OpenStack*[3] and 2) *Apache Spark*[4]. Each one of them will be in charge of the correct execution of the architecture in two aspects:

- On the one hand, *OpenStack* provides Infrastructure as a Service (IaaS), abstracting and manages the physical machines that will give the support to the virtual machines. *OpenStack* works like a cloud operating system that controls large pools of compute, storage, and networking resources throughout a datacenter, all managed through a dashboard that gives administrators control while empowering their users to provision resources through a web interface.

- On the other hand, *Apache Spark* is a distributed in-memory processing framework that works over the virtual machines (managed by *OpenStack*) and allows to implement MapReduce[5] distributed programming model [18]. Also, *Apache Spark* implements a fault-tolerant abstraction for in-memory cluster computing, and provides fast and general data processing on large distributed platforms. It supports simple one-pass computations and can also be extended to the case of multi-pass, iterative algorithms.

[3] https://wiki.openstack.org/wiki/Main_Page

[4] http://spark.apache.org/

[5] The MapReduce model takes full advantage of the high-performance capabilities provided by cloud computing architectures. The operation is easy: a task is processed by two distributed operations, map and reduce. The datasets are organized as key/value pairs, and the map function processes a key/value pair to generate a set of intermediate pairs, dividing a task into several independent subtasks to be run in parallel. The reduce function is in charge of processing all intermediate values associated with the same intermediate key, then collecting all the subtask results to gather the result for the whole task.

 ISBN: 978-84-617-8694-7

The full architecture of our newly developed system for hyperspectral image classification is shown in Fig. 1. In Fig. 2 we display the services offered by *OpenStack* and the *Apache Spark* framework used.

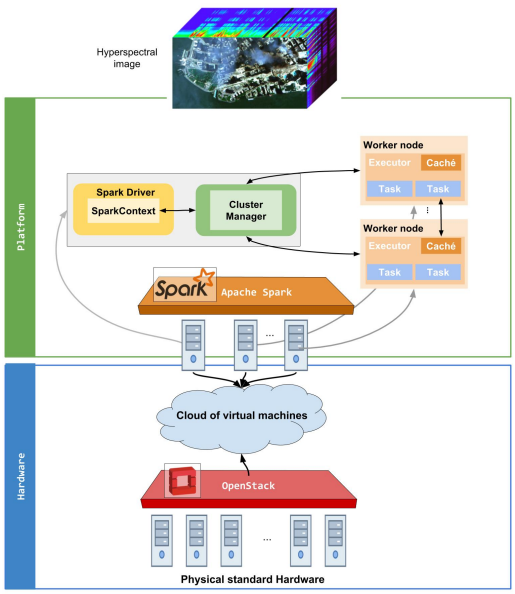

Figure 1: Integrated OpenStack and Apache Spark framework for Logistic Regression.

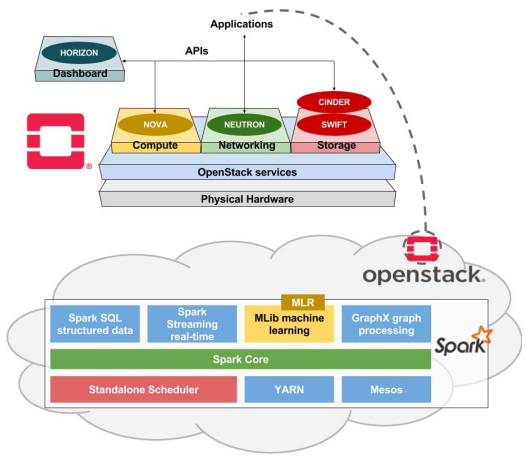

Figure 2: Description of the proposed Apache Spark and Open Stack architecture.

2.3 Cloud Implementation

Proposed cloud MLR divides the execution between one master (Spark driver) and several slaves (Spark executors). The driver prepares the environment (reserves resources), launches the executors and initializes β. Each executor loads their corresponding patch of the hyperspectral image and for each data calculates the loss function and the gradient (Map) that are summed up (Resume) and sent back to the driver. The driver calculates the loss and the gradient of regularizer and plugs the gradient and loss of the model and the regularizer into optimizer to get the new β. If the loss is less than the stopping criterion, the algorithm ends.

To execute our cloud implementation of MLR we need several parameters: the number of classes (k), the input training data (a percentage of hyperspectral image's pixels with which MLR will train), the number of maximum iterations and the tolerance of the L-BFGS optimizer. On the other hand, the input data is regularized by L2.

3 Experimental results

3.1 Experimental Configuration

In order to evaluate the performance of the adopted MLR implementation, we use a hardware environment composed by a Intel(R) Xeon(R) CPUs E5430 @ 2.66GHz (8 cores), 16 GB RAM, Shared storage, NetApp FAS3140. Virtual nodes have two virtual CPUs, 4GB of RAM and 40 GB hard disk each. In addition, we have developed a parallel version of the algorithm for comparative purposes. This version has been implemented on a paltform with Intel(R) Core(TM) i7-4790 CPUs @ 3.60GHz (8 cores), 16 GB RAM, SanDisk SDSSDA240G. In our experiments, we used Ubuntu 14.04 x64 LTS as operating system. For the parallel version of MLR, a virtual machine of the cluster with 2 cores, 4GB of RAM and 40GB of hard disk, and the same software configuration has been used.

3.2 Hyperspectral data sets

In our experiments, we use two different hyperspectral images. The first one was collected by AVIRIS [4] in 1992 over a set of agricultural fields with regular geometry and irregular patches of forest in Northwestern Indiana (Indian Pines image). This scene has 145×145 pixels with 224 spectral bands in the range 0.4-2.5μm, with 0.01μm of spectral resolution, 0.020μm moderate spatial resolution and 16 bits of radiometric resolution. 4 zero bands plus 20 bands with lower signal-to-noise ratio (SNR) have been removed, retaining 200 spectral

 ISBN: 978-84-617-8694-7

channels. The data has 16 ground-truth classes (Fig. 3). Also, we use a larger version of

the Indian Pines scene, with a size of 2678×614 pixels. It was collected over the same area, but spanning a much larger extent. It contains 220 spectral bands an the total number of classes is 58 (Fig. 4).

3.3 Performance Evaluation

To evaluate the performance of our cloud implementation of MLR, we make a comparison between the cloud version and a multi-core parallel implementation of the same MLR algorithm. Our experiments have been launched for each hyperspectral image, using different training percentages (15%, 25% and 50% of the training samples available in each

class). For the cloud version we have considered 2, 4 and 8 distributed nodes. The optimal number of iterations and λ value are obtained by cross-validation. Each configuration has been repeated five times, and the results reported are the average across the executions for statistical consistency.

Training percentage	**Parallel**	**Distributed**		
		2 nodes	**4 nodes**	**8 nodes**

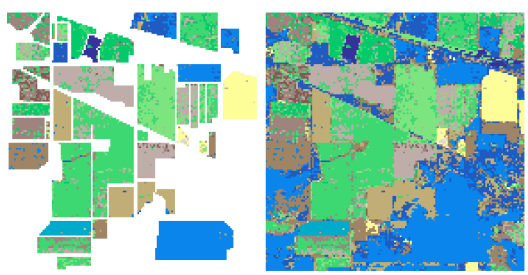

Figure 5: Classification results for the Small Indian Pines image: classification map without background (left) and classification map with background (right), obtained using 15% training.

Table 1 shows the results obtained by different implementations of the MLR using the Small Indian Pines dataset. The classification accuracies are worse as we add nodes to the cluster, due to the lack of data within the nodes, and the processing times tend to be worse too. This is because the nodes have not enough data to optimize. Fig. 5 shows the obtained classification result. As mentioned before, the processing times increase slightly as we add nodes to the distributed environment (with 8 nodes the weight of the communication prevents to improve the speed up). However, the increase of training samples affects non-uniformly the obtained classification results (this depends on the calculation of

Table 2: Average processing time, classification accuracy (and standard deviation) for different implementations of multinomial logistic regression using the Big Indian Pines Image.

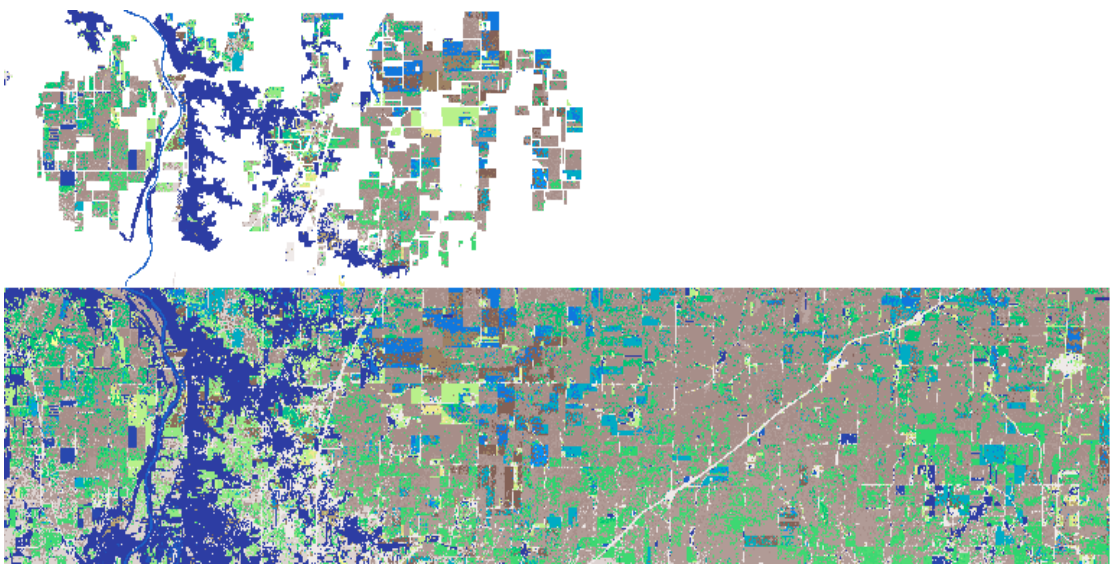

Figure 6: Classification results for the Big Indian Pines image: classification map without background (top) and classification map with background (bottom), obtained using 15% training.

On the other hand, Table 2 shows the results obtained by MLR using the Big Indian Pines dataset. As we can see, as we increase the number of nodes, time decreases. The highest speed up is achieved with 8 nodes (a 3.29), while the accuracy results are quite

acceptable given the complexity of this scene (although is less than in the parallel version). These results reveal that our cloud implementation benefits from the availability of large data volumes and complex analysis scenarios, such as the one given by the Big Indian Pines scene. The complexity of the classification of this scene can be appreciated in Fig. 6.

4 Conclusions and Future Lines

In this paper, we have discussed the possibility of exploiting cloud computing architectures for hyperspectral image classification. As a case study, we have presented a cloud computing implementation of the multinomial logistic regression classifier (a technique that has been used successfully for hyperspectral data interpretation) on the Apache Spark and Openstack platforms. Our experimental results show the effectiveness of the proposed distributed implementation with large hyperspectral datasets (i.e., the proposed technique provides satisfactory results with very large images and complex analysis scenarios given by a large numbers of samples and classes). As future work, we will implement other techniques for hyperspectral image classification using cloud computing platforms, as it is our feeling that there are many open and unexplored possibilities for the exploitation of these kind of platforms in remotely sensed hyperspectral imaging.

emails: hitzer@icu.ac.jp

Abstract

In this paper we use the general steerable one-sided Clifford Fourier transform (CFT), and relate the classical convolution of Clifford algebra-valued signals over $\mathbb{R}^{p,q}$ with the (equally steerable) Mustard convolution. A Mustard convolution can be expressed in the spectral domain as the point wise product of the CFTs of the factor functions. In full generality do we express the classical convolution of Clifford algebra signals in terms of a linear combination of Mustard convolutions, and vice versa the Mustard convolution of Clifford algebra signals in terms of a linear combination of classical convolutions. Finally, we derive auto-correlation theorems for the cross-correlation and for the auto-correlation of Clifford signals.

Key words: Convolution, Clifford Fourier transform, Clifford algebra signals, spatial domain, frequency domain, auto-correlation theorem

1 Introduction

The steerable one-sided Clifford Fourier transformation (CFT) was introduced in [10]. It generalizes related transforms, like the classical complex Fourier transform, the one-sided single kernel quaternion Fourier transform [5], and the Clifford Fourier transforms with pseudoscalar kernels [4, 6] to higher dimensions. These CFTs essentially replace the imaginary unit $i \in \mathbb{C}$ by a general multivector square root of -1, which usually populate continuous Clifford algebra submanifolds [9, 11]. The classical complex Fourier transform needs only one fully commuting kernel factor, due to the commutativity of complex numbers. To have

a non-commutative kernel factor under the transform integral on one side of the signal function is meaningful due to the inherent non-commutativity in Clifford algebras. An extensive discussion of the historical development and the application relevance of the CFTs can be found in [1] and [14].

This paper is organized as follows. Section 2 gives some background on the steerable one-sided CFT. Next, Section 3 defines the classical convolution of two Clifford signal functions, their steerable Mustard convolution, their cross-correlation, and the auto-correlation of a Clifford signal function. The rest of the section is devoted to representing the classical convolution in terms of a sum of Mustard convolutions (Theorem 3.3) and dually to expressing the Mustard convolution in terms of a sum of classical convolutions (Theorem 3.4). Furthermore, direct single convolution product identities between classical and Mustard convolutions are established (Theorem 3.6), together with the theoretical equivalence (for general Clifford signal convolution product factor functions) of expressing the classical convolution in terms of the Mustard convolution and the reverse (Equation (3.17)). Finally, Section 4 derives auto-correlation theorems for the cross-correlation and for the auto-correlation of Clifford signals.

2 General steerable one-sided Clifford Fourier transforms

We will make use of the following notation.

Notation 2.1 (Argument reflection)**.** *For a function $h : \mathbb{R}^{p,q} \to Cl(p',q')$ we set*[1]

$$h^1(\boldsymbol{x}) := h(-\boldsymbol{x}). \tag{2.1}$$

Note that we obviously have

$$(h^1)^1(\boldsymbol{x}) = h^1(-\boldsymbol{x}) = h(\boldsymbol{x}). \tag{2.2}$$

We will make use of the following lemma [11].

Lemma 2.2. *Every multivector $A \in Cl(p,q)$ has, with respect to a square root $f \in Cl(p,q)$ of -1, i.e., $f^{-1} = -f$, the unique decomposition*

$$\begin{aligned} A_{+f} = \frac{1}{2}(A + f^{-1}Af), \qquad A_{-f} = \frac{1}{2}(A - f^{-1}Af) \\ A = A_{+f} + A_{-f}, \qquad A_{+f}\, f = f A_{+f}, \qquad A_{-f}\, f = -f A_{-f}, \end{aligned} \tag{2.3}$$

$A_{+f} \in \text{centralizer}(f, Cl_{p,q})$.

[1] We are aware that this notation could be confused with an ordinary taking to the power of 1, but as will be seen in the current context no danger of confusion is likely to arise.

 ISBN: 978-84-617-8694-7

The *general steerable one-sided Clifford Fourier transform* (CFT) [10], can be understood as a generalization of previously known one-sided CFTs [6], to a general Clifford algebra setting. Most known CFTs (prior to [10]) used in their kernels specific square roots of -1, like bivectors, pseudoscalars, unit pure quaternions, or sets of coorthogonal blades (commuting or anticommuting blades) [2]. All those restrictions on the square roots of -1 used in a CFT do not apply in our definition below. Note further, that the definition we are about to introduce is even more general than Definition 3.1 given in [10], because we generalize to multivector signal functions in $L^1(\mathbb{R}^{p,q};Cl(p',q'))$ and not only in $L^1(\mathbb{R}^{p,q};Cl(p,q))$.

Definition 2.3 (Steerable CFT with respect to one square root of -1)**.** Let $i \in Cl(p',q')$, $i^2=-1$, be any square root of -1. The general Clifford Fourier transform (CFT) of $f \in L^1(\mathbb{R}^{p,q};Cl(p',q'))$, with respect to i is

$$\mathcal{F}^i\{f\}(\boldsymbol{\omega}) = \int_{\mathbb{R}^{p,q}} f(\boldsymbol{x})\, e^{-iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{x}, \tag{2.4}$$

where $d^n\boldsymbol{x} = dx_1 \dots dx_n$, $\boldsymbol{x},\boldsymbol{\omega} \in \mathbb{R}^{p,q}$, and $u : \mathbb{R}^{p,q} \times \mathbb{R}^{p,q} \to \mathbb{R}$.

Since square roots of -1 in $Cl(p',q')$ populate *continuous submanifolds* in $Cl(p',q')$, the CFT of Definition 2.3 is generically *steerable* within these manifolds, see (2.6). In Definition 2.3, the square roots $i \in Cl(p',q')$ of -1 may be from any component of any conjugacy class. The choice of the Clifford's geometric product between multivector signal function f and the multivector kernel $e^{-iu(\boldsymbol{x},\boldsymbol{\omega})}$, in the integrand of (2.4) is very important. Because only this choice allowed, e.g. in [4], to define and apply a holistic vector field convolution, without loss of information.

Note that two-sided CFTs can be decomposed to pairs of one-sided CFTs [12].

Remark 2.4. *In order to avoid clutter we often drop the upper index i as in $\mathcal{F}\{h\} = \mathcal{F}^i\{h\}$, but in principle the one-sided CFT always depends on the particular choice i of the multivector square root of -1. Since square roots of -1 in $Cl(p',q')$ populate continuous submanifolds in $Cl(p',q')$, the CFT of Definition 2.3 is generically steerable within these submanifolds. In Definition 2.3, the square root $i \in Cl(p',q')$ of -1, may be from any conjugacy class and component, respectively.*

Within the same conjugacy class of square roots of -1 the CFTs of Definition 2.3 are related by the following equation, and therefore steerable. Let $i, i' \in Cl(p',q')$ be any two square roots of -1 in the same conjugacy class, i.e. $i' = a^{-1}ia$, $a \in Cl(p',q')$, a being invertible. As a consequence of this relationship we also have

$$e^{-i'u} = a^{-1}e^{-iu}a, \ \ \forall u \in \mathbb{R}. \tag{2.5}$$

This in turn leads to the following *steerability relationship* of all CFTs with square roots of -1 from the same conjugacy class:

$$\mathcal{F}^{i'}\{h\}(\boldsymbol{\omega}) = \mathcal{F}^i\{ha^{-1}\}(\boldsymbol{\omega})a, \tag{2.6}$$

 ISBN: 978-84-617-8694-7

where ha^{-1} means to multiply the signal function h by the constant multivector $a^{-1} \in Cl(p',q')$.

For establishing an *inversion* formula and other properties of the CFT in Definition 2.3, certain *assumptions* about the phase function $u(\boldsymbol{x},\boldsymbol{\omega})$ need to be made. In principle these assumptions could be made based on the desired properties of the resulting CFT. One possibility is, e.g., to assume

$$u(\boldsymbol{x},\boldsymbol{\omega}) = \boldsymbol{x} * \widetilde{\boldsymbol{\omega}} = \sum_{l=1}^{n} x^l \omega^l = \sum_{l=1}^{n} x_l \omega_l, \tag{2.7}$$

which will be assumed in the rest of this paper.

We then get the following *inversion* theorem[2].

Theorem 2.5 (Inversion of one-sided CFT)**.** *For $\mathcal{F}^i\{h\} \in L^1\left(\mathbb{R}^{p,q}; Cl(p',q')\right)$, provided that in any finite interval h and the partial coordinate derivatives of h are piecewise continuous, and have at most a finite number of extrema and discontinuities, and that h is continuous at $\boldsymbol{x} \in \mathbb{R}^{p,q}$, we have*

$$h(\boldsymbol{x}) = \mathcal{F}^i_{-1}\{\mathcal{F}^i\{h\}\}(\boldsymbol{x}) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}^i\{h\}(\boldsymbol{\omega})\, e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega}, \tag{2.8}$$

where $d^n\boldsymbol{\omega} = d\omega_1 \dots d\omega_n$, $\boldsymbol{x},\boldsymbol{\omega} \in \mathbb{R}^{p,q}$.

The proof of theorem 2.5 is strictly analogous to the proof of equation (4.8) on page 231 of [10], and therefore left as an exercise to the reader.

We further note the following useful relationship using the argument reflection of Notation 2.1

$$\mathcal{F}^{-i}\{h\} = \mathcal{F}^i\{h^1\} = \mathcal{F}\{h^1\}. \tag{2.9}$$

The main properties of the CFT of Definition 2.3 have been studied for the special case of multivector signal functions $f \in L^1(\mathbb{R}^{p,q}; Cl(p,q))$ in detail in [10], and can easily be generalized to the more general case of $f \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$.

3 Convolution and steerable Mustard convolution, cross-correlation and auto-correlation

We define the *convolution* of two Clifford (algebra) signals $a, b \in L^1(\mathbb{R}^{p,q};\, Cl(p',q'))$ as

$$(a \star b)(\boldsymbol{x}) = \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b(\boldsymbol{x}-\boldsymbol{y}) d^n\boldsymbol{y}, \tag{3.1}$$

[2]Note, that we show the inversion symbol -1 as lower index in $\mathcal{F}^i_{-1}$, in order to avoid a possible confusion by using two upper indice. The inversion could also be written with the help of the CFT itself as $\mathcal{F}^i_{-1} = \frac{1}{(2\pi)^n}\mathcal{F}^{-i}$.

 ISBN: 978-84-617-8694-7

provided that the integral exists.

Note that the real continuous Clifford geometric algebra wavelet transform can be written as a convolution of the multivector signal function with the daughter wavelet (a rotated, dilated and translated mother wavelet), essentially evaluated at the center of the daughter wavelet, see [7].

The *Mustard* convolution [15, 3] of two Clifford signals $a, b \in L^1(\mathbb{R}^{p,q};\, Cl(p',q'))$ is defined as

$$(a \star_M b)(\boldsymbol{x}) = (\mathcal{F}^i)^{-1}(\mathcal{F}^i\{a\}\mathcal{F}^i\{b\})(\boldsymbol{x}), \tag{3.2}$$

provided that the integral exists.

Remark 3.1. *The Mustard convolution has the conceptual and computational advantage to simply yield, independent of the particular Clifford algebra $Cl(p',q')$ involved and of the particular multivector square root of -1 in the CFT kernel, as spectrum in the CFT Fourier domain the point wise product of the CFTs of the two signals, just as for the classical complex Fourier transform. On the other hand, by its very definition, the Mustard convolution itself depends on the choice of i, i.e. of the multivector square root of -1, used in the Definition 2.3 of the CFT. The Mustard convolution* (3.2) *is therefore a steerable operator, dependent on the choice of i.*

We further define the *cross-correlation* of two Clifford signals $a, b \in L^1(\mathbb{R}^{p,q};\, Cl(p',q'))$ as

$$(a \star_c b)(\boldsymbol{x}) = \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y})\widetilde{b(\boldsymbol{y}-\boldsymbol{x})}d^n\boldsymbol{y} = \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}+\boldsymbol{x})\widetilde{b(\boldsymbol{y})}d^n\boldsymbol{y}, \tag{3.3}$$

provided that the integral exists.

We finally define the *auto-correlation* of a Clifford signal $a \in L^1(\mathbb{R}^{p,q};\, Cl(p',q'))$ as

$$(a \star_a a)(\boldsymbol{x}) = \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y})\widetilde{a(\boldsymbol{y}-\boldsymbol{x})}d^n\boldsymbol{y} = \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}+\boldsymbol{x})\widetilde{a(\boldsymbol{y})}d^n\boldsymbol{y}, \tag{3.4}$$

provided that the integral exists.

In the following two Subsections we will express the convolution (3.1) in terms of the Mustard convolution (3.2), and vice versa, and study the mutual relations of these expressions. Then we will give auto-correlation theorems for the cross- and auto-correlations of Clifford signals.

3.1 Expressing the convolution in terms of the Mustard convolution

In this Subsection we assume the use of the one-sided CFT with a general multivector square roots of -1, $i \in Cl(p',q')$. The definition of the classical convolution (3.1) is independent of the application of a CFT. The Mustard convolution of (3.2) depends on the definition of the CFT and in particular on the choice of the multivector square root i of -1.

 ISBN: 978-84-617-8694-7

In our approach we generalize equation (4.17) on page 233 of [10], which expresses the convolution of two Clifford signal functions in the Clifford Fourier domain with the help of the CFT of Definition 2.3. We generalize this equation to the case of multivector signal functions $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q')$, and to the CFT of Definition 2.3. Nevertheless the proof works perfectly analogous to the one given in [10], we therefore leave this as an exercise to the reader.

Theorem 3.2 (CFT of convolution)**.** *We assume that the function u is linear with respect to its first argument. The CFT of the convolution* (3.1) *of two multivector signals $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q')$ can then be expressed as*

$$\begin{aligned}\mathcal{F}^i\{a \star b\} &= \mathcal{F}^{-i}\{a\}\mathcal{F}^i\{b_{-i}\} + \mathcal{F}^i\{a\}\mathcal{F}^i\{b_{+i}\} \\ &= \mathcal{F}^i\{a^1\}\mathcal{F}^i\{b_{-i}\} + \mathcal{F}^i\{a\}\mathcal{F}^i\{b_{+i}\}. \end{aligned} \tag{3.5}$$

We can now easily express the convolution of two multivector signals $\mathcal{F}^i\{a \star b\}(\boldsymbol{\omega})$ in terms of only two Mustard convolutions (3.2), by applying the inverse CFT.

Theorem 3.3 (Convolution in terms of Mustard convolution)**.** *Assuming a general multivector square root i of -1, the convolution* (3.1) *of two Clifford functions $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$ can be expressed in terms of two Mustard convolutions* (3.2) *as*

$$a \star b = a^1 \star_M b_{-i} + a \star_M b_{+i}. \tag{3.6}$$

An alternative direct proof of Theorem 3.3 is the following:

$$\begin{aligned}(a \star b)(\boldsymbol{x}) &= \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b(\boldsymbol{x}-\boldsymbol{y}) d^n\boldsymbol{y} \\ &= \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}\{b\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x}-\boldsymbol{y},\boldsymbol{\omega})} d^n\boldsymbol{\omega} d^n\boldsymbol{y} \\ &= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) \int_{\mathbb{R}^{p,q}} [\mathcal{F}\{b_+\}(\boldsymbol{\omega}) + \mathcal{F}\{b_-\}(\boldsymbol{\omega})] e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} d^n\boldsymbol{y} \\ &= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}} [a(\boldsymbol{y}) e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} d^n\boldsymbol{y} \mathcal{F}\{b_+\}(\boldsymbol{\omega}) \\ &\qquad + a(\boldsymbol{y}) e^{iu(\boldsymbol{y},\boldsymbol{\omega})} d^n\boldsymbol{y} \mathcal{F}\{b_-\}(\boldsymbol{\omega})] e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} \\ &= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} [\mathcal{F}\{a\}(\boldsymbol{\omega})\mathcal{F}\{b_+\}(\boldsymbol{\omega}) + \mathcal{F}\{a\}(-\boldsymbol{\omega})\mathcal{F}\{b_-\}(\boldsymbol{\omega})] e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} \\ &= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} [\mathcal{F}\{a\}(\boldsymbol{\omega})\mathcal{F}\{b_+\}(\boldsymbol{\omega}) + \mathcal{F}\{a^1\}(\boldsymbol{\omega})\mathcal{F}\{b_-\}(\boldsymbol{\omega})] e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} \\ &= a \star_M b_{+i} + a^1 \star_M b_{-i}, \end{aligned} \tag{3.7}$$

where we have applied the inverse CFT by substituting for the second equality $b = \mathcal{F}^i\mathcal{F}^i_{-1}\{b\}$, and that for $\alpha \in \mathbb{R}$, $\mathcal{F}^i\{b_\pm\}e^{i\alpha} = e^{\pm i\alpha}\mathcal{F}^i\{b_\pm\}$ for the fourth equality.

 ISBN: 978-84-617-8694-7

3.2 Expressing the Mustard convolution in terms of the convolution

Now we will first simply write out the Mustard convolution (3.2) and simplify it until only standard convolutions (3.1) remain.

We begin by writing the Mustard convolution (3.2) of two multivector functions $a, b \in L^2(\mathbb{R}^{p,q}; Cl(p',q'))$

$$
\begin{aligned}
& a \star_M b(\boldsymbol{x}) \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}\{a\}(\boldsymbol{\omega}) \mathcal{F}\{b\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} d^n\boldsymbol{y} \int_{\mathbb{R}^{p,q}} b(\boldsymbol{z}) e^{-iu(\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{z} e^{iu(\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega} \\
&= \tfrac{1}{(2\pi)^n} \iiint a(\boldsymbol{y}) e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} [b_{+i}(\boldsymbol{z}) + b_{-i}(\boldsymbol{z})] e^{iu(\boldsymbol{x}-\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{y} d^n\boldsymbol{z} d^n\boldsymbol{\omega} \\
&= \tfrac{1}{(2\pi)^n} \iiint a(\boldsymbol{y}) b_{+i}(\boldsymbol{z}) e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} e^{iu(\boldsymbol{x}-\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{y} d^n\boldsymbol{z} d^n\boldsymbol{\omega} \\
&\quad + \tfrac{1}{(2\pi)^n} \iiint a(\boldsymbol{y}) b_{-i}(\boldsymbol{z}) e^{iu(\boldsymbol{y},\boldsymbol{\omega})} e^{iu(\boldsymbol{x}-\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{y} d^n\boldsymbol{z} d^n\boldsymbol{\omega} \\
&= \tfrac{1}{(2\pi)^n} \iiint a(\boldsymbol{y}) b_{+i}(\boldsymbol{z}) e^{iu(\boldsymbol{x}-\boldsymbol{y}-\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{y} d^n\boldsymbol{z} d^n\boldsymbol{\omega} \\
&\quad + \tfrac{1}{(2\pi)^n} \iiint a(\boldsymbol{y}) b_{-i}(\boldsymbol{z}) e^{iu(\boldsymbol{x}+\boldsymbol{y}-\boldsymbol{z},\boldsymbol{\omega})} d^n\boldsymbol{y} d^n\boldsymbol{z} d^n\boldsymbol{\omega} \\
&= \iint a(\boldsymbol{y}) b_{+i}(\boldsymbol{z}) \delta(\boldsymbol{x}-\boldsymbol{y}-\boldsymbol{z}) d^n\boldsymbol{y} d^n\boldsymbol{z} \\
&\quad + \iint a(\boldsymbol{y}) b_{-i}(\boldsymbol{z}) \delta(\boldsymbol{x}+\boldsymbol{y}-\boldsymbol{z}) d^n\boldsymbol{y} d^n\boldsymbol{z} \\
&= \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b_{+i}(\boldsymbol{x}-\boldsymbol{y}) d^n\boldsymbol{y} + \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b_{-i}(\boldsymbol{x}+\boldsymbol{y}) d^n\boldsymbol{y} \\
&= \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b_{+i}(\boldsymbol{x}-\boldsymbol{y}) d^n\boldsymbol{y} + \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) b_{-i}(-(-\boldsymbol{x}-\boldsymbol{y})) d^n\boldsymbol{y} \\
&= a \star b_{+i}(\boldsymbol{x}) + a \star b^1_{-i}(-\boldsymbol{x}) \\
&= a \star b_{+i}(\boldsymbol{x}) + a^1 \star b_{-i}(\boldsymbol{x}). \qquad (3.8)
\end{aligned}
$$

We have abbreviated $\int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}}$ to $\iint$, and $\int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}}$ to $\iiint$. For the third equality we applied the split of Lemma 2.2 to $b(\boldsymbol{x})$ and used the linearity of u with respect to its first argument. For the fourth equality we used the linearity of Clifford's geometric product, the linearity of the triple integral, and we used the commutation and anti-commutation properties of $b_{\pm i}(\boldsymbol{x})$ with the multivector square root $i \in Cl(p',q')$, which produces the sign change $e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} \to e^{+iu(\boldsymbol{y},\boldsymbol{\omega})}$ in the case of anti-commutation. For the fifth equality we again applied the linearity of u with respect to its first argument. The integrations

 ISBN: 978-84-617-8694-7

$\frac{1}{(2\pi)^n}\int e^{iu(\boldsymbol{x}\pm\boldsymbol{y}-\boldsymbol{z},\boldsymbol{\omega})}d^n\boldsymbol{\omega}$ produce the n-dimensional Dirac delta functions $\delta(\boldsymbol{x}\pm\boldsymbol{y}-\boldsymbol{z})$, giving the sixth equality.
We illustrate the last identity of (3.8), $a\star b^1_{-i}(-\boldsymbol{x}) = a^1\star b_{-i}(\boldsymbol{x})$, in the one-dimensional case $\mathbb{R}^{p,q}=\mathbb{R}$, the generalization to $\mathbb{R}^{p,q}$ is then straightforward

$$\begin{aligned} a\star b^1(-x) &= \int_{\mathbb{R}} a(y)b(-(-x-y))dy = \int_{-\infty}^{+\infty} a(y)b(x+y)dy \\ &= \int_{+\infty}^{-\infty} a(-g)b(x-g)(-1)dg = \int_{-\infty}^{+\infty} a(-g)b(x-g)dg \\ &= \int_{\mathbb{R}} a^1(g)b(x-g)dg = a^1\star b(x). \end{aligned} \tag{3.9}$$

where we have substituted $g=-y$, $dg=-dy$, including substitution of the integration boundaries for the third equality. The interchange of the integration boundaries eliminates the overall minus sign in the fourth equality of (3.9).

Note that in (3.8), $a\star b^1_{-i}(-\boldsymbol{x})$, means to first apply the convolution to the pair of functions a and b^1_{-i}, and only then to evaluate the result of the convolution integral with the argument $(-\boldsymbol{x})$. So in general $a\star b^1_{-i}(-\boldsymbol{x})\neq a\star b_{-i}(+\boldsymbol{x})$.

We finally obtain the desired decomposition of the Mustard convolution (3.2) in terms of the classical convolution.

Theorem 3.4 (Mustard convolution in terms of standard convolution)**.**
The Mustard convolution (3.2) *of two multivector signal functions* $a,b\in L^1(\mathbb{R}^{p,q};Cl(p',q'))$ *can be expressed in terms of two standard convolutions* (3.1) *as*

$$a\star_M b(\boldsymbol{x}) = a^1\star b_{-i}(\boldsymbol{x}) + a\star b_{+i}(\boldsymbol{x}). \tag{3.10}$$

Remark 3.5 (Theorem duality)**.** *Comparing Theorems 3.3 and 3.4 we notice an interesting duality: interchanging convolution and Mustard convolution in either theorem yields the other, independent over which vector space* $\mathbb{R}^{p,q}$ *the multivector signals are defined, independent from the signal value Clifford algebra* $Cl(p',q')$*, and independent from the particular choice of multivector square root of* -1*,* $i\in Cl(p',q')$*. The last form of independence also means, that the observed duality is stable with respect to steering the CFT and the Mustard convolution by changing* $i\in Cl(p',q')$*. Note further, that a corresponding duality will be valid for the left-sided version of the CFT in Definition 2.3, by placing the kernel factor on the left side and going analogously through all arguments up to Theorem 3.4.*

Yet, it is an interesting non-trivial question, whether a similar duality may hold for other forms of the CFT, e.g. with more than one kernel factor, see e.g. [12, 13].

 ISBN: 978-84-617-8694-7

3.3 Single convolution product identities for classical and Mustard convolutions

Let us now apply Theorem 3.3 to the three functions $a, b_{\pm i}$, observing that

$$(b_{+i})_{-i} = (b_{-i})_{+i} = 0, \quad (b_{+i})_{+i} = b_{+i}, \quad (b_{-i})_{-i} = b_{-i}. \tag{3.11}$$

Then we obtain

$$a \star b_{+i} = a^1 \star_M (b_{+i})_{-i} + a \star_M (b_{+i})_{+i} = 0 + a \star_M b_{+i} = a \star_M b_{+i}, \tag{3.12}$$

and similarly,

$$a \star b_{-i} = a^1 \star_M b_{-i} \quad \Longleftrightarrow \quad a^1 \star b_{-i} = a \star_M b_{-i}, \tag{3.13}$$

since double reflection of the argument returns the function itself (2.2). Note, that the very same identities are easily obtained by analogously applying Theorem 3.4 to $a, b_{\pm i}$. We therefore summarize them in the following theorem.

Theorem 3.6 (Partial identities between convolutions and Mustard convolutions)**.** *For pairs of functions (a, b_{-i}) and (a, b_{+i}) with $a, b_{\pm i} \in L^1(\mathbb{R}^{p,q}; Cl(p', q'))$, where the second factor either commutes or anti-commutes with the multivector square root of -1, $i \in Cl(p', q')$ of the Definition 2.3, the following convolution product identities between convolution* (3.1) *and Mustard convolution* (3.2) *hold*

$$\begin{gathered} a^1 \star b_{-i} = a \star_M b_{-i} \quad \Longleftrightarrow \quad a \star b_{-i} = a^1 \star_M b_{-i}, \\ a \star b_{+i} = a \star_M b_{+i}. \end{gathered} \tag{3.14}$$

Theorem 3.6 can therefore either be derived from Theorem 3.3 or from Theorem 3.4. Moreover, Theorem 3.6 can also be established independently by *direct* computation. Then adding two convolution terms would give the Mustard convolution

$$a^1 \star b_{-i} + a \star b_{+i} \overset{\text{Th. } 3.6}{=} a \star_M b_{-i} + a \star_M b_{+i} = a \star_M b. \tag{3.15}$$

And conversely adding two Mustard convolution terms would give the convolution

$$a^1 \star_M b_{-i} + a \star_M b_{+i} \overset{\text{Th. } 3.6}{=} a \star b_{-i} + a \star b_{+i} = a \star b. \tag{3.16}$$

This establishes the following important *threefold theorem equivalence*

$$\text{Theorem 3.3} \quad \Longleftrightarrow \quad \text{Theorem 3.6} \quad \Longleftrightarrow \quad \text{Theorem 3.4}. \tag{3.17}$$

Remark 3.7. *Note that the need to always decompose the right convolution product factor function $b = b_{-i} + b_{+i}$ is manifestly due to the kernel in Definition 2.3 being placed on the right side. Using a corresponding left side kernel CFT, would lead to analogous results with decomposing the left convolution product factor $a = a_{-i} + a_{+i}$.*

 ISBN: 978-84-617-8694-7

Furthermore, we can ask under what conditions we get a *full direct single convolution product identity* of the two convolution products $a \star b = a \star_M b$? This identity holds under any of the following conditions:

1. For all functions $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$, with $b_{-i} \equiv 0$. This condition depends on the choice of i.
2. For central multivector square roots $i \in Cl(p',q')$ of -1 and *all* functions $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$. An important practical example is $i = e_1e_2e_3 \in Cl(3,0)$ [4].
3. For all functions $a, b \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$, with reflection symmetry $a^1 = a$. This condition does not depend on the choice of i, and poses no restriction on b.

4 Auto-correlation theorem for Clifford signals

Using the classical complex Fourier transform, the auto-correlation of a signal can be expressed as the inverse Fourier transform of the spectral density. It provides information on how closely related a signal is to the same signal at some other time (or location). For unrelated noise, the auto-correlation function will be nearly zero, but if there is temporal (or spatial) structure in the signal, the auto-correlation will provide interesting information about it, see [16], Chapter 15.7.

In the following we assume $b \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$, that in any finite interval b and the partial coordinate derivatives of b are piecewise continuous, and have at most a finite number of extrema and discontinuities, that b is continuous at $\boldsymbol{x} \in \mathbb{R}^{p,q}$, that $\mathcal{F}\{b\} \in L^1(\mathbb{R}^{p,q}; Cl(p',q'))$, and that $\widetilde{i} = -i$. For establishing the auto-correlation theorem for Clifford signals we begin with the cross correlation (3.3) and apply the inverse CFT of Theorem 2.5.

$$\begin{aligned}
(a \star_c b)(\boldsymbol{x}) &= \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) \widetilde{b(\boldsymbol{y}-\boldsymbol{x})} d^n\boldsymbol{y} \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y}) \int_{\mathbb{R}^{p,q}} [\mathcal{F}^i\{b\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{y}-\boldsymbol{x},\boldsymbol{\omega})} d^n\boldsymbol{\omega}]^{\sim} d^n\boldsymbol{y} \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y})\, e^{-iu(\boldsymbol{y}-\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{b\}}(\boldsymbol{\omega}) d^n\boldsymbol{\omega} d^n\boldsymbol{y} \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \int_{\mathbb{R}^{p,q}} a(\boldsymbol{y})\, e^{-iu(\boldsymbol{y},\boldsymbol{\omega})} d^n\boldsymbol{y}\, e^{iu(\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{b\}}(\boldsymbol{\omega})\, d^n\boldsymbol{\omega} \\
&= \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}^i\{a\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{b\}}(\boldsymbol{\omega})\, d^n\boldsymbol{\omega}
\end{aligned} \tag{4.1}$$

Setting $b = a$, we get an important identity for the auto-correlation

$$(a \star_a a)(\boldsymbol{x}) = \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}^i\{a\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{a\}}(\boldsymbol{\omega}) d^n\boldsymbol{\omega}. \tag{4.2}$$

 ISBN: 978-84-617-8694-7

Hence we obtain one theorem and one corollary.

Theorem 4.1 (Auto-correlation theorem for cross-correlation of Clifford signals)**.** *We assume two Clifford signals $a, b \in L^1(\mathbb{R}^{p,q}, Cl(p',q'))$, that in any finite interval b and the partial coordinate derivatives of b are piecewise continuous, and have at most a finite number of extrema and discontinuities, that b is continuous at $\boldsymbol{x} \in \mathbb{R}^{p,q}$, and that $\mathcal{F}\{b\} \in L^1(\mathbb{R}^{p,q}, Cl(p',q'))$. The cross-correlation of a, b can then be expressed as*

$$(a \star_c b)(\boldsymbol{x}) = \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}^i\{a\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{b\}}(\boldsymbol{\omega}) d^n\boldsymbol{\omega}. \tag{4.3}$$

Corollary 4.2 (Auto-correlation theorem for auto-correlation of Clifford signals)**.** *We assume a Clifford signal $a \in L^1(\mathbb{R}^{p,q}, Cl(p',q'))$, that in any finite interval a and the partial coordinate derivatives of a are piecewise continuous, and have at most a finite number of extrema and discontinuities, that a is continuous at $\boldsymbol{x} \in \mathbb{R}^{p,q}$, and that $\mathcal{F}\{a\} \in L^1(\mathbb{R}^{p,q}, Cl(p',q'))$. The auto-correlation of a can then be expressed as*

$$(a \star_a a)(\boldsymbol{x}) = \tfrac{1}{(2\pi)^n} \int_{\mathbb{R}^{p,q}} \mathcal{F}^i\{a\}(\boldsymbol{\omega}) e^{iu(\boldsymbol{x},\boldsymbol{\omega})} \widetilde{\mathcal{F}^i\{a\}}(\boldsymbol{\omega}) d^n\boldsymbol{\omega}. \tag{4.4}$$

ELEMENTARY DISCRET HOLOMORPHIC FUNCTIONS

Abstract

Based on finite differences the discrete Laplacian can be factorized. By using one of these factors it is possible to study discrete holomorphic functions similar to the continuous case. In this paper discrete polynomials as well as an exponential function and a sine- and cosine function are defined such that all of them have the property to be discrete holomorphic. All investigations start in the one-dimensional case and extend the information to the complex case. An extension to the hypercomplex case seems to be possible but is not practiced here.

Key words: Finite Differences, Discrete Holomorphic Functions, Polynomials.

1 Introduction

Using finite differences and the factorization of the Laplacian, discrete holomorphic functions can be studied which are discrete harmonic, too. The paper starts with discrete polynomials which fulfill the so-called Appell property. Especially in the one-dimensional case such polynomials were already studied by Faustino und Kähler in [2]. The authors extend their polynomials to multi-index polynomials in order to obtain a Fischer decomposition with respect to the discrete Dirac operator and they use Euler- and Gamma operators in unbounded domains. The aim of this article is the extension of the polynomials to the complex case and the study of their properties. Furthermore the exponential function and the cosine and sine function are investigated. Starting again with the one-dimensional case it is possible to use some information to develop discrete holomorphic functions in the complex case.

 ISBN: 978-84-608-6082-2

2 Discrete polynomials and the Appell property

In the following section the Appell property is important so that the complex derivation of a basic function leads again to a multiple of a basic function (see [1]). In detail a system of polynomials $\{P^n(z)\}$ is called an Appell system if $\frac{d}{dz}P^n(z) = nP^{n-1}(z)$ holds with $n = 1, 2, \ldots$. Let $\{mh = (m_1h, m_2h)\ with\ m_1, m_2 \in \mathbf{Z}\}$ be an uniform lattice with step width h.

Theorem 2.1 *The polynomials* $P^n(m_1h, m_2h) = \begin{pmatrix} P_0^n(m_1h, m_2h) \\ P_1^n(m_1h, m_2h) \end{pmatrix}$ *with*

$$\begin{aligned} P_0^n &= \sum_{s=0(2)}^{n} \begin{pmatrix} n \\ s \end{pmatrix} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-1} (m_1-k)h \prod_{l=1-s/2}^{s/2} (m_2+l)h \quad \textit{and} \\ P_1^n &= \sum_{s=1(2)}^{n} \begin{pmatrix} n \\ s \end{pmatrix} (-1)^{(s-1)/2} \prod_{k=(s-1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \end{aligned}$$

have in case $n \geq 1$ *the properties*

$$\frac{1}{2} \begin{pmatrix} D_h^{-1} & -D_h^2 \\ D_h^{-2} & D_h^1 \end{pmatrix} \begin{pmatrix} P_0^n(m_1h, m_2h) \\ P_1^n((m_1-1)h, m_2h) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad \textit{and}$$

$$\frac{1}{2} \begin{pmatrix} D_h^1 & D_h^2 \\ -D_h^{-2} & D_h^{-1} \end{pmatrix} \begin{pmatrix} P_0^n(m_1h, m_2h) \\ P_1^n(m_1h, m_2h) \end{pmatrix} = n \begin{pmatrix} P_0^{n-1}(m_1h, m_2h) \\ P_1^{n-1}((m_1-1)h, m_2h) \end{pmatrix}.$$

In this notation D_h^1 *and* D_h^2 *denote forward differences and* D_h^{-1} *and* D_h^{-2} *denote backward differences with respect to the first or second component, respectively. The product of the two matrices leads to the factorization of the discrete Laplacian in the form*

$$D^{1h}\, D^{2h} = \begin{pmatrix} D_h^{-1} & -D_h^2 \\ D_h^{-2} & D_h^1 \end{pmatrix} \begin{pmatrix} D_h^1 & D_h^2 \\ -D_h^{-2} & D_h^{-1} \end{pmatrix} = \begin{pmatrix} \Delta_h & 0 \\ 0 & \Delta_h \end{pmatrix}.$$

Each complex function which fulfill the first property is called discret holomorphic. The second property is the Appell property in the discrete case. For more information about the difference operators which are used here we refer to [3]. A possibility for using the discrete polynomials is discussed in [4].

Before this theorem is proved, the first polynomials are specified in order to illustrate the structure of the them. It is

$$\begin{aligned} P^1(m_1h, m_2h) &= \begin{pmatrix} m_1h \\ m_2h \end{pmatrix} \\ P^2(m_1h, m_2h) &= \begin{pmatrix} m_1h\,(m_1-1)h - m_2h\,(m_2+1)h \\ 2m_1h\,m_2h \end{pmatrix} \\ P^3(m_1h, m_2h) &= \begin{pmatrix} m_1h\,(m_1-1)h\,(m_1-2)h - 3(m_1-1)h\,m_2h\,(m_2+1)h \\ 3m_1h\,(m_1-1)h\,m_2h - (m_2-1)h\,m_2h\,(m_2+1)h \end{pmatrix} \end{aligned}$$

 ISBN: 978-84-608-6082-2

Proof of Theorem 2.1: Having in mind the Appell property, the first component of the left-hand side is considered:

$$\begin{aligned}
&\frac{1}{2}(D_h^1 P_0^n(m_1h, m_2h) + D_h^2 P_1^n(m_1h, m_2h)) \\
= \;& \frac{1}{2h}\left(\sum_{s=0(2)}^{n} \binom{n}{s} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-1} (m_1-(k-1))h \prod_{l=1-s/2}^{s/2} (m_2+l)h \right. \\
& - \sum_{s=0(2)}^{n} \binom{n}{s} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-1} (m_1-k))h \prod_{l=1-s/2}^{s/2} (m_2+l)h \\
& + \sum_{s=1(2)}^{n} \binom{n}{s} (-1)^{(s-1)/2} \prod_{k=(s-1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l+1)h \\
& \left. - \sum_{s=1(2)}^{n} \binom{n}{s} (-1)^{(s-1)/2} \prod_{k=(s-1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \right)
\end{aligned}$$

In case of $s = n$ for the first two summation signs it holds

$$\binom{n}{n} (-1)^{n/2} \prod_{l=1-n/2}^{n/2} (m_2+l)h - \binom{n}{n} (-1)^{n/2} \prod_{l=1-n/2}^{n/2} (m_2+l)h = 0.$$

Therefore it is possible to substitute the upper summation index by $n-1$. Furthermore it is possible to sum up the first two terms by using the property

$$\binom{n}{s} (n-s) = n \binom{n-1}{s}. \tag{1}$$

It follows

$$\begin{aligned}
& \sum_{s=0(2)}^{n-1} \binom{n}{s} (-1)^{s/2} \left(\prod_{k=s/2-1}^{n-s/2-2} (m_1-k)h - \prod_{k=s/2}^{n-s/2-1} (m_1-k)h \right) \prod_{l=1-s/2}^{s/2} (m_2+l)h \\
= \;& \sum_{s=0(2)}^{n-1} \binom{n}{s} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-2} (m_1-k)h \prod_{l=1-s/2}^{s/2} (m_2+l)h \cdot (n-s)h \\
= \;& nh \sum_{s=0(2)}^{n-1} \binom{n-1}{s} (-1)^{s/2} \prod_{k=s/2}^{n-1-s/2-1} (m_1-k)h \prod_{l=1-s/2}^{s/2} (m_2+l)h\,.
\end{aligned}$$

In order to sum up the last two summands the property

$$\binom{n}{s} s = n \binom{n-1}{s-1} \tag{2}$$

 ISBN: 978-84-608-6082-2

is used. This leads to

$$\begin{aligned}
&\sum_{s=1(2)}^{n}\binom{n}{s}(-1)^{(s-1)/2}\prod_{k=(s-1)/2}^{n-s/2-3/2}(m_1-k)h\left(\prod_{l=(1-s)/2+1}^{(s-1)/2+1}(m_2+l)h-\prod_{l=(1-s)/2}^{(s-1)/2}(m_2+l)h\right)\\
=&\sum_{s=1(2)}^{n}\binom{n}{s}(-1)^{(s-1)/2}\prod_{k=(s-1)/2}^{n-s/2-3/2}(m_1-k)h\prod_{l=(3-s)/2}^{(s-1)/2}(m_2+l)h\cdot sh\\
=&\ nh\sum_{s=1(2)}^{n}\binom{n-1}{s-1}(-1)^{(s-1)/2}\prod_{k=(s-1)/2}^{n-s/2-3/2}(m_1-k)h\prod_{l=(3-s)/2}^{(s-1)/2}(m_2+l)h\\
=&\ nh\sum_{s=0(2)}^{n-1}\binom{n-1}{s}(-1)^{s/2}\prod_{k=s/2}^{n-1-s/2-1}(m_1-k)h\prod_{l=1-s/2}^{s/2}(m_2+l)h
\end{aligned}$$

Because both results are equal, it follows

$$\frac{1}{2}(D_h^1P_0^n(m_1h,m_2h)+D_h^2P_1^n(m_1h,m_2h))=n\,P_0^{n-1}(m_1h,m_2h)\,.$$

Now the second component is considered:

$$\begin{aligned}
&\frac{1}{2}(-D_h^{-2}P_0^n(m_1h,m_2h)+D_h^{-1}P_1^n(m_1h,m_2h))\\
=&\ \frac{1}{2h}\left(-\sum_{s=0(2)}^{n}\binom{n}{s}(-1)^{s/2}\prod_{k=s/2}^{n-s/2-1}(m_1-k)h\prod_{l=1-s/2}^{s/2}(m_2+l)h\right.\\
&+\sum_{s=0(2)}^{n}\binom{n}{s}(-1)^{s/2}\prod_{k=s/2}^{n-s/2-1}(m_1-k))h\prod_{l=1-s/2}^{s/2}(m_2+l-1)h\\
&+\sum_{s=1(2)}^{n}\binom{n}{s}(-1)^{(s-1)/2}\prod_{k=(s-1)/2}^{n-s/2-3/2}(m_1-k)h\prod_{l=(1-s)/2}^{(s-1)/2}(m_2+l)h\\
&\left.-\sum_{s=1(2)}^{n}\binom{n}{s}(-1)^{(s-1)/2}\prod_{k=(s-1)/2}^{n-s/2-3/2}(m_1-(k+1))h\prod_{l=(1-s)/2}^{(s-1)/2}(m_2+l)h\right)
\end{aligned}$$

In case of $s=0$ for the first two sums it follows

$$-\binom{n}{0}(-1)^{0/2}\prod_{k=0}^{n-1}(m_1-k)h+\binom{n}{0}(-1)^{0/2}\prod_{k=0}^{n-1}(m_1-k)h=0.$$

Therefore in both sums the lower summation index can be substituted by 2. Furthermore both expressions can be summarized because of property (2) in the following form:

$$\sum_{s=2(2)}^{n}\binom{n}{s}(-1)^{s/2}\prod_{k=s/2}^{n-s/2-1}(m_1-k)h\left(-\prod_{l=1-s/2}^{s/2}(m_2+l)h+\prod_{l=-s/2}^{s/2-1}(m_2+l)h\right)$$

 ISBN: 978-84-608-6082-2

$$
\begin{aligned}
&= \sum_{s=2(2)}^{n} \binom{n}{s} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-1} (m_1-k)h \prod_{l=1-s/2}^{s/2-1} (m_2+l)h \cdot (-s)h \\
&= -nh \sum_{s=2(2)}^{n} \binom{n-1}{s-1} (-1)^{s/2} \prod_{k=s/2}^{n-s/2-1} (m_1-k)h \prod_{l=1-s/2}^{s/2-1} (m_2+l)h \\
&= -nh \sum_{s=1(2)}^{n-1} \binom{n-1}{s} (-1)^{(s+1)/2} \prod_{k=(s+1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \\
&= -nh \sum_{s=1(2)}^{n-1} \binom{n-1}{s} (-1)^{(s+1)/2} \prod_{k=(s-1)/2}^{n-1-s/2-3/2} (m_1-1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h\,.
\end{aligned}
$$

In order to combine the last two summands in the second component the relation (1) is used. In case $s=n$ it holds additionally

$$
\binom{n}{n} (-1)^{(n-1)/2} \prod_{l=(1-n)/2}^{(n-1)/2} (m_2+l)h - \binom{n}{n} (-1)^{(n-1)/2} \prod_{l=(1-n)/2}^{(n-1)/2} (m_2+l)h = 0,
$$

such that the upper summation index can be replaced by $n-1$. These steps leads to

$$
\begin{aligned}
&\sum_{s=1(2)}^{n-1} \binom{n}{s} (-1)^{(s-1)/2} \left(\prod_{k=(s-1)/2}^{n-s/2-3/2} (m_1-k)h - \prod_{k=(s-1)/2+1}^{n-s/2-1/2} (m_1-k)h \right) \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \\
&= \sum_{s=1(2)}^{n-1} \binom{n}{s} (-1)^{(s-1)/2} \prod_{k=(s+1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \cdot (n-s)h \\
&= nh \sum_{s=1(2)}^{n-1} \binom{n-1}{s} (-1)^{(s-1)/2} \prod_{k=(s+1)/2}^{n-s/2-3/2} (m_1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h \\
&= nh \sum_{s=1(2)}^{n-1} \binom{n-1}{s} (-1)^{(s-1)/2} \prod_{k=(s-1)/2}^{n-1-s/2-3/2} (m_1-1-k)h \prod_{l=(1-s)/2}^{(s-1)/2} (m_2+l)h\,.
\end{aligned}
$$

Based on the property $(-1)^{(s+1)/2} = (-1)^{(s-1)/2+1} = -(-1)^{(s-1)/2}$ both results can be added and it follows

$$
\frac{1}{2}(-D_h^{-2} P_0^n(m_1h, m_2h) + D_h^{-1} P_1^n(m_1h, m_2h)) = n\, P_1^{n-1}((m_1-1)h, m_2h).
$$

In this way the Appell property is proved. Repeating all steps adapted to the changed finite differences it is easy to prove that the polynomials considered are discret holomorphic in

 ISBN: 978-84-608-6082-2

the sense of the property

$$\frac{1}{2}\begin{pmatrix} D_h^{-1} & -D_h^2 \\ D_h^{-2} & D_h^1 \end{pmatrix}\begin{pmatrix} P_0^n(m_1h,m_2h) \\ P_1^n((m_1-1)h,m_2h) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad \blacksquare$$

From the last property it follows immediately

$$\begin{aligned} & \frac{1}{4}\begin{pmatrix} D_h^{-1} & -D_h^2 \\ D_h^{-2} & D_h^1 \end{pmatrix}\begin{pmatrix} D_h^1 & D_h^2 \\ -D_h^{-2} & D_h^{-1} \end{pmatrix}\begin{pmatrix} P_0^n(m_1h,m_2h) \\ P_1^n(m_1h,m_2h) \end{pmatrix} \\ = & \frac{n}{2}\begin{pmatrix} D_h^{-1} & -D_h^2 \\ D_h^{-2} & D_h^1 \end{pmatrix}\begin{pmatrix} P_0^{n-1}(m_1h,m_2h) \\ P_1^{n-1}((m_1-1)h,m_2h) \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \end{aligned}$$

Because of the factorization of the discrete Laplacian it is obviously shown that the discrete polynomials are discrete harmonic, too.

The next step is to investigate whether the polynomials are linear independent. In the whole plane it is possible to show that

$$\begin{pmatrix} P_0(m_1h,m_2h) \\ P_1(m_1h,m_2h) \end{pmatrix} := \sum_{i=0}^{n} a_i \begin{pmatrix} P_0^i(m_1h,m_2h) \\ P_1^i(m_1h,m_2h) \end{pmatrix} \equiv \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

holds for all (m_1h,m_2h) only if all a_i with $i=0,\ldots,n$ are identically to zero. Based on the structure of the polynomials it follows

$$\begin{pmatrix} P_0(0,0) \\ P_1(0,0) \end{pmatrix} = \begin{pmatrix} a_0 \\ 0 \end{pmatrix}.$$

Consequently, only in case of $a_0=0$ the real part is equal to zero. Using the Appell property of the polynomials and a small correction concerning the difference operator in order to do the transition from the mesh point $((m_1-1)h,m_2h)$ to the mesh point (m_1h,m_2h), it is easy to see that the identity

$$\begin{aligned} & \frac{1}{2}\begin{pmatrix} D_h^1 & D_h^2 \\ -D_h^{-2}-hD_h^1D_h^{-2} & D_h^{-1}+hD_h^1D_h^{-1} \end{pmatrix}\begin{pmatrix} P_0(m_1h,m_2h) \\ P_1(m_1h,m_2h) \end{pmatrix} \\ = & \sum_{i=0}^{n} ia_i \begin{pmatrix} P_0^{i-1}(m_1h,m_2h) \\ P_1^{i-1}(m_1h,m_2h) \end{pmatrix} \equiv \begin{pmatrix} 0 \\ 0 \end{pmatrix} \end{aligned}$$

in the mesh point $(m_1h,m_2h)=(0,0)$ is only fulfilled if $a_1=0$ holds. By repeated application of the modified difference operator it can be shown that for all a_i, $i=0,\ldots,n$ the identity $a_i=0$ must be fulfilled.

From the continuous case it is well-known that polynomials can not only be developed according to powers of z, but also according to powers of $z-z_0$, where z_0 is an arbitrary

 ISBN: 978-84-608-6082-2

fixed complex number. In the following this strategy is transferred to the discrete case. Let $N = N_1 \cdot N_2$. For a fixed degree of polynomials $n = N - 1$ the identity

$$\sum_{n_1=1}^{N_1} \sum_{n_2=1}^{N_2} a_{n_1,n_2} \begin{pmatrix} P_0^n((m_1-n_1)h,(m_2-n_2)h) \\ P_1^n((m_1-n_1)h,(m_2-n_2)h) \end{pmatrix} \equiv \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

is investigated. It is possible to add n further equations by applying step by step the modified difference operator

$$\frac{1}{2} \begin{pmatrix} D_h^1 & D_h^2 \\ -D_h^{-2} - hD_h^1 D_h^{-2} & D_h^{-1} + hD_h^1 D_h^{-1} \end{pmatrix}.$$

Based on the Appell property the degree of the polynomial decreases from equation to equation. The whole equation system can be written in matrix representation with complex elements. Because the right-hand side is in each component equal to zero, all coefficients a_{n_1,n_2} have to be zero if the matrix of the polynomials has a determinant different from zero. Therefore the structure of the matrix is to be investigated in more detail. By transposing the matrix it becomes obviously that it is a Vandermonde matrix. By investigating the column vectors of the transposed matrix it is possible to show that these column vectors are linear independent. Therefore a linear combination of the column vectors is formed and the resulting problem is considered line by line. In each line, polynomials of ascending degree are located in one and the same lattice point. For these polynomials, the linear independence has been shown already, so that the linear independence of the column vectors follows directly from this property.

3 Diskrete Exponential,- Sinus- und Cosinusfunktionen

In order to discretize the exponential function the investigations start with the one-dimensional case. The aim is to find a function, which difference derivation is the function themselve.

Lemma 3.1 *In the one-dimensional case it holds*

$$D_h^1(1+h)^{m_1} = (1+h)^{m_1} \qquad D_h^{-1}(1-h)^{-m_1} = (1-h)^{-m_1}$$
$$D_h^1(1-h)^{m_1} = -(1-h)^{m_1} \qquad D_h^{-1}(1+h)^{-m_1} = -(1+h)^{-m_1}.$$

Proof: The steps of the proof are demonstrated for the first equation. All other relations are proved in the same way. Using the definition of forward differences it holds

$$D_h^1(1+h)^{m_1} = h^{-1}[(1+h)^{m_1+1} - (1+h)^{m_1}] = h^{-1}(1+h)^{m_1}(1+h-1) = (1+h)^{m_1} \quad \blacksquare$$

 ISBN: 978-84-608-6082-2

The function $(1+h)^{m_1}$ considered in Lemma 3.1 is now studied in more detail. Using the binomial theorem it follows

$$\begin{aligned}(1+h)^{m_1} &= \sum_{k=0}^{m_1} \left(\begin{array}{c} m_1 \\ k \end{array} \right) h^k \\ = \quad 1 + m_1 h + \frac{m_1 h \cdot (m_1-1)h}{2!} &+ \frac{m_1 h \cdot (m_1-1)h \cdot (m_1-2)h}{3!} + \ldots + m_1 h^{m_1-1} + h^{m_1}.\end{aligned}$$

On the other hand the exponential function in the continuous case can be developed into the infinit series $e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots$. Therefore it is obviously to consider polynomials of the form

$$x_+^n = \prod_{k=0}^{n-1} (m_1 - k)\, h.$$

These polynomials have the property $D_h^1\, x_+^n = n\, x_+^{n-1}$, since

$$\begin{aligned} D_h^1\, x_+^n &= \frac{1}{h} \left(\prod_{k=0}^{n-1} (m_1 + 1 - k)\, h - \prod_{k=0}^{n-1} (m_1 - k)\, h \right) \\ &= \frac{1}{h} \left(\prod_{k=0}^{n-1} (m_1 - (k-1))\, h - \prod_{k=0}^{n-1} (m_1 - k)\, h \right) \\ &= \frac{1}{h} \left(\prod_{k=-1}^{n-2} (m_1 - k)\, h - \prod_{k=0}^{n-1} (m_1 - k)\, h \right) \\ &= \frac{1}{h} \left(\prod_{k=0}^{n-2} (m_1 - k)\, h \right) \Big((m_1+1)h - (m_1 - (n-1))h \Big) \\ &= \frac{1}{h} \cdot x_+^{n-1} \cdot n \cdot h\ . \end{aligned}$$

In analogy to this strategy it is possible by using polynomials of the form

$$x_-^n = \prod_{k=0}^{n-1} (m_1 + k)\, h$$

to prove the property

$$\begin{aligned} D_h^{-1}\, x_-^n &= \frac{1}{h} \left(\prod_{k=0}^{n-1} (m_1 + k)\, h - \prod_{k=0}^{n-1} (m_1 - 1 + k)\, h \right) \\ &= \frac{1}{h} \left(\prod_{k=0}^{n-1} (m_1 + k)\, h - \prod_{k=-1}^{n-2} (m_1 + k)\, h \right) \end{aligned}$$

 ISBN: 978-84-608-6082-2

$$\begin{aligned} &= \frac{1}{h}\left(\prod_{k=0}^{n-2}(m_1+k)\,h\right)\Big((m_1+(n-1))h-(m_1-1)h\Big) \\ &= n\cdot x_-^{n-1}\,. \end{aligned}$$

With regard to the note in the introduction the here mentioned polynomials were already studied by Faustino und Kähler in [2]. They were the basis for the construction of the discrete holomorphic polynomials in Theorem 2.1.

The question is how to find a discret holomorphic exponential function in the complex case by using the information from the one-dimensional case. In detail the one-dimensional case should be generalized so that the following two properties remain intact: On the one hand side the function should be discret holomorphic. Using the notation from section 2 we are looking for a function $\mathrm{EXP}_h(m_1h,m_2h)=\begin{pmatrix}\mathrm{EXP}_h^0(m_1h,m_2h)\\ \mathrm{EXP}_h^1(m_1h,m_2h)\end{pmatrix}$ with the property

$$D^{1h}\,\mathrm{EXP}_h=0.$$

On the other hand the complex derivation of the function should return the function itself. Based on the information that the operator D^{2h} converges to $\left(\frac{\partial}{\partial x}-\mathbf{i}\frac{\partial}{\partial y}\right)$ and looking at the definition $\partial_z=\frac{1}{2}\left(\frac{\partial}{\partial x}-\mathbf{i}\frac{\partial}{\partial y}\right)$ the desired discrete function should have the property

$$\frac{1}{2}\,D^{2h}\,\mathrm{EXP}_h=\mathrm{EXP}_h.$$

The function described in the following theorem essentially satisfies these requirements, even if some neighboring grid points are included.

Theorem 3.1 *The function* $EXP_h(m_1h,m_2h)$ *with*

$$\begin{aligned} EXP_h^0(m_1h,m_2h) &= \frac{1}{2}(1+h)^{m_1-1}[(1+\mathbf{i}h)^{m_2+1}+(1-\mathbf{i}h)^{m_2+1}] \\ EXP_h^1(m_1h,m_2h) &= \frac{1}{2\mathbf{i}}(1+h)^{m_1}[(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}] \end{aligned}$$

has the properties

$$\begin{aligned} D_h^{-1}EXP_h^0((m_1+1)h,(m_2-1)h)-D_h^2EXP_h^1((m_1-1)h,m_2h) &= 0 \\ D_h^{-2}EXP_h^0(m_1h,m_2h)+D_h^1EXP_h^1((m_1-1)h,m_2h) &= 0 \end{aligned}$$

and

$$\begin{aligned} &\frac{1}{2}D_h^1EXP_h^0(m_1h,m_2h)+\frac{1}{2}D_h^2EXP_h^1(m_1h,m_2h) \\ =\;&\frac{1}{2}[EXP_h^0(m_1h,m_2h)+EXP_h^0((m_1+1)h,(m_2-1)h)] \end{aligned}$$

 ISBN: 978-84-608-6082-2

as well as

$$-\frac{1}{2}D_h^{-2}EXP_h^0((m_1+1)h,m_2h)+\frac{1}{2}D_h^{-1}EXP_h^1((m_1+1)h,m_2h)=EXP_h^1(m_1h,m_2h).$$

Proof: With regard to the first property it holds

$$\begin{aligned}
& D_h^{-1}\mathrm{EXP}_h^0((m_1+1)h,(m_2-1)h)-D_h^2\mathrm{EXP}_h^1((m_1-1)h,m_2h)\\
= \;& \frac{1}{2h}[(1+h)^{m_1}-(1+h)^{m_1-1}][(1+\mathbf{i}h)^{m_2}+(1-\mathbf{i}h)^{m_2}]\\
& -\frac{1}{2\mathbf{i}h}(1+h)^{m_1-1}[(1+\mathbf{i}h)^{m_2+1}-(1-\mathbf{i}h)^{m_2+1}-(1+\mathbf{i}h)^{m_2}+(1-\mathbf{i}h)^{m_2}]\\
= \;& \frac{1}{2h}(1+h)^{m_1-1}(1+h-1)[(1+\mathbf{i}h)^{m_2}+(1-\mathbf{i}h)^{m_2}]\\
& -\frac{1}{2\mathbf{i}h}(1+h)^{m_1-1}[(1+\mathbf{i}h)^{m_2}(1+\mathbf{i}h-1)+(1-\mathbf{i}h)^{m_2}(-1+\mathbf{i}h+1)]\\
= \;& 0.
\end{aligned}$$

The second property results from

$$\begin{aligned}
& D_h^{-2}\mathrm{EXP}_h^0(m_1h,m_2h)+D_h^1\mathrm{EXP}_h^1((m_1-1)h,m_2h)\\
= \;& \frac{1}{2h}(1+h)^{m_1-1}[(1+\mathbf{i}h)^{m_2+1}+(1-\mathbf{i}h)^{m_2+1}-(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}]\\
& +\frac{1}{2\mathbf{i}h}[(1+h)^{m_1}-(1+h)^{m_1-1}][(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}]\\
= \;& \frac{1}{2h}(1+h)^{m_1-1}[(1+\mathbf{i}h)^{m_2}((1+\mathbf{i}h-1)-(1-\mathbf{i}h)^{m_2}(-1+\mathbf{i}h+1)]\\
& +\frac{1}{2ih}(1+h)^{m_1-1}(1+h-1)[(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}]\\
= \;& 0.
\end{aligned}$$

Now the third term is investigated. It follows

$$\begin{aligned}
& \frac{1}{2}D_h^1\mathrm{EXP}_h^0(m_1h,m_2h)+\frac{1}{2}D_h^2\mathrm{EXP}_h^1(m_1h,m_2h)\\
= \;& \frac{1}{4h}[(1+h)^{m_1}-(1+h)^{m_1-1}][(1+\mathbf{i}h)^{m_2+1}+(1-\mathbf{i}h)^{m_2+1}]\\
& +\frac{1}{4\mathbf{i}h}(1+h)^{m_1}[(1+\mathbf{i}h)^{m_2+1}-(1-\mathbf{i}h)^{m_2+1}-(1+\mathbf{i}h)^{m_2}+(1-\mathbf{i}h)^{m_2}]\\
= \;& \frac{1}{4h}(1+h)^{m_1-1}(1+h-1)[[(1+\mathbf{i}h)^{m_2+1}+(1-\mathbf{i}h)^{m_2+1}]\\
& +\frac{1}{4\mathbf{i}h}(1+h)^{m_1}[(1+\mathbf{i}h)^{m_2}((1+\mathbf{i}h-1)+(1-\mathbf{i}h)^{m_2}(-1+\mathbf{i}h+1)].
\end{aligned}$$

 ISBN: 978-84-608-6082-2

Finally the last property is considered.

$$\begin{aligned}
& -\frac{1}{2}D_h^{-2}\mathrm{EXP}_h^0((m_1+1)h,m_2h)+\frac{1}{2}D_h^{-1}\mathrm{EXP}_h^1((m_1+1)h,m_2h)\\
= \;& \frac{1}{4h}(1+h)^{m_1}[-(1+\mathbf{i}h)^{m_2+1}-(1-\mathbf{i}h)^{m_2+1}+(1+\mathbf{i}h)^{m_2}+(1-\mathbf{i}h)^{m_2}]\\
& +\frac{1}{4\mathbf{i}h}[(1+h)^{m_1+1}-(1+h)^{m_1}][(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}]\\
= \;& \frac{1}{4h}(1+h)^{m_1}[(1+\mathbf{i}h)^{m_2}(-1-\mathbf{i}h+1)-(1-\mathbf{i}h)^{m_2}(1-\mathbf{i}h-1)]\\
& +\frac{1}{4\mathbf{i}h}(1+h)^{m_1}(1+h-1)[(1+\mathbf{i}h)^{m_2}-(1-\mathbf{i}h)^{m_2}] \quad \blacksquare
\end{aligned}$$

In the second part of this section we look for a discretization of the sine and cosine function. Again we start with the one-dimensional case. Using the relations $\cos(x)=\frac{1}{2}(e^{\mathbf{i}x}+e^{-\mathbf{i}x})$ and $\sin(x)=\frac{1}{2\mathbf{i}}(e^{\mathbf{i}x}-e^{-\mathbf{i}x})$ the discrete sine and cosine functions investigated in the following lemma were obtained.

Lemma 3.2 *The discrete functions* $\cos_h^+(m_1h)=\frac{1}{2}[(1+\mathbf{i}h)^{m_1}+(1-\mathbf{i}h)^{m_1}]$ *and* $\sin_h^+(m_1h)=\frac{1}{2\mathbf{i}}[(1+\mathbf{i}h)^{m_1}-(1-\mathbf{i}h)^{m_1}]$ *have the properties*

$$\begin{aligned}
& D_h^1\,D_h^1\,\cos_h^+(m_1h)=-D_h^1\sin_h^+(m_1h)=-\cos_h^+(m_1h) \quad \textit{and}\\
& D_h^1\,D_h^1\,\sin_h^+(m_1h)=D_h^1\cos_h^+(m_1h)=-\sin_h^+(m_1h).
\end{aligned}$$

On the other hand for functions $\cos_h^-(m_1h)=\frac{1}{2}[(1-\mathbf{i}h)^{-m_1}+(1+\mathbf{i}h)^{-m_1}]$ *and* $\sin_h^-(m_1h)=\frac{1}{2\mathbf{i}}[(1-\mathbf{i}h)^{-m_1}-(1+\mathbf{i}h)^{-m_1}]$ *it follows*

$$\begin{aligned}
& D_h^{-1}\,D_h^{-1}\,\cos_h^-(m_1h)=-D_h^{-1}\sin_h^-(m_1h)=-\cos_h^-(m_1h) \quad \textit{and}\\
& D_h^{-1}\,D_h^{-1}\,\sin_h^-(m_1h)=D_h^{-1}\cos_h^-(m_1h)=-\sin_h^-(m_1h).
\end{aligned}$$

Additionally it is possible to prove

$$\begin{aligned}
(\cos_h^+(m_1h))^2+(\sin_h^+(m_1h))^2 &= (1+h^2)^{m_1}\\
(\cos_h^-(m_1h))^2+(\sin_h^-(m_1h))^2 &= (1+h^2)^{-m_1}\,,
\end{aligned}$$

where the right-hand sides converges to one for $h\to 0$ *and the product of both left-hand sides gives exactly one.*

The proof of Lemma 3.2 as well as the proof of Lemma 3.1 is based on straight forward calculations using forward and backward differences. Now it is possible to explain the origin of the complex exponential function in Theorem 3.1. It is based on the equation $e^z=e^{x+\mathbf{i}y}=e^x(\cos(x)+\mathbf{i}\sin(x))$.

 ISBN: 978-84-608-6082-2

Fortunately, using the relation

$$\cos z = \frac{1}{2}(e^{\mathbf{i}z} + e^{-\mathbf{i}z})) = \frac{1}{2}(e^{\mathbf{i}x-y} + e^{-\mathbf{i}x+y}) = \frac{1}{2}(e^{y} + e^{-y})\cos x + \frac{\mathbf{i}}{2}(e^{-y} - e^{y})\sin x$$

in the complex case, a discrete cosine function $\mathrm{COS}_h(m_1h, m_2h) = \begin{pmatrix} \mathrm{COS}_h^0(m_1h, m_2h) \\ \mathrm{COS}_h^1(m_1h, m_2h) \end{pmatrix}$ can be defined. Even in the special combination of the grid points, the function fits excellently with the exponential function in Theorem 3.1. By applying the operator $\frac{1}{2}D^{2h}$ the correspon-ding discrete sine function $\mathrm{SIN}_h(m_1h, m_2h)$ is explained.

Theorem 3.2 *The function $COS_h(m_1h, m_2h)$ with*

$$\begin{aligned} COS_h^0(m_1h, m_2h) &= \frac{1}{4}[(1-h)^{m_2+1} + (1+h)^{m_2+1}][(1+\mathbf{i}h)^{m_1-1} + (1-\mathbf{i}h)^{m_1-1}] \\ COS_h^1(m_1h, m_2h) &= \frac{1}{4\mathbf{i}}[(1-h)^{m_2} - (1+h)^{m_2}][(1+\mathbf{i}h)^{m_1} - (1-\mathbf{i}h)^{m_1}] \end{aligned}$$

has the properties

$$\begin{aligned} D_h^{-1}COS_h^0((m_1+1)h, (m_2-1)h) - D_h^2 COS_h^1((m_1-1)h, m_2h) &= 0 \\ D_h^{-2}COS_h^0(m_1h, m_2h) + D_h^1 COS_h^1((m_1-1)h, m_2h) &= 0 \end{aligned}$$

and

$$\frac{1}{2}\,D^{2h}COS_h(m_1h, m_2h) = -\begin{pmatrix} \frac{1}{2}[SIN_h^0(m_1h, m_2h) + SIN_h^0((m_1+1)h, (m_2-1)h] \\ SIN_h^1((m_1-1)h, m_2h) \end{pmatrix}$$

with

$$\begin{aligned} SIN_h^0(m_1h, m_2h) &= \frac{1}{4\mathbf{i}}[(1+h)^{m_2+1} + (1-h)^{m_2+1}][(1+\mathbf{i}h)^{m_1-1} - (1-\mathbf{i}h)^{m_1-1}] \\ SIN_h^1(m_1h, m_2h) &= \frac{1}{4}[(1+h)^{m_2} - (1-h)^{m_2}][(1+\mathbf{i}h)^{m_1} + (1-\mathbf{i}h)^{m_1}]\,. \end{aligned}$$

Conversely, the equations

$$\begin{aligned} D_h^{-1}SIN_h^0((m_1+1)h, (m_2-1)h) - D_h^2 SIN_h^1((m_1-1)h, m_2h) &= 0 \\ D_h^{-2}SIN_h^0(m_1h, m_2h) + D_h^1 SIN_h^1((m_1-1)h, m_2h) &= 0 \end{aligned}$$

and

$$\frac{1}{2}\,D^{2h}SIN_h(m_1h, m_2h) = \begin{pmatrix} \frac{1}{2}[COS_h^0(m_1h, m_2h) + COS_h^0((m_1+1)h, (m_2-1)h)] \\ COS_h^1((m_1-1)h, m_2h) \end{pmatrix}$$

are fulfilled. When using the operator D^{2h}, there is only one shift in the two summands in the first component concerning the lattice points, which prevents a summation.

 ISBN: 978-84-608-6082-2

The proof of Theorem 3.2 is entirely analogous to the proof steps of Theorem 3.1.

In addition it is possible to get results like

$$\begin{aligned} & \frac{1}{4} D^{2h} D^{2h} \mathrm{SIN}_h(m_1 h, m_2 h) \\ = & \begin{pmatrix} -\mathrm{SIN}_h^0(m_1 h, (m_2-1)h) + O(h) \\ -\mathrm{SIN}_h^1((m_1-2)h, (m_2-1)h) + O(h) \end{pmatrix}. \end{aligned}$$

By the help of the discrete holomorphic functions a tool is created which is very helpful for the solution of difference equations. For instance the discrete exponential function can be used to extend the theory of discrete Cauchy-Riemann operators in the sense of Vekua. The next step can be the generalization of the results in the complex case to the hypercomplex case.

Abstract

In this paper we obtain some theoretical results about iterative methods with memory for nonlinear equations. The main idea consists of using for the predictor step of each iteration a quantity that has already been calculated in the previously, usually the quantity governing the slope from the previous corrector step. In this way we do not introduce any extra computation, and more importantly we avoid new functional evaluations, allowing us to obtain high iterative methods in a simple way. A specific class of methods of this type is introduced, and we prove that the convergence order is $2^n + 2^{n-2}$ with $n + 1$ functional evaluations. Finally, an exhaustive efficiency study is performed to show the competitiveness of these methods.

Key words: Iterative methods with memory, convergence rate, efficiency, Kung-Traub conjecture.

MSC 2000: 47H99, 65H10, 65B05, 47H17, 49M15.

1 Introduction

Nonlinear equations appear in a natural way in many applications of science and engineering. The solutions are typically approximated via iterative methods. Newton's method and other "simple" techniques are common, and historically have been sufficient. However, nowadays high-order methods are very important, as many scientific applications (astronomy, climate

simulations, etc.) need high precision in their computations. These methods allow getting the required precession without a significant increase of the number of iterations.

The convergence order of an iterative method is directly related with the efficiency in the sense of the conjecture of Kung-Traub, [3], which states that a method without memory that uses $n+1$ function evaluations per iterate can have a convergence rate of at most 2^n.

This paper focuses on the consequences of memory reuse rather than just using the historical points in new ways. It is well known that iterative methods with memory can surpass the Kung-Traub conjecture, but often the computational cost of obtaining high-order methods is very expensive. Therefore we concentrate in this work on trying to use memory to obtain a high-order of convergence, but without introducing extra computation to the iterative expression.

Our idea in this work is to simplify this cost by constructing high-order methods in a way that the iterative expression remains as simple as possible. We use the idea of using for the predictor step of each iteration a quantity that has already been calculated in the previous iteration. While high-order methods are important, the operational cost of getting them must also be taken into account. For this reason an exhaustive efficiency study is performed to show the effectiveness of these methods.

2 Predictor-Corrector iterative methods

While Newton's Method is one of the most popular root-finding algorithms due both to its simplicity and its quadratic rate of convergence, many more powerful methods exist with faster convergence rates. The methods of derivation for these powerful methods often result in implicit equations. For example, if one integrates $f'(x)$ between the current iterate and the (unknown) root, $\int_{x_n}^{\alpha} f'(x)dx = -f(x_n)$ and apply the Midpoint Rule to the integral, we get $f'(\frac{1}{2}[x_n+\alpha])(\alpha - x_n) \approx -f(x_n)$, which can be rearranged into the implicit equation $\alpha \approx x_n - \dfrac{f(x_n)}{f'(\frac{1}{2}[x_n+\alpha])}$. These equations are typically applied algorithmically as a predictor-corrector set ([1]-[2]); for example,

$$\begin{aligned} y_n &= x_n - f(x_n)\Psi(x_n) \\ x_{n+1} &= x_n - \frac{f(x_n)}{f'(\frac{1}{2}[x_n+y_n])} \end{aligned} \tag{1}$$

for some function Ψ. It is common to use Newton's Method for the predictor step,

$$\begin{aligned} y_n &= x_n - \frac{f(x_n)}{f'(x_n)} \\ x_{n+1} &= x_n - f(x_n)\Phi(x_n, y_n). \end{aligned} \tag{2}$$

 ISBN: 978-84-617-8694-7

In this sense, one could view this type of algorithm as Newton's Method with a corrective factor. We would like to use for the predictor step a quantity that has already been calculated, namely $\Phi(x_{n-1}, y_{n-1})$, that is the quantity governing the slope from the previous corrector step.

$$\begin{aligned} y_n &= x_n - f(x_n)\Phi(x_{n-1}, y_{n-1}) \\ x_{n+1} &= x_n - f(x_n)\Phi(x_n, y_n). \end{aligned} \tag{3}$$

This type of method will be referred to as the *Standard 2-step Predictor-Corrector* algorithm, denoted by SA.

We again consider the effect of incorporating the previous slope into the predictor step

$$\begin{aligned} y_n &= x_n - f(x_n)\Phi(x_{n-1}, y_{n-1}) \\ x_{n+1} &= y_n - f(y_n)\Phi(x_n, y_n), \end{aligned} \tag{4}$$

and refer to this as the *Improved 2-step Predictor-Corrector* algorithm, denoted by IA. This can be further expanded into an *Improved multi-step Predictor-Corrector* algorithm with a similar scheme.

3 Convergence Analysis

We begin by establishing convergence results for the two-step predictor-corrector iterative schemes previously defined to locate a zero $x = \alpha$ of $f(x)$. Define the error terms $\varepsilon_n = x_n - \alpha$ and $\varepsilon_n^* = y_n - \alpha$ for all n. The sequence $\{x_n\}_{n=0}^{\infty}$ is said to converge to $x = \alpha$ with *rate of convergence* ρ if $\lim\limits_{n\to\infty} \dfrac{|\varepsilon_{n+1}|}{|\varepsilon_n|^\rho} = \lambda$ for positive constants ρ, λ. The relationship between ε_{n+1} and ε_n can therefore be written $\varepsilon_{n+1} = A_n\varepsilon_n^\rho + h.o.t.$ where $A_n \to \lambda$ as $n \to \infty$ and $h.o.t.$ denotes *higher-order terms* which satisfy $\lim\limits_{n\to\infty} \dfrac{h.o.t.}{\varepsilon_n^\rho} = 0$. This relationship will be denoted by $\varepsilon_{n+1} \sim \varepsilon_n^\rho$.

Theorem 1. *Suppose that the error condition for the corrector step of the Standard 2-step Predictor-Corrector algorithm is given by $\varepsilon_{n+1} \sim \varepsilon_n^p(\varepsilon_n^*)^q$, with p and q real positive numbers, and that f is sufficiently differentiable. Then the convergence rate for the algorithm is given by $\rho = \dfrac{p + q + \sqrt{(p+q)^2 + 4q}}{2}$.*

 ISBN: 978-84-617-8694-7

3.1 Applying theorem 1 to the Midpoint method with memory

We consider the Midpoint Method with memory, denoted by MP, derived at the beginning of Section 2. It is given by:

$$y_n = x_n - \frac{f(x_n)}{f'(\frac{1}{2}[x_{n-1} + y_{n-1}])}$$
$$x_{n+1} = x_n - \frac{f(x_n)}{f'(\frac{1}{2}[x_n + y_n])}. \tag{5}$$

This is a Standard 2-step Predictor-Corrector algorithm. The error relationship from the corrector step is derived in [5] and shown to be $\varepsilon_{n+1} \sim \varepsilon_n \varepsilon_n^*$, so that $p = q = 1$. Therefore the rate of convergence is $\rho = \dfrac{1 + 1 + \sqrt{(1+1)^2 + 4}}{2} = 1 + \sqrt{2} \approx 2.414$.

Theorem 2. *Suppose that the error condition for the corrector step of the Improved 2-step Predictor-Corrector algorithm is given by $\varepsilon_{n+1} \sim \varepsilon_n^p (\varepsilon_n^*)^q$, with p and q real positive numbers, and f is sufficiently differentiable. Then the convergence rate for the algorithm, denoted by IA, is given by $\rho = \dfrac{(p+q+1) + \sqrt{(p+q+1)^2 - 4p}}{2}$.*

3.2 Efficiency Indices

The *efficiency index* of an iterative algorithm as defined in [2] measures the balance between the rate of convergence (ρ) and the number of functional evaluations (m) required per iterate, and is defined by $EI = \rho^{1/m}$. Obviously methods are preferable when they have a higher efficiency index.

The algorithms stated in the previous section, SA and IA, have slower convergence order than their Newton analogs, NP. These algorithms reuse conveniently the predictor step, resulting in one fewer functional evaluation and surpassing the optimal convergence rate stated by the Kung-Traub conjecture.

The following theorem addresses the efficiency of the respective algorithms.

Theorem 3. *Suppose one iterative scheme has convergence rate ρ_1, requiring m functional evaluations per iterate, while a second iterative scheme has convergence rate ρ_2 with $1 < \rho_2 < \rho_1$, requiring $m - 1$ functional evaluations per iterate. The efficiency index of the second scheme is greater than the first scheme for $m < \dfrac{\ln(\rho_1)}{\ln(\rho_1) - \ln(\rho_2)}$.*

According to this Theorem, the Standard 2-step Predictor-Corrector is more efficient than its Newton analog when:

$$m < \frac{\ln(p+2q)}{\ln\left(\frac{2(p+2q)}{p+q+\sqrt{(p+q)^2+4q}}\right)},$$

 ISBN: 978-84-617-8694-7

while the Improved 2-step Predictor-Corrector is more efficient than its Newton analog when:

$$m < \frac{\ln(p+2q)}{\ln\left(\frac{2(p+2q)}{p+q+1\sqrt{(p+q+1)^2-4p}}\right)}.$$

Next we consider the convergence rate of the Improved multi-step Predictor-Corrector (IMS).

Theorem 4. *Suppose that the error conditions for the predictor steps* $(1),...,(k)$ *of the Improved k-step Predictor-Corrector algorithm are given by* $\varepsilon_n^{(\ell)} \sim \varepsilon_n^{r_\ell}(\varepsilon_n^{(0)})^{s_\ell}$*, that of the corrector step is given by* $\varepsilon_{n+1} \sim \varepsilon_n^p(\varepsilon_n^{(0)}))^q$*, and that* f *is sufficiently differentiable. Then the convergence rate for the algorithm is given by:*

$$\rho = \frac{(p+q+s_k) \pm \sqrt{(p+q+s_k)^2 - 4(ps_k - qr_k)}}{2}.$$

4 Proposed iterative methods

In this section we propose a new multistep algorithm that utilizes the idea that we have introduced in the previous sections, that is, to use the prior corrector slope for the current first predictor slope.

We consider the ZLH (Zheng-Li-Huang) family presented in [7]. The family uses $n+1$ points $(y_k^{(-1)}, y_k^{(0)}, \cdots, y_k^{(n-1)})$, utilizes $n+1$ function evaluations per iterate, and is shown to have the optimal convergence rate of 2^n. However, the algorithm that we propose interchanges the roles of $y_k^{(-1)}$and $y_k^{(0)}$ and reuses the slope from the previous corrector step to obtain the first step in a new iteration. This modification introduces memory into the expression, and this algorithm is shown in the following proof to have a convergence rate of $2^n + 2^{n-2}$ by using the same number of functional evaluations per iterate than that of the ZLH family. The function iteration for the proposed algorithm, (OP), has $n-1$ intermediate steps and is given by:

$$\begin{aligned}
y_k^{(0)} &= x_k - \frac{f(x_k)}{P'_{k-1,n-1}(y_k^{(n-1)})}, \qquad y_k^{(-1)} = x_k \\
y_k^{(\ell+1)} &= y_k^{(\ell)} - \frac{f(y_k^{(\ell)})}{P'_{k,\ell}(y_k^{(\ell)})}, \quad \ell = 0,1,...,n-2 \\
x_{k+1} &= y_k^{(n-1)} - \frac{f(y_k^{(n-1)})}{P'_{k,n-1}(y_k^{(n-1)})}.
\end{aligned} \tag{6}$$

 ISBN: 978-84-617-8694-7

Obviously we need for the first iteration a starting guess x_0 and a constant value for $P'_{0,n-1}(y_0^{(n-1)})$. The following theorem uses the result of Theorem 3 to obtain the convergence rate.

Theorem 5. *Suppose that α is a simple root of $f(x)$. Then the numerical algorithm outlined in equations (6), denoted by OP, has order of convergence $2^n + 2^{n-2}$, provided the method is convergent.*

4.1 An exhaustive efficiency study

It is preceptive in a new proposal to compare our methods with already existing methods exhibiting similar characteristics in order to show their efficiency. In this sense we cite a very interesting paper due to Džunić and Petković, see [6], and compare our proposed methods with theirs. In [6] the authors perform a complete study about iterative methods with memory by using Newton's interpolating polynomials, considering biparametric multipoint methods with the following form:

$$\begin{aligned} y_k^{(0)} &= x_k \\ y_k^{(1)} &= x_k + \gamma f(x_k) \\ y_k^{(2)} &= x_k - \frac{f(x_k)}{f[x_k, y_k^{(1)}] + pf(y_k^{(1)})} \\ y_k^{(\ell+1)} &= y_k^{(\ell)} - \frac{f(y_k^{(\ell)})}{P'_{k,\ell}(y_k^{(\ell)})}, \quad \ell = 1, ..., n-2 \\ x_{k+1} &= y_k^{(n-1)} - \frac{f(y_k^{(n-1)})}{P'_{k,n-1}(y_k^{(n-1)})} \end{aligned} \tag{7}$$

From this multipoint method are obtained two different families with memory. In the first one, denoted by $DP1$, it is shown that if $\gamma = \dfrac{-1}{f'(\alpha)}$, then the rate of convergence increases to $2^n + 2^{n-1}$.

The second parameter p can also be approximated by using historical data in order to increase the convergence order of the iterative method to $2^n + 2^{n-1} + 2^{n-2}$. The method obtained, denoted by $DP2$, is written as:

 ISBN: 978-84-617-8694-7

$$
\begin{aligned}
y_k^{(0)} &= x_k, \quad \gamma_k = \frac{-1}{N'_m(y_k^{(0)})} \\
y_k^{(1)} &= x_k + \gamma_k f(x_k), \quad p_k = \frac{-N''_{m+1}(y_k^{(0)})}{2N'_{m+1}(y_k^{(0)})} \\
y_k^{(2)} &= x_k - \frac{f(x_k)}{f[x_k, y_k^{(1)}] + p_k f(y_k^{(1)})} \\
y_k^{(\ell+1)} &= y_k^{(\ell)} - \frac{f(y_k^{(\ell)})}{P'_{k,\ell}(y_k^{(\ell)})}, \quad \ell = 1, ..., n-2 \\
x_{k+1} &= y_k^{(n-1)} - \frac{f(y_k^{(n-1)})}{P'_{k,n-1}(y_k^{(n-1)})}
\end{aligned} \tag{8}
$$

where $N'_{m+1}(y_k^{(0)})$ and $N''_{m+1}(y_k^{(0)})$ denote the evaluation in $y_k^{(0)}$ of the derivatives for the Newton interpolatory polynomial of degree $m+1$ based on two points of the new iteration and $m = n+1$ points of previous iteration. Obviously the iterative methods with memory, OP, $DP1$ and $DP2$, derived from the optimal iterative method without memory, ZLH, perform the same number of functional evaluations, $n+1$, so the corresponding efficiency indices, EI, increases when the order increases.

However, for high-order methods one can also take into account the computational efficiency, CE ([4]), which is defined in terms of the number of operations performed per iteration (N), specifically products and quotients, for a method with order of convergence ρ. It is obtained by $CE = \rho^{1/N}$.

In order to obtain these values we recall the number of products and quotients that the iterative methods OP, $DP1$ and $DP2$ perform per iteration. We have taken into account the information for obtaining polynomials of degree $n-1$ in order to obtain polynomials of degree n, which takes $n(n+1)/2$, plus the number of operations for computing its derivative if it is needed. Our proposed method has better computational efficiency for different values of n than methods $DP1$ and $DP2$.

For completing the efficiency study we have to analyze the total cost of computing a root, because normally high-order methods perform less iterations than a method with lower convergence order. We obtain the computational efficiency by taking into account the number of iterations performed (k) as well as the work performed per iterate (N). We define the total computational efficiency as $TCE = \rho^{\frac{1}{kN}}$.

In these terms we consider the following question: how many fewer iterations must be performed for the iterative methods $DP1$ and $DP2$ to be more efficient than OP?. We prove the following result that establish the relation between the total computational effi-

 ISBN: 978-84-617-8694-7

ciency for the methods of the previous sections.

Theorem 6. *Suppose one iterative scheme has convergence rate ρ_1, requiring k iterations for reaching the solution with tolerance tol and N_1 operations per iteration, while a second iterative scheme has convergence rate ρ_2 with $1 < \rho_1 < \rho_2$, requiring $k - i$ iterations and N_2 operations per iteration The TCE index of the second scheme is greater than the first scheme for:*

$$i < k\left(1 - \frac{N_1}{N2}\frac{\ln(\rho_1)}{\ln(\rho_2)}\right). \tag{9}$$

For the iterative methods under consideration we have that $TCE(OP) > TCE(DP1)$ if the difference between the number of iterations i is bounded for:

$$i < k\left(1 - \frac{n}{n+2}\frac{n-1+\log_2 3}{n-2+\log_2 5}\right)$$

For the highest order iterative method we have that $TCE(OP) > TCE(DP2)$ if:

$$i < k\left(1 - \frac{n(n+1)}{(n+2)(n+3)}\frac{n-2+\log_2 7}{n-2+\log_2 5}\right).$$

5 Conclusions

Numerical algorithms for approximating zeros of nonlinear functions have a rich history. The primary study of these methods has historically been focused on methods without memory, which possess an upper bound on their rate of convergence as stated by the conjecture of Kung-Traub. This bound does not apply to methods with memory, resulting in methods incorporating memory becoming a current topic of research. These methods typically utilize historical data in new ways to boost convergence rates. In this paper we aim to minimize computations while still allowing one to exceed the theoretical maximum that exists for methods without memory. In a predictor-corrector scheme, this is achieved by using the slope from the previous corrector step to generate the current predictor step. Convergence rates for various algorithms of this general form were calculated, followed by an analysis of their efficiency. Two specific cases were examined: the Midpoint method with memory ([5]) and the OP method. The OP method was compared to two other modifications of the ZLH algorithm.

Stability of running localized waves in fluid-filled elastic membrane tubes: weakly nonlinear approach

Andrej T. Il'ichev[1]

[1] *Department of Mechanics, Steklov Mathematical Institute*

emails: ilichev@mi.ras.ru

Abstract

We examine the problem of stability of solitary waves, propagating in a fluid-filled membrane tube. We consider only waves with speeds close to those given by the linear dispersion relation (it is known that there may exist four families of solitary waves having such speeds), i. e. waves of a small (but finite) amplitude bifurcating from the quiescent state of the system. In other words we adopt weakly nonlinear description of solitary waves. It is shown that if a solitary wave speed is bounded away from zero, then the solitary wave itself is orbitally stable, either the fluid initially stationary or not.

Key words: memrane tubes, spectral stability, solitary waves
MSC 2000: AMS codes (74J30,76B25)

1 Introduction

Governing equations for quasi-one dimensional motion of the perfect fluid in an axisymmetric membrane tube were obtained in [1] by means of straightforward derivation. Study of spectral stability of a branch of steady solitary-wave solutions (so-called aneurysm solutions) in the absence of the fluid inside the tube (pressure-controlled case) is given in [2]. A bifurcation parameter was the inflation pressure, and the authors found that all family of solitary waves is always spectrally unstable (i. e. a perturbation of a wave form exponentially grows with time). In [3] stability of the whole branch aneurysm solutions is studied when the fluid inside the tube is present, but a mean flow (a constant speed of the fluid at infinity) is zero. It was found there that the aneurysm is still unstable, but the presence of fluid has a strong stabilizing effect. The authors of [4] undertook a stability analysis of

 ISBN: 978-84-617-8694-7

aneurysm solution in the presence of the mean flow and found that if a speed of the fluid at infinity is bounded away from zero, then the aneurysm is spectrally stable.

In the present paper we examine the problem of stability of solitary waves, propagating with a non-zero speed in a fluid-filled axisymmetric membrane tube. In this case a bifurcation parameter is not the inflation pressure any more (it may take arbitrary values), but a solitary wave's speed. We consider only waves with speeds close to those given by the linear dispersion relation, i. e. the waves of a small (but finite) amplitude bifurcating from the quiescent state of the system. In other words we adopt weakly nonlinear description of solitary waves.

2 Formulation of the problem

We model the tube as incompressible, isotropic, hyperelastic, cylindrical membrane. The tube has a constant undeformed radius R and a constant undeformed thickness H. The tube is assumed to be infinitely long, and end conditions are imposed at infinity. We use cylindrical coordinates, and undeformed configuration is given by coordinates R, Θ, Z.

We assume that the axisymmetry remains throughout the entire deformation; the deformed configuration is expressed using cylindrical polar coordinates r, θ, z, where $r = r(Z,t)$, $\theta = \theta(Z,t)$, $z = z(Z,t)$, and t denotes time.

The principal directions of the deformation correspond to the lines of latitude, the meridian and the normal to the deformed surface, and the principal stretches are given by

$$\lambda_1 = \frac{r}{R}, \quad \lambda_2 = (r'^2 + z'^2)^{\frac{1}{2}}, \quad \lambda_3 = \frac{h}{H}, \tag{1}$$

where the indices 1, 2, 3 are used for the circumferential, axial and radial directions respectively, a prime represents differentiation with respect to Z, and h denotes the deformed thickness.

The principal Cauchy stresses σ_1, σ_2, σ_3 in the deformed configuration for an incompressible material are given by

$$\sigma_i = \lambda_i W_i - p, \qquad i = 1,2,3 \quad \text{(no summation)},$$

where $W = W(\lambda_1, \lambda_2, \lambda_3)$ is the strain-energy function, $W_i = \partial W / \partial \lambda_i$, and p is a Lagrange multiplier, associated with the constraint of incompressibility. Utilizing the incompressibility constraint $\lambda_1\lambda_2\lambda_3 = 1$ and the membrane assumption of no stress through the thickness direction $\sigma_3 = 0$, we find [5]

$$\sigma_i = \lambda_i \hat{W}_i, \qquad i = 1,2$$

where $\hat{W}(\lambda_1, \lambda_2) = W(\lambda_1, \lambda_2, \lambda_1^{-1}\lambda_2^{-1})$ and $\hat{W}_1 = \partial \hat{W} / \partial \lambda_1$, etc.

 ISBN: 978-84-617-8694-7

As an example we give here frequently used three strain-energy functions, the Varga, Ogden and Gent materials, given respectively by,

$$W = 2\mu(\lambda_1 + \lambda_2 + \lambda_3 - 3),$$

$$W = \mu \sum_{r=1}^{3} \mu_r(\lambda_1^{\alpha_r} + \lambda_2^{\alpha_r} + \lambda_3^{\alpha_r} - 3)/\alpha_r,$$

$$W = -\frac{1}{2}\mu J_m \ln\left(1 - \frac{\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3}{J_m}\right),$$

where μ is the shear modulus for infinitesimal deformations, $J_m > 0$ is a material constant representing the maximum stretch of the material and $\alpha_1 = 1.3$, $\alpha_2 = 5.0$, $\alpha_3 = -2.0$, $\mu_1 = 1.491$, $\mu_2 = 0.003$, $\mu_3 = -0.023$. The Ogden and Gent materials were proposed in [6] and [7] respectively, and are popularly used to model rubber.

The equations of motion for the tube can be derived from the exact field equations of general nonlinear shell theory, (see e. g. [8]), but in [1] a very readable self-contained derivation is given based on linear momentum balance applied to an infinitesimal material form of tube's wall. In terms of the Lagrangian coordinate Z and the time t the equations of motion for the fluid inside the tube were obtained in [1], (for derivation, see [3, 4]). In the dimensionless form these equations read

$$\left[\sigma_2 \frac{z'}{\lambda_2^2}\right]' - Prr' = \ddot{z}, \quad \left[\sigma_2 \frac{r'}{\lambda_2^2}\right]' - \frac{\sigma_1}{\lambda_1} + Prz' = \ddot{r}, \tag{2}$$

$$\dot{r}z' - r'\dot{z} + v_f r' + \frac{1}{2} r v_f' = 0, \quad b_f[\dot{v}_f z' - v_f'\dot{z} + v_f v_f'] + P' = 0, \tag{3}$$

where

$$z = z_\infty Z + u(Z,t), \quad r = r_\infty + w(Z,t), \quad u, w \to 0, \text{ as } Z \to \infty,$$

and P is the dimensionless internal pressure in the fluid, and the dot denotes the differentiation with respect to time; b_f is defined by

$$b_f = \frac{\rho_f R}{\rho H}.$$

where ρ_f is the fluid density and ρ is density of solid walls.

The governing equations (2) and (3) admit the uniform solution

$$r = r_\infty, \quad z' = z_\infty = \lambda_{2\infty}, v_f = v_{f\infty}, P = P_\infty \equiv \frac{W_1(c, r_\infty, \lambda_{2\infty})}{r_\infty \lambda_{2\infty}}. \tag{4}$$

 ISBN: 978-84-617-8694-7

We look for a general localized traveling wave solution for which the dependence on Z and t is through $Z - \hat{c}t$, where $\hat{c}$ denotes the wave speed of the wave. Localization means that as $Z - \hat{c}t \to \pm\infty$, the fluid-filled tube is in a uniform state given by (4).

We shall also need to refer to the dispersion relation for small-amplitude traveling waves superimposed on the uniform state (4). Assuming that the small-amplitude perturbations are proportional to

$$\exp\left(\frac{\lambda_{2\infty}}{r_\infty}k(Z-\hat{c}t)\right),$$

then the scaled wavenumber k and wave speed $c = \hat{c}\lambda_{2\infty}$ satisfy the dispersion relation [3]

$$\begin{aligned}&\left(k^2m+2\right)c^4 - 4v_{f\infty}c^3 - \left(m\alpha_0k^2 + m\gamma_1k^2 - 2v_{f\infty}^2 - m\beta_0 + m\beta_1 + 2\gamma_1\right)c^2\\ &+4v_{f\infty}\gamma_1 c - 2v_{f\infty}^2\gamma_1 + m\gamma_1(k^2\alpha_0 + \beta_1 - \beta_0) - m(\alpha_1-\beta_0)^2 = 0,\end{aligned} \tag{5}$$

where $m = 1/(b_f r_\infty^2 \lambda_{2\infty})$, and the expressions for the quantities α_0, α_1, γ_1, β_0, β_1 are given in [9] (with remarks in [4]). When $v_{f\infty} = 0$, the above equation becomes a bi-quadratic on c at the limit $k \to 0$, and the roots can be written as

$$4c^2 = 2\gamma_1 + m(\beta_1 - \beta_0) \pm \sqrt{[2\gamma_1 - m(\beta_1-\beta_0)]^2 + 8m(\alpha_1-\beta_0)^2}, \tag{6}$$

so that the four roots are all real. These characteristic speeds correspond to four branches of long waves: two of them propagate to the right, the other two propagate symmetrically to the left.

It can be easily shown [1] that the fluid equations (3) in this case can be integrated to yield

$$P = P_\infty + v_{f0}\left(1 - \frac{r_\infty^4}{r^4}\right), \quad v_f = \frac{v_{f\infty}r_\infty^2}{r^2}, \tag{7}$$

where the constant v_{f0} is defined by

$$v_{f0} = \frac{1}{2}b_f(v_{f\infty} - c)^2, \quad c = \hat{c}\lambda_{2\infty}.$$

It is also known [1, 4] that the equations in (2) together with (7) have two integrals. They are given by

$$W - \lambda_2 W_2 + \frac{1}{2}c^2\lambda_2^2 = C_1, \quad \frac{W_2 z'}{\lambda_2} - \frac{1}{2}P^* r^2 - c^2 z' = C_2, \tag{8}$$

where a prime again denotes differentiation with respect to $Z - \hat{c}t$,

$$P^* = P_\infty + v_{f0}\left(1 + \frac{\lambda_{1\infty}^4}{r^4}\right),$$

and the constants C_1 and C_2 can be determined by evaluating the corresponding left hands at the uniform state (4).

 ISBN: 978-84-617-8694-7

3 Weakly nonlinear theory of running solitary waves

We first note that the two integrals (8) are of the forms $f(\lambda_1, \lambda_2) = 0$ and $z' = g(\lambda_1, \lambda_2)$, respectively. These two equations always admit the trivial solution (4). To characterize non-trivial solutions, we write $\lambda_1 = r = r_\infty + w(Z - \hat{c}t)$ and proceed to derive a governing equation for $w(Z-\hat{c}t)$. To this end, we note that in principle we may solve the first integral to express λ_2 in terms of w. Although in general this expression cannot be obtained explicitly, a Taylor expansion of this expression valid for small w can be obtained in a straightforward manner [4]. The second integral can then be used to find the Taylor expansion of z' in terms of w as well. On substituting these expressions into (1), we then obtain

$$\left(w'\right)^2 = \omega(c, r_\infty, \lambda_{2\infty}, v_{f\infty})w^2 + \gamma(c, r_\infty, \lambda_{2\infty}, v_{f\infty})w^3 + O(w^4), \tag{9}$$

where the expression for $\omega(c, r_\infty, \lambda_{2\infty}, v_{f\infty})$ is given in [4], eqn (35), and the expression for $\gamma(c, r_\infty, \lambda_{2\infty}, v_{f\infty})$ is given by [9], eqn (3.7).

On differentiating (9), we obtain

$$w'' = \omega(c, r_\infty, \lambda_{2\infty}, v_{f\infty})\, w + \frac{3}{2}\gamma(c, r_\infty, \lambda_{2\infty}, v_{f\infty})w^2 + O(w^3). \tag{10}$$

It can then be seen that a bifurcation takes place when the coefficient $\omega(c, r_\infty, \lambda_{2\infty}, v_{f\infty})$ vanishes. Considering c as a bifurcation parameter, we further assume $v_{f\infty} = 0$, (because, as shown in [4], the mean flow stabilize the motion) and put r_∞ and $\lambda_{2\infty}^2$ arbitrary. The critical value of c, c_{cr} say, is then determined by the bifurcation condition $\omega(c_{cr}, r_\infty, \lambda_{2\infty}) = 0$, which can be reduced to (6).

On expanding the coefficients in (10) around $c = c_{cr}$, we obtain

$$V'' - V + V^2 + e(\epsilon, V) = 0, \tag{11}$$

where

$$w = \frac{2\epsilon\, \omega'_{cr}}{3\gamma_{cr}} V(\xi), \quad \xi = \sqrt{|\epsilon \omega'_{cr}|}(Z - \hat{c}t),$$

$$\omega'_{cr} = \left.\frac{d\omega}{dc}\right|_{c=c_{cr}}, \quad \gamma_{cr} = \gamma(c_{cr}, r_\infty, \lambda_{2\infty}), \quad e(\epsilon, V) = O(\epsilon),$$

$$\begin{aligned} &\varepsilon = |c_{cr} - c|, \quad \text{if } \omega'_{cr} > 0,\ \gamma_{cr} < 0, \\ &\varepsilon = -\mathrm{sgn}(\omega_{cr})|c_{cr} - c|, \quad \text{if } \gamma_{cr} > 0. \end{aligned}$$

Therefore, when $\gamma_{cr} < 0$ and $\omega'_{cr} > 0$ or $\gamma_{cr} > 0$ and $\omega'_{cr} < 0$ the solitary wave family bifurcate from the quiescent state in result of a supercritical bifurcation ($c > c_{cr}$), in the case $\gamma_{cr} > 0$ and $\omega'_{cr} > 0$ this bifurcation is a subcritical one ($c < c_{cr}$).

 ISBN: 978-84-617-8694-7

When the $O(\epsilon)$ term is neglected, equation (11) has an exact solitary wave-type solution given by

$$V = V_0 \equiv \frac{3}{2}\,\mathrm{sech}^2\frac{\xi}{2}. \tag{12}$$

Equation (11) is a special case of reversible differential equations for which general persistence results have previously been established in [10]. In other words, the solution of the full nonlinear equation (11) which is given by (12) for $\epsilon \to 0$ is close to the expression given by (12) for small enough $|\epsilon|$ and tend to zero as $\xi \to \pm\infty$, namely

$$|V - V_0| \le C\epsilon \exp(-|\xi|), \tag{13}$$

where $C > 0$ is some constant. Very good correspondence of the asymptotic (12) and exact result (which relates to a solution of (11), see [9], Fig. 1), without any doubt serves a demonstration of the persistence property (13).

4 Orbital stability of the weakly nonlinear running solitary waves

We now investigate the stability of the weakly nonlinear solitary wave (12). We assume that perturbations of the quiescent state (4) depend on the slow time variable $\tau = \epsilon^{3/2}t$, where $\epsilon = |c_{cr} - c|$, as well as on the variable ξ. We look for a perturbation solution of the form

$$\begin{aligned} &r = r_\infty + \epsilon[w_1(\xi,\tau) + \epsilon w_2(\xi,\tau) + ...],\\ &z = z_\infty Z + \sqrt{\epsilon}[u_1(\xi,\tau) + \epsilon u_2(\xi,\tau) + ...],\\ &v_f = \epsilon v_{f1}(\xi,\tau) + v_{f2} + ...,\\ &P = P_\infty + \epsilon[p_1(\xi,\tau) + \epsilon p_2(\xi,\tau) + ...]. \end{aligned} \tag{14}$$

For P_∞ given by Eq. (4) we have the Taylor expansion

$$P_\infty = \frac{W_1(c_{cr}, r_\infty, \lambda_{2\infty})}{r_\infty \lambda_{2\infty}} + \epsilon P_1 + ... \tag{15}$$

On substitution (14), (15) into Eqs. (2) and (3), and then equating the coefficients of ϵ we obtain

$$\begin{aligned} &\mathbf{L}\begin{bmatrix} w_1 \\ \sqrt{|\omega'|}u_{1\xi} \end{bmatrix} = \mathbf{0},\\ &\mathbf{L} = \begin{bmatrix} -W_1/z_\infty + W_{12} & W_{22} - z_\infty^2 {c_{cr}}^2 \\ z_\infty(W_1 - r_\infty W_{11}) - \frac{2b_f r_\infty^2}{z_\infty}c_{cr}^2 & r_\infty(W_1 - z_\infty W_{12}) \end{bmatrix}, \end{aligned} \tag{16}$$

 ISBN: 978-84-617-8694-7

where W_1, W_{11}, W_{12}, W_{22} are all evaluated at $c = c_{cr}$ and $(r, z) = (r_\infty, z_\infty)$. It is easy to see that $\omega(c_{cr}, r_\infty, z_\infty) = 0$ implies $\det \mathbf{L} = 0$, and thus the equation (16) has a nontrivial solution for w_1 and $u_{1\xi}$. Proceeding to the next order, we find

$$\mathbf{L} \begin{bmatrix} w_{2\xi} \\ \sqrt{|\omega'|} u_{2\xi\xi} \end{bmatrix} = \mathbf{b}, \tag{17}$$

$$\begin{aligned} v_{1f} &= \frac{2c_{cr}}{r_\infty} w_1, \quad p_{1\xi} = \frac{2b_f c_{cr}^2}{r_\infty} w_{1\xi}, \quad v_{2f} = \frac{2c_{cr}}{r_\infty} w_2 - \frac{6c_{cr}}{r_\infty^2} w_1 w_{1\xi} - \frac{2z_\infty}{r_\infty} \dot{w}_1, \\ p_{2\xi} &= \frac{2b_f c_{cr}^2}{r_\infty} w_{2\xi} - \frac{10 b_f c_{cr}^2}{r_\infty^2} w_1 w_{1\xi} - \frac{4 b_f c_{cr}}{r_\infty} \dot{w}_1 - \frac{4 b_f c_{cr}^2}{r_\infty z_\infty} u_{1\xi} w_{1\xi}, \end{aligned} \tag{18}$$

where after substitution of (18) the vector $\mathbf{b}$ only contains w_1 and its derivatives. On forming the dot product of the vector $\mathbf{b}$ in Eq. (17) with the left zero eigenvector of $\mathbf{L}$, we then obtain the evolution equation in the form

$$\frac{\partial w_1}{\partial \tau} - c_0 \frac{\partial w_1}{\partial \xi} + c_1 w_1 \frac{\partial w_1}{\partial \xi} + c_2 \frac{\partial^3 w_1}{\partial \xi^3} = 0, \tag{19}$$

where c_0, c_1, and c_2 are constants. Since (19) reduces to (11) when time independence is assumed, it must take the form

$$\frac{\partial \tilde{V}}{\partial \tau} - c_0 \frac{\partial \tilde{V}}{\partial \xi} + c_0 2\tilde{V} \frac{\partial \tilde{V}}{\partial \xi} + c_0 \frac{\partial^3 \tilde{V}}{\partial \xi^3} = 0, \tag{20}$$

where

$$\tilde{V} = -\mathrm{sgn}(\omega'_{cr} \gamma_{cr}) \frac{3\gamma_{cr}}{2\omega'_{cr}} w_1,$$

and the remaining constant can be found by looking for a traveling wave solution of the linearized form of (20) and then comparing the resulting dispersion relation with (5). However, for our purpose the explicit expression of c_0 is not needed.

Under the variable transformation $T = |c_0|\tau - \mathrm{sgn} c_0\, \xi$, $x = \mathrm{sgn} c_0\, \xi$, $u = 2\tilde{V}$ the equation (20) reduces to the standard form

$$\frac{\partial u}{\partial T} + u \frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0. \tag{21}$$

The solution (12) of (20) corresponds to the following traveling solitary wave solution of (21)

$$u = 3\mathrm{sech}^2 \left(\frac{x - T}{2} \right). \tag{22}$$

 ISBN: 978-84-617-8694-7

A nonlinear small perturbation of a solitary wave of the KdV equation (21) (and, in particular, (22)) can yield a solitary wave with slightly different speed. Therefore it is reasonable to study the orbital stability of solitary waves, namely when a solution $u(x,T)$, which is initially close to a solitary wave $u_c(x-cT)$ in the Sobolev space of square integrable functions with their derivatives $H^1(\mathbb{R})$, will remain close to the set of translates of the solitary wave (or the orbit of the solitary wave under the group of time translations) for any time $t > 0$). This is true for solitary waves (solitons) of Eq. (21) as was established in [11] (see also [12]). In other words, it was shown that for sufficiently small ε, there exists δ, such that, if

$$||u(\cdot,0) - u_c(\cdot)||_{H^1(\mathbb{R})} < \delta,$$

then one has

$$\inf_s ||u(\cdot,T) - u_c(+s)| \cdot |_{H^1(\mathbb{R})} < \varepsilon.$$

The orbital stability property of solitary wave solutions to (21) was established in [11] (see also [12]). This definition of stability states that that a shape of the wave is stable, so it is often also called stability in form.

Abstract

In this paper we present a Quadrature-Difference Method (QDM) to solve a system of two second order Fredholm integro-differential equations with constant coefficients. We fully discretize the coupled equations using finite difference operators on the differential part of the equations and numerical quadrature formulas on the integral part. This procedure leads to two systems of linear algebraic equations, which can be solved simultaneously as a block matrix system. Moreover, we illustrate the method on a benchmark problem for which we construct the exact solution, and test its performance and accuracy, as well as the numerical order of convergence.

Key words: Coupled Systems, FIDE, Finite Difference, Direct Methods, Quadrature Formulas.

1 Introduction

Many relevant physical, biological and financial phenomena can be modelled using Integro-Differential Equations (IDEs) [17]. For instance, the use of IDEs is quite common in scattering theory, heat transfer in the presence of memory effects [9], floating structures and viscoelastic materials[18], economics [17] and finance [14]. More applications of IDEs can be found in [4]. Generally speaking, an IDE is an equation involving an unknown function u, its derivatives and integral terms associated with convolution kernels.

We focus on Fredholm integro-differential Equations (FIDEs), for which the integral terms have fixed integration limits. This class of problems has gained importance in the literature with a variety of applications [13]. For a comprehensive study on FIDEs and other types of IDEs we refer to [11].

 ISBN: 978-84-617-8694-7

Closed form analytical solution are rarely available for FIDEs and, in most cases of interest, we must resort to numerical methods. A significant amount of literature is available regarding the numerical solution of FIDEs, namely using Galerkin and Wavelet-Galerkin methods [2, 12], Tau method [15], shifted Legendre polynomials [10], Hybrid Functions [1] and Quadrature-Difference Methods [7].

In this paper we consider a Quadrature-Difference Method to solve a system of second order coupled FIDEs with constant coefficients, arising from a model in financial option pricing with memory effects [8]. The paper is organized as follows. In Section 2 we discretize the continuous problem using finite differences and numerical quadrature, obtaining a system of linear algebraic equations. In Sections 3 and 4, we analyse the numerical performance of the method, with respect to consistency and local truncation error. In Section 5, we present a toy problem for which we construct the exact solution and use it to show the accuracy of the method as well as the order of convergence. Conclusions and future perspectives are discussed in Section 6.

Preliminaries

We will consider the following system of Fredholm integro-differential equations:

$$\begin{cases} a_0u''(x) + a_1u'(x) + a_2u(x) + \lambda_0 \displaystyle\int_a^b K^0(x,z)v(z)dz = f(x), \\ b_0v''(x) + b_1v'(x) + b_2v(x) + \lambda_1 \displaystyle\int_a^b K^1(x,z)u(z)dz = g(x), \\ u(a) = u_a, u(b) = u_b, v(a) = v_a, v(b) = v_b. \end{cases} \tag{1}$$

where a_i, b_i, λ_0, λ_1 are real constants, $K^0, K^1 : [a,b]^2 \to \mathbb{R}$ and $f, g : [a,b] \to \mathbb{R}$ are given functions with suitable regularity. We search for a classical solution of the problem, $(u,v) \in (C^2(]a,b[))^2 \cap (C^0([a,b]))^2$, which we want to approximate numerically.

The existence and uniqueness of solution can be shown converting (1) to a system of first order FIDEs and using the results derived in [3]. This involves transforming our boundary value problem into an initial value problem with the same solution, which is achieved by setting up a shooting method. This requires additional regularity with respect to [3] and we refer to [19].

2 Discretization of the system of FIDEs

We use a computational grid over the interval $[a,b]$, over which our problem will be approximated. Let $x_1, \cdots, x_M$ be equally spaced points in the interval $[a,b]$, such that:

$$a = x_1, x_2, \cdots, x_M = b, \quad h = \frac{b-a}{M-1}, \quad x_{i+1} - x_i = h, \quad i = 1, ..., M. \tag{2}$$

 ISBN: 978-84-617-8694-7

At each grid point x_i the solutions $u(x_i)$ and $v(x_i)$ are approximated by $u_n(x_i)$ and $v_n(x_i)$, where the index n stand for numerically computed. In order to ease the writing, we set $u_n(x_i) = u_i$ and $v_n(x_i) = v_i$. The solution can be written as a single vector $W \in \mathbb{R}^{2M}$:

$$W = (U|V) = (u_1, u_2, \cdots, u_M, v_1, v_2, \cdots, v_M). \tag{3}$$

Approximation of the differential part

The differential parts of our system are discretized replacing the first and second order derivatives by centered finite differences on a stencil coinciding with the computational grid.

$$W'(x_i) \approx \frac{W_{i+1} - W_{i-1}}{2h}, \quad W''(x_i) \approx \frac{W_{i-1} - 2W_i + W_{i+1}}{h^2}, \quad i = 2, ..., 2M-1. \tag{4}$$

Both these approximations are second order accurate.

Approximation of the integral part

In order to obtain a full discretization of (1), the integral terms are approximated by using a quadrature rule which uses the grid points as integration nodes.

$$\int_a^b K^s(x_i, t)W(t)dt \approx \sum_{j=1}^{M} q_j K_{ij}^s W_{sM+j}, \quad s \in \{0, 1\}, \quad i = 2, ..., M-1, \tag{5}$$

where q_j are the weights of the chosen quadrature rule. In this work we make use of a composite trapezoidal rule and a composite Simpson's $\frac{1}{3}$ rule [5]. Substituting (4) and (5) in (1) we get a full discretization of the coupled system:

$$\begin{aligned} a_0\frac{W_{i+1} - 2W_i + W_{i-1}}{h^2} + a_1\frac{W_{i+1} - W_{i-1}}{2h} + a_2W_i + \lambda_0\sum_{j=1}^{M} q_j K_{ij}^1 W_{M+j} = f_i \\ , i = 2, ..., M-1, \\ b_0\frac{W_{i+1} - 2W_i + W_{i-1}}{h^2} + b_1\frac{W_{i+1} - W_{i-1}}{2h} + b_2W_i + \lambda_1\sum_{j=1}^{M} q_j K_{i-M,j}^2 W_j = g_i \\ i = M+1, ..., 2M-1. \end{aligned} \tag{6}$$

 ISBN: 978-84-617-8694-7

2.1 The System of Linear Algebraic Equations

Grouping the coefficients in (6), we obtain:

$$\begin{aligned}
&\left(\frac{a_0}{h^2}-\frac{a_1}{2h}\right)W_{i-1}+\left(-\frac{2a_0}{h^2}+a_2\right)W_i+\left(\frac{a_0}{h^2}+\frac{a_1}{2h}\right)W_{i+1}+\lambda_0\sum_{j=1}^{M}q_jK_{ij}W_{M+j}=f_i,\\
&\left(\frac{b_0}{h^2}-\frac{b_1}{2h}\right)W_{i-1}+\left(-\frac{2b_0}{h^2}+b_2\right)W_i+\left(\frac{b_0}{h^2}+\frac{b_1}{2h}\right)W_{i+1}+\lambda_1\sum_{j=1}^{M}q_jK_{i-M,j}W_j=g_i.
\end{aligned} \tag{7}$$

Let us define $Q=\mathrm{Diag}(q_1,\cdots,q_M)$, $[K^s_{ij}]=[K^s(x_i,x_j)]$, $D_s=K^sQ$, $F=(f(x_1),...,f(x_M))$, $G=(g(x_1),...,g(x_M))$, and A,B are tridiagonal matrices with line coefficients given by $\left(\frac{a_0}{h^2}-\frac{a_1}{2h},-\frac{2a_0}{h^2}+a_2,\frac{a_0}{h^2}+\frac{a_1}{2h}\right)$, and $\left(\frac{b_0}{h^2}-\frac{b_1}{2h},-\frac{2b_0}{h^2}+b_2,\frac{b_0}{h^2}+\frac{b_1}{2h}\right)$, respectively. The discretized system reduces to the following $2M\times 2M$ linear algebraic system of equations, written in matrix form:

$$\left(\begin{array}{c:c}A & D_0\\ \hdashline D_1 & B\end{array}\right)\underbrace{\left(\begin{array}{c}U\\ \hdashline V\end{array}\right)}_{W}=\left(\begin{array}{c}F\\ \hdashline G\end{array}\right) \tag{8}$$

Boundary conditions are enforced by replacing rows corresponding to boundary points, *i.e.* rows $1, M, M+$ and $2M$, by the corresponding lines in the identity matrix I_{2M}. For these lines, the RHS of the system is set to be the corresponding boundary data.

Different methods can be used for solving this system: direct methods such as Gaussian Elimination, LU-decomposition, ILU decomposition, etc; or iterative methods such as Gauss-Sidel, SOR or Krylov subspace methods. In this first approach, given the moderate dimension of the system, we used Gaussian elimination. Considering the sparsity pattern of system (8), illustrated in Fig. 1, we used sparse representations of the linear system, leading to a significant gain in memory use.

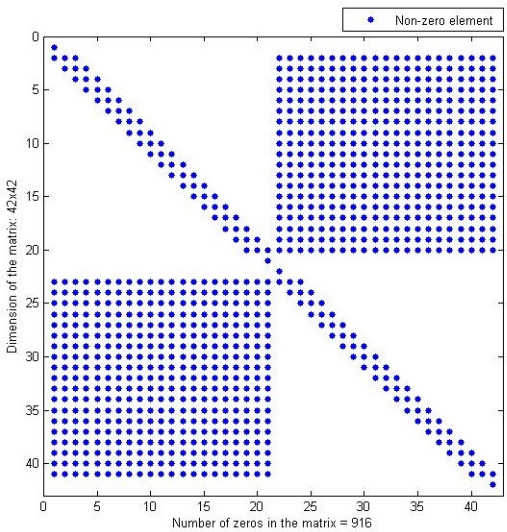
3 Consistency and Local Truncation Error

This section is dedicated to the analysis of consistency of the QDM. Consistency is a property of a discretization that ensures that the discrete equations converge to the continuous equations as the discretization parameter goes to zero ($h\to 0$). When a numerical scheme is not consistent with the continuous equations, it is probably modelling a different process and, even if convergent, is not suitable to approximate the desired equation [6]. We start by rewriting (1) splitting the differential and integral parts:

$$\left\{\begin{array}{l}\mathcal{D}^0u+\mathcal{J}^0v=f,\\ \mathcal{D}^1v+\mathcal{J}^1u=g,\end{array}\right. \tag{9}$$

 ISBN: 978-84-617-8694-7

Figure 1: The $(2N \times 2N)$ matrix block sparsity pattern of the discretized system (8). (N=21)



where

$$\mathcal{D}^0 w = a_0 w'' + a_1 w' + a_2 w, \quad \mathcal{D}^1 w = b_0 w'' + b_1 w' + b_2 w$$
$$\mathcal{J}^0 w = \lambda_0 \int_a^b K^0(x,z) w(z) dz, \quad \mathcal{J}^1 w = \lambda_1 \int_a^b K^1(x,z) w(z) dz.$$

The continuous operators $\mathcal{D}^{0,1}$ and $\mathcal{J}^{0,1}$ are approximated, at each grid point, by the discrete operators $\mathcal{D}_\Delta^{0,1}$ and $\mathcal{J}_\Delta^{0,1}$, *i.e* $\mathcal{D}^{0,1} w(x_i) \approx \mathcal{D}_\Delta^{0,1} w_i$ and $\mathcal{J}^{0,1} w(x_i) \approx \mathcal{J}_\Delta^{0,1} w_i$. The following theorem establishes the consistency of our QDM.

Theorem 1. *Let u and $v \in C^\infty([a,b])$ satisfy the boundary conditions of (1). Then, for sufficiently small $h > 0$, and for each $x_i, i = 2, \cdots, M-1$*

$$\begin{cases} \mathcal{D}^0 u(x_i) + \mathcal{J}^0 v(x_i) - \mathcal{D}_\Delta^0 u_i - \mathcal{J}_\Delta^0 v_i = \mathcal{O}(h^2) \\ \mathcal{D}^1 v(x_i) + \mathcal{J}^1 u(x_i) - \mathcal{D}_\Delta^1 v_i - \mathcal{J}_\Delta^1 u_i = \mathcal{O}(h^2) \end{cases} . \tag{10}$$

Proof. Starting with the integral operator $\mathcal{J}^0$ for the first equation on (10) and using, for instance, the composite trapezoidal rule, we have

$$J^0 v(x_i) = \int_a^b K^0(x_i, z) v(z) dz = \frac{h}{2} \left[K_{i,1}^0 v_1 + 2 \sum_{j=2}^{M-1} K_{i,j}^0 v_j + K_{i,M}^0 v_M \right] + \mathcal{O}(h^2) \tag{11}$$

Hence, the error of approximating the continuous $\mathcal{J}^0 v$ by the discretized $\mathcal{J}_\Delta^0 v$ is

$$\mathcal{J}^0 v(x_i) - \mathcal{J}_\Delta^0 v_i = \mathcal{O}(h^2). \tag{12}$$

 ISBN: 978-84-617-8694-7

The same argument can be used for the second equation in (10), leading to

$$\mathcal{J}^1 u(x_i) - \mathcal{J}^1_\Delta u_i = \mathcal{O}(h^2). \tag{13}$$

Regarding the differential operators $\mathcal{D}^{0,1}$, simple third order Taylor's expansions can be used to derive error bounds to the difference operators, yielding

$$\begin{aligned} \mathcal{D}^0 u(x_i) - \mathcal{D}^0_\Delta u_i &= \mathcal{O}(h^2) \\ \mathcal{D}^1 v(x_i) - \mathcal{D}^1_\Delta v_i &= \mathcal{O}(h^2). \end{aligned} \tag{14}$$

Finally, combining (12), (13) and (14) we obtain (10), showing the consistency of the quadrature-difference method.

□

4 Numerical Experiments

In this section we consider a benchmark problem in order to test the efficiency and accuracy of our QDM. We consider the system (1), where the given functions and constants are as follows:

$$a = 0, b = 2, a_0 = a_1 = a_2 = b_0 = b_1 = b_2 = 1, \lambda_0 = \lambda_1 = 1, \quad K^0(x,z) = K^1(x,z) = xz.$$

$$f(x) = -\frac{x}{\pi} - 2\pi \sin(2\pi x) - 4\pi^2 \cos(2\pi x) + \cos(2\pi x).$$

$$g(x) = -4\pi^2 \sin(2\pi x) + \sin(2\pi x) + 2\pi \cos(2\pi x),$$

$$u(0) = u(2) = 1, \quad v(0) = v(2) = 0.$$

The exact solution to this problem is $(u(x), v(x)) = (\cos(2\pi x), \sin(2\pi x))$. Tables 1 and 2 show a comparison between the numerical solution and the exact solution. Table 1 shows the absolute difference between QDM and the analytical solution. The maximum value is highlighted. Table 2 presents the errors measured in two different norms (l_2 and l_∞). In Figure 4, we plot in logarithmic scale the error measured in l^*_∞ and Root Mean Squared Error ($RMSE^*$), as function of the number of discretization points M, where

$$\begin{aligned} & l^*_\infty = \max\left\{\|u - u'\|_\infty, \|v - v'\|_\infty\right\} \\ & RMSE^* = \max\left\{\sqrt{\tfrac{1}{M}\sum_{i=1}^{M}\left(u(x_i) - u_i\right)^2}, \sqrt{\tfrac{1}{M}\sum_{i=1}^{M}\left(v(x_i) - v_i\right)^2}\right\} \\ & \text{end} \\ & u = \left(u(x_1), \ldots, u(x_M)\right), v = \left(v(x_1), \ldots, v(x_M)\right) \\ & u' = \left(u_1, \ldots, u_M\right), v' = \left(v_1, \ldots, v_M\right). \end{aligned} \tag{15}$$

Numerical estimation of the order of convergence

Here we intend to analyze the numerical convergence rate of our algorithm. Let W be the exact solution to our problem and W_h the approximate solution in a uniform grid with spacing h. The method that has order α if there is a constant K, independent of h, such that

$$|W - W_h| \leq Kh^\alpha, \tag{16}$$

for sufficiently small values of h [16]. Now, considering the sequence $h_j = \dfrac{h}{2^j}$, $j = 0, 1, \cdots, N$, the order of convergence can be estimated as

$$\alpha_j = \log_2 \frac{\|W - W_{h_j}\|_\infty}{\|W - W_{h_{j+1}}\|_\infty}, \tag{17}$$

where $\|W - W_{h_j}\|_\infty = \max\left(\|u(x_i) - u_i\|_\infty, \|v(x_i) - v_i\|_\infty\right)$. Table 3 shows that the last column of the sequence α_j is close to 2, which is consistent with second order convergence in the l_∞ norm.

5 Conclusions and future work

This paper presents a simple method to solve numerically a class of systems of second order Fredholm integro-differential equations. A finite difference scheme and a numerical quadrature rule are used to fully discretize the system, and the resulting linear algebraic system is solved as a block matrix system. The accuracy and convergence order of the method was demonstrated in a benchmark problem. We are currently working on a direct proof of existence and uniqueness of the boundary value problem, which will require less regularity. On another direction, we are extending the procedure to a time evolution system of Fredholm integro-differential equations with possible applications to financial derivative markets [14].

Abstract

A class of tests for testing independence whose test statistic is an L_2-norm of the difference between the joint empirical characteristic function and the product of the marginal empirical characteristic functions associated with a sample is considered. Since the null distribution of these test statistics is unknown, some approximations are investigated. Specifically, the permutation, bootstrap and weighted bootstrap estimators are examined. All of them provide consistent estimators. A simulation study analyzes the performance of these approximations for small and moderate sample sizes.

Key words: testing for independence, permutation, bootstrap, weighted bootstrap.

1 Introduction

Independence is a key concept in Statistics, which plays a fundamental role in many statistical procedures. Because of this reason, a number of tests have been proposed for testing the null hypothesis that two or more random vectors are independent. This paper deals with the issue of approximating the null distribution of a certain class of test statistics for such testing problem. To keep the notation as simple as possible, in our development we will only consider the case of a bivariate random vector (X, Y). Nevertheless, the methods proposed here can be applied in an obvious way to testing for the independence of any collection of subvectors from vectors with arbitrary dimensions. With this notation, the hypothesis of interest is

$$H_0 : X \text{ and } Y \text{ are independent.}$$

 ISBN: 978-84-617-8694-7

The problem of testing for independence by using the familiar equation linking the joint characteristic function (CF) and the product of component CFs has been exploited in several papers (see, for example, Csörgő [3], Kankainen and Ushakov [5], Bilodeau and Lafaye de Micheaux [1], Székely et al. [7], Meintanis and Iliopoulos [6], Hlávka et al. [4], and the references therein). Here we consider the approach in [4, 6, 7], that proposed to reject the null hypothesis for large values of

$$T_n(w) = \|\sqrt{n}\{C_n(t,s) - C_n(t,0)C_n(0,s)\}\|_w^2,$$

where C_n is the empirical CF (ECF) associated with a sample, $(X_1, Y_1), \ldots, (X_n, Y_n)$, which are independent, identically distributed (IID) from (X, Y),

$$C_n(t,s) = \frac{1}{n}\sum_{j=1}^{n} \exp(\mathrm{i}tX_j + \mathrm{i}sY_j),$$

and $\|\cdot\|_w$ stands for the norm in the separable Hilbert space $L_2(w) = \{f : \mathbb{R}^2 \to \mathbb{C} : \|f\|_w^2 = \int |f(t)|^2 w(t)dt < \infty\}$, for some nonnegative function w satisfying

$$\int w(t,s)dtds < \infty \tag{1}$$

where an unspecified integral denotes integration over $\mathbb{R}^2$ and for any complex number $x = a + \mathrm{i}b$, $|x| = \sqrt{a^2 + b^2}$.

In order to determine what are large values of $T_n(w)$, one must calculate or approximate its null distribution. Székely et al. [7] proposed to approximate the null distribution of $T_n(w)$ by a permutation estimator. Here we consider two further estimators: a bootstrap estimator and a weighted bootstrap (WB) estimator, in the sense of Burke [2]. This piece of research shows that each of these three estimators provide a consistent approximation to the null distribution of $T_n(w)$. Their finite sample behaviour is numerically compared in a simulation study.

Before ending this section we introduce some notation: all limits in this paper are taken when $n \to \infty$; $\xrightarrow{\mathcal{L}}$ denotes convergence in distribution; P_0 denotes probability under the null hypothesis; P_* denotes the conditional probability law given the data $(X_1, Y_1), \ldots, (X_n, Y_n)$.

2 Approximations

2.1 The permutation estimator

Let $\pi(1), \ldots, \pi(n)$ and $\sigma(1), \ldots, \sigma(n)$ be two independent random permutations of $1, \ldots, n$. Let $(X_1^*, Y_1^*) = (X_{\pi(1)}, Y_{\sigma(1)}), \ldots, (X_n^*, Y_n^*) = (X_{\pi(n)}, Y_{\sigma(n)})$. Let $T_n^*(w)$ be defined as $T_n(w)$ with (X_j, Y_j) replaced by (X_j^*, Y_j^*), $1 \le j \le n$. The permutation null distribution estimator of $T_n(w)$ is defined as the conditional distribution, given the data, of $T_n^*(w)$.

 ISBN: 978-84-617-8694-7

The next theorem shows that the permutation distribution of $T_n(w)$ consistently estimates its null distribution when any weight function satisfying (1) is used.

Theorem 1 *Let $(X_1, Y_1), \ldots, (X_n, Y_n)$ be a random sample from a random vector (X, Y) and suppose that (1) holds, then*

$$\sup_{x \in \mathbb{R}} |P_*\{T_n^*(w) \leq x\} - P_0\{T_n(w) \leq x\}| \to 0, \ \ a.s.$$

2.2 The bootstrap estimator

Let $X_1^\dagger, \ldots, X_n^\dagger$ be a random sample from $F_{n,X}$ and let $Y_1^\dagger, \ldots, Y_n^\dagger$ be a random sample from $F_{n,Y}$, selected independently from $X_1^\dagger, \ldots, X_n^\dagger$, where $F_{n,X}$ and $F_{n,Y}$ stand for the empirical distribution function associated to $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_n$, respectively. Let $T_n^\dagger(w)$ be defined as $T_n(w)$ with (X_j, Y_j) replaced by $(X_j^\dagger, Y_j^\dagger)$, $1 \leq j \leq n$.

The next theorem shows that the bootstrap distribution of $T_n(w)$ consistently estimates its null distribution when any weight function satisfying (1) is used.

Theorem 2 *Let $(X_1, Y_1), \ldots, (X_n, Y_n)$ be a random sample from a random vector (X, Y) and suppose that (1) holds, then*

$$\sup_{x \in \mathbb{R}} \left| P_*\{T_n^\dagger(w) \leq x\} - P_0\{T_n(w) \leq x\} \right| \to 0, \ \ a.s.$$

2.3 The weighted bootstrap estimator

Let $S_n(t,s) = \sqrt{n}\{C_n(t,s) - C(t,s)\}$, where C stands for the CF of (X, Y). Since $S_n \xrightarrow{\mathcal{L}} Z$ in $L_2(w)$, where Z is a zero-mean Gaussian process on $L_2(w)$, it follows that under H_0

$$\begin{aligned} \xi_n(t,s) &= \sqrt{n}\{C_n(t,s) - C_n(t,0)C_n(0,s)\} \\ &= \sqrt{n}\{C_n(t,s) \pm C(t,0)C(0,s)\} - \sqrt{n}\{C_n(t,0) \pm C(t,0)\}\{C_n(0,s) \pm C(0,s)\} \\ &= \xi_{0n}(t,s) + r_n(t,s), \end{aligned}$$

where $\|r_n\|_w^2 = o_P(1)$ and

$$\xi_{0n}(t,s) = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} U_j(t,s),$$

with

$$U_j(t,s) = \exp(\mathrm{i}tX_j + \mathrm{i}sY_j) - C(t,0)\exp(\mathrm{i}sY_j) - C(0,s)\exp(\mathrm{i}tX_j) + C(t,0)C(0,s),$$

 ISBN: 978-84-617-8694-7

$1 \leq j \leq n$. Let $\varsigma_1, \ldots, \varsigma_n$ be IID random variables with mean 0 and variance 1, which are independent of the data $(X_1, Y_1), \ldots, (X_n, Y_n)$. Let

$$\xi^{\star}_{1n}(t,s) = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} U_{n,j}(t,s)\varsigma_j,$$

where

$$U_{n,j}(t,s) = \exp(\mathrm{i}tX_j + \mathrm{i}sY_j) - C_n(t,0)\exp(\mathrm{i}sY_j) - C_n(0,s)\exp(\mathrm{i}tX_j) + C_n(t,0)C_n(0,s),$$

$1 \leq j \leq n$. The WB distribution estimator of $T_n(w)$ is defined as the conditional distribution, given the data, of $T^{\star}_n(w) = \|\xi^{\star}_{1n}\|^2_w$. The weighted bootstrap estimator provides a consistent approximation to the null distribution of $T_n(w)$.

The next theorem shows that the weighted bootstrap estimator provides a consistent approximation to the null distribution of $T_n(w)$.

Theorem 3 *Let $(X_1, Y_1), \ldots, (X_n, Y_n)$ be a random sample from a random vector (X, Y), suppose that (1) holds and that H_0 is true, then*

$$\sup_{x \in \mathbb{R}} |P_*\{T^{\star}_n(w) \leq x\} - P_0\{T_n(w) \leq x\}| \to 0, \ \ a.s.$$

2.4 Practical calculation

The calculation of the exact permutation (bootstrap, WB) distribution of $T_n(w)$ is, from a practical point of view, unaffordable, so the permutation (bootstrap, WB) p-value is usually approximated by simulation as follows:

1. Compute the test statistic $T_{n,obs}(w)$.
2. For some large integer B, repeat for every $b \in \{1, \ldots, B\}$:
   (a) Generate $(X^{*b}_1, Y^{*b}_1), \ldots, (X^{*b}_n, Y^{*b}_n)$ $((X^{\dagger b}_1, Y^{\dagger b}_1), \ldots, (X^{\dagger b}_n, Y^{\dagger b}_n)$, $\varsigma^b_1, \ldots, \varsigma^b_n)$.
   (b) Calculate $T^{*b}_n(w)$ $(T^{\dagger b}_n(w)$, $T^{\star b}_n(w))$,
3. Approximate the p-value of the observed value of the test statistic by

$$\hat{p}^* = \frac{1}{B} \sum_{b=1}^{B} I\{T^{*b}_n(w) > T_{n,obs}(w)\}$$

$$(\hat{p}^{\dagger} = \tfrac{1}{B}\textstyle\sum_{b=1}^{B} I\{T^{\dagger b}_n(w) > T_{n,obs}(w)\},\ \hat{p}^{\star} = \tfrac{1}{B}\textstyle\sum_{b=1}^{B} I\{T^{\star b}_n(w) > T_{n,obs}(w)\}).$$

3 Numerical comparisons

This section summarizes the results of an intensive simulation experiment whose objective is to investigate and compare the goodness of these approximations for small and moderate sample sizes. All computations in this paper were performed by using programs written in the R language.

The first step is to study the goodness of the bootstrap, the permutation and the WB approximations to the null distribution of the test statistic $T_n(w)$. With this aim, we generated 5000 samples with size n, for $n = 20, 30, 40, 50, 100$, from a bivariate normal distribution with independent components; the approximations of the p-value were calculated by simulation, as indicated in Subsection 2.4 with $B = 1000$. As weight function $w(t)$, several choices are possible, here we considered two of the most used in other papers related to the use of the ECF for inferential purposes: the probability density function (PDF) of a univariate normal distribution with zero mean and standard deviation $\sigma = a$ and the PDF of a univariate Laplace distribution with zero mean and variance $\sigma^2 = 2a^2$. The obtained results are shown in Table 1, that displays the actual levels for nominal values 0.05 (left column) and 0.10 (right column) for each method. The approximations of the p-value are labeled as P, B and WB for the permutation, bootstrap and WB approximations, respectively. The function w considered is indicated in the tables as N, for the normal PDF, and L, for the Laplace PDF. The same experiment were repeated for data from other populations, obtaining quite similar results. Looking at this table we see that the bootstrap and the permutation give significance levels which are quite close to the nominal values in all tried cases; the goodness of the WB approximation depends on the weight function, giving quite satisfactory results for the normal weight and rather conservative tests for the Laplace weight.

To compare the powers of the resulting tests, we repeated the above experiment for data from a bivariate normal distribution with correlated marginals with correlation coefficient $\rho = 0.2$. Table 2 displays the obtained results. Looking at this table we conclude that the bootstrap and permutation approximation behave very closely; that these two approximations with normal weight and $a = 0.5$ yield the most powerful results; as the sample size increases, the differences between the three studied approximations becomes negligible.

Finally, we also compared the three studied approximations in terms of the required time to get a p-value. Table 3 displays the average time consumed in the seconds needed to obtain each approximation to the p-value (Intel(R) Core(TM) i7-4710MQ, 2.5 Ghz). In this respect, the bootstrap approximation is a little more time consuming than the permutation one. Anyway, both approximations require much more time than the WB.

Summarizing, in the light of the numerical results, our recommendation is to use the permutation approximation for $n < 100$ and the WB for $n \geq 100$; as for the weight function w, it is advisable to use the normal PDF with standard deviation 0.5.

Abstract

Recent advances in subwavelength metal optics, *e.g.* nanophotonics, metamaterials, and plasmonics, provide several new examples where nanostructured metals perform the separate tasks of absorption and charge separation necessary for solar power conversion. Nanostructured metals are extremely efficient broadband absorbers of radiation, with tailorable optical properties throughout the visible and infrared spectrum.

This preliminary report concerns a compact splitting difference method for solving Helmholtz partial differential equations in subwavelength metal in radially symmetric fields. We consider a highly accurate transverse approximation for nanostructured performance simulations. Proper auxiliary expansions are carried out, and a decomposition strategy is employed. It is proven that the highly reliable and efficient compact splitting algorithm is asymptotically stable. Simulation illustrations are given.

1 Introduction

Maxwell's field equations have been playing a crucial role in modeling electromagnetic fields and subwavelength optical waves. The equations provide a ultimate theoretical backbone for numerous cutting-edge technologies such as high efficiency energy transforms. Maxwell's equations describe how electric and magnetic fields propagate and interact. Although these equations are difficult to use for immediate initial-boundary value problem computations,

 ISBN: 978-84-617-8694-7

if being decoupled properly, they yield straightforward computational models such as the following time-dependent Helmholtz equation,

$$u_{tt} = c^2 \left(u_{xx} + u_{yy} + u_{zz}\right), \quad (x, y) \in \mathcal{D}_2,\ z > 0,\ t > t_0, \tag{1.1}$$

where $u = u(x, y, z, t)$ is the intensity function of the electric field, z is the beam propagation direction, c is the speed of light, and $\mathcal{D}_2$ is the two-dimensional transverse domain. When a monochromatic light is assumed, we may define $u(x, y, z, t) = v(x, y, z)e^{2\pi i\kappa_0 t}$, where $i = \sqrt{-1}$, κ_0 is the optical wave frequency in the free space, and v is the complex wavefunction [1, 6]. Thus, from (1.1) we have the following:

$$v_{xx} + v_{yy} + v_{zz} = -\kappa^2 v, \quad (x, y) \in \mathcal{D}_2,\ z > 0,$$

where $\kappa = 2\pi\kappa_0/c > 10^2$ is the wave number of the light beam. We continue letting w be the complex envelope of v. Therefore, from the above we observe that

$$2i\kappa w_z = w_{xx} + w_{yy} + w_{zz}, \quad (x, y) \in \mathcal{D}_2,\ z > 0. \tag{1.2}$$

Explorations and investigations of fast and effective numerical methods for computing oscillatory solutions of (1.1), (1.2) with relatively small wave numbers can be found in numerous recent publications. However, the investigation of highly efficient and accurate algorithms beyond finite-difference time-domain methods for solving highly oscillatory optical beam propagation problems is still in its early stages [5, 8]. Diffraction and Fourier integral formalism is still dominating solution procedures for paraxial optical systems.

In this presentation, we are primarily interested in decomposition strategies which offer high accuracy in transverse directions while providing both computational efficiency and effectiveness. We turn our main attention to cases where radially symmetric electric fields in transverse directions are expected. The singularity that emerges in the resulting Helmholtz equation in polar coordinates is also successively removed via a decomposition strategy in the transverse direction [7, 11, 13]. Special consideration is given to the investigation of asymptotic stability of the compact splitting scheme derived.

2 Approximations in Transverse Direction

For the simplicity in discussions, we consider only monochromatic lights, and cases in which electric fields in transverse directions may be treated as radially symmetric [6, 10]. Now, if $\mathcal{D}_2$ is radially symmetric, then (1.2) can be conveniently reformulated to yield

$$w_z = \beta \left(w_{rr} + \frac{1}{r} w_r + w_{zz}\right), \quad 0 < r \leq R,\ z \geq 0, \tag{2.1}$$

 ISBN: 978-84-617-8694-7

where $z_0 > 0$ and $\beta = -i/(2\kappa)$ via a standard polar transformation. Consider a transparent boundary condition [9, 14]:

$$w_r|_{r=R} = 0, \quad z \geq 0, \tag{2.2}$$

where w_r is the outgoing normal derivative of w along the boundary of $\mathcal{D}_2$. We likewise adopt a typical Gaussian beam type initial function [1, 3],

$$w(r, 0; z_0) = \frac{e^{-r^2/[2(1+iz_0)]}}{1 + iz_0}, \quad 0 \leq r \leq R. \tag{2.3}$$

Theorem 2.1. *Let $0 < \tilde{r} \ll R$ and w be sufficiently smooth in the transverse direction. Then for $0 < r < \tilde{r}$ and $z > z_0$,*

$$\frac{1}{r}w_r(r, z) - w_{rr}(r, z) = g(w) - \frac{r^4}{30}w_{r^6}(\xi_1, z) - \frac{r^4}{24}w_{r^7}(\xi_0, z)(\xi_2 - \xi_1),$$

where

$$g(w) = -\frac{r}{2}w_{rrr}(0, z) - \frac{r^2}{3}w_{r^4}(0, z) - \frac{r^3}{8}w_{r^5}(0, z)$$

and $0 < \xi_k < \tilde{r},\ k = 0, 1, 2$.

To eliminate the singularity in (2.1) as $r \to 0$, we replace the equation by the following coupled decomposed equations:

$$w_z = \beta\left(2w_{rr} + w_{zz} + g(w)\right), \quad 0 \leq r < \tilde{r}, \tag{2.4}$$

$$w_z = \beta\left(w_{rr} + \frac{1}{r}w_r + w_{zz}\right), \quad \tilde{r} \leq r \leq R. \tag{2.5}$$

Note that the error induced is of $\mathcal{O}(r^4)$ where $0 < r < \tilde{r} \ll R$. Moreover, since the singularity has been removed, for calculations involving (2.4) we may consider a slightly extended transverse domain, $[0, \tilde{r})$.

The structures of the underlying differential equations often play a critical role in developing proper compact or essentially compact algorithms [4, 12, 13, 15]. Continuing differentiations of (2.4) yield

$$w_{rrrr} = \frac{1}{2\beta}w_{zrr} - \frac{1}{2}w_{zzrr} + \frac{1}{3}w_{r^4}(0, z) + \frac{3r}{8}w_{r^5}(0, z), \quad 0 \leq r < \tilde{r},\ z > z_0. \tag{2.6}$$

By the same token, from (2.5) we acquire

$$\begin{aligned} w_{rrrr} + \frac{2}{r}w_{rrr} &= \frac{1}{\beta}w_{zrr} + \frac{1}{\beta r}w_{zr} - w_{zzrr} - \frac{1}{r}w_{zzr} \\ &\quad + \frac{1}{r^2}w_{rr} - \frac{1}{r^3}w_r, \quad \tilde{r} \leq r \leq R,\ z > z_0. \end{aligned} \tag{2.7}$$

 ISBN: 978-84-617-8694-7

Now, let $h = R/(n-1) < \tilde{r}$ be sufficiently small, and denote $\mathcal{D}_h = \{r_k : \ r_k = (k-1)h, \ k = 1, 2, \ldots, n\}$. Since $w(-h, z) = w(h, z), \ z \geq z_0$, we derive from (2.4), (2.5) that

$$\begin{aligned}
(w_z)_k &= 2\beta \frac{w_{k+1} - 2w_k + w_{k-1}}{h^2} - \frac{\beta h^2}{3!}(w_{r^4})_k - \frac{4\beta h^4}{6!}(w_{r^6})_k \\
&\quad + \beta(w_{zz})_k + \beta g(w_0) + \mathcal{O}\left(h^6\right), \quad k = 1, 2, \ldots, \tilde{k}, \qquad (2.8) \\
(w_z)_k &= \beta \frac{w_{k+1} - 2w_k + w_{k-1}}{h^2} + \frac{\beta}{r_k}\left(\frac{w_{k+1} - w_{k-1}}{2h}\right) + \beta(w_{zz})_k \\
&\quad - \beta\left[\frac{h^2}{3!}\left(\frac{1}{2}(w_{r^4})_k + \frac{1}{r_k}(w_{r^3})_k\right) + \frac{h^4}{5!}\left(\frac{1}{3}(w_{r^6})_k\right.\right. \\
&\quad \left.\left. + \frac{1}{r_k}(w_{r^5})_k\right)\right] + \mathcal{O}\left(h^6\right), \quad k = \tilde{k}+1, \tilde{k}+2, \ldots, n; \qquad (2.9)
\end{aligned}$$

where $\tilde{k} \geq 1$ is a small integer for which $0 < \tilde{k}h < \tilde{r}$ and $(\tilde{k}+1)h \geq \tilde{r}$ [11]. Note that the values of w_0 and w_{n+1} can be determined via (2.3) and (2.2), respectively.

A substitution of (2.6), (2.7) into (2.8), (2.9) leads to

$$\begin{aligned}
(w_z)_k &= 2\beta\left(\frac{w_{k+1} - 2w_k + w_{k-1}}{h^2}\right) + \beta(w_{zz})_k - \frac{(w_z)_{k+1} - 2(w_z)_k + (w_z)_{k-1}}{12} \\
&\quad + \beta\frac{(w_{zz})_{k+1} - 2(w_{zz})_k + (w_{zz})_{k-1}}{12} + \beta\tilde{g}(w_0) + \mathcal{O}\left(h^4\right), \\
&\quad k = 1, 2, \ldots, \tilde{k}, \ z > z_0; \qquad (2.10) \\
(w_z)_k &= \beta\left(\frac{w_{k+1} - 2w_k + w_{k-1}}{h^2} + \frac{w_{k+1} - w_{k-1}}{2r_k h}\right) + \beta(w_{zz})_k \\
&\quad - \frac{\beta h}{12}\left[\frac{(w_z)_{k+1} - 2(w_z)_k + (w_z)_{k-1}}{\beta h} + \frac{(w_z)_{k+1} - (w_z)_{k-1}}{2\beta r_k}\right. \\
&\quad - \frac{(w_{zz})_{k+1} - 2(w_{zz})_k + (w_{zz})_{k-1}}{h} - \frac{(w_{zz})_{k+1} - (w_{zz})_{k-1}}{2r_k} \\
&\quad \left. + \frac{w_{k+1} - 2w_k + w_{k-1}}{r_k^2\, h} - \frac{w_{k+1} - w_{k-1}}{2r_k^3}\right] + \mathcal{O}\left(h^4\right), \\
&\quad k = \tilde{k}+1, \tilde{k}+2, \ldots, n, \ z > z_0, \qquad (2.11)
\end{aligned}$$

where

$$\tilde{g}(w_0) = g(w) - \frac{h^2}{18}w_{r^4}(0, z) - \frac{h^2 r_k}{16}w_{r^5}(0, z).$$

 ISBN: 978-84-617-8694-7

3 Approximations in Propagation Direction

Adopt a standard central difference approximation for the z-derivatives, from (2.10), (2.11) we have

$$\begin{aligned}
\frac{w_k^{j+1}-w_k^{j-1}}{2\tau} &= 2\beta\left(1+\frac{h^2}{12\tau^2}\right)\left[\frac{w_{k+1}^j-2w_k^j+w_{k-1}^j}{h^2}\right]+\beta\left[\frac{w_k^{j+1}-2w_k^j+w_k^{j-1}}{\tau^2}\right]\\
&\quad-\frac{1}{12}\left[\frac{w_{k+1}^{j+1}-2w_k^{j+1}+w_{k-1}^{j+1}-w_{k+1}^{j-1}+2w_k^{j-1}-w_{k-1}^{j-1}}{2\tau}\right]\\
&\quad+\frac{\beta}{12}\left[\frac{w_{k+1}^{j+1}-2w_k^{j+1}+w_{k-1}^{j+1}+w_{k+1}^{j-1}-2w_k^{j-1}+w_{k-1}^{j-1}}{\tau^2}\right]\\
&\quad+\beta\tilde{g}\left(w_0^j\right)+\mathcal{O}\left(h^4+\tau^2\right),\quad k\in\theta_0; \qquad (3.1)\\
\frac{w_k^{j+1}-w_k^{j-1}}{2\tau} &= \beta\left(1-\frac{h^2}{12r_k^2}\right)\left[\frac{w_{k+1}^j-2w_k^j+w_{k-1}^j}{h^2}\right]+\beta\left[\frac{w_k^{j+1}-2w_k^j+w_k^{j-1}}{\tau^2}\right]\\
&\quad+\frac{\beta}{r_k}\left(1+\frac{h^2}{12r_k^2}\right)\left[\frac{w_{k+1}^j-w_{k-1}^j}{2h}\right]-\frac{h}{24r_k}\left[\frac{w_{k+1}^{j+1}-w_{k-1}^{j+1}-w_{k+1}^{j-1}+w_{k-1}^{j-1}}{2\tau}\right]\\
&\quad-\frac{1}{12}\left[\frac{w_{k+1}^{j+1}-2w_k^{j+1}+w_{k-1}^{j+1}-w_{k+1}^{j-1}+2w_k^{j-1}-w_{k-1}^{j-1}}{2\tau}\right]\\
&\quad+\frac{\beta}{12}\left[\frac{w_{k+1}^{j+1}-2w_k^{j+1}+w_{k-1}^{j+1}-2w_{k+1}^j+4w_k^j-2w_{k-1}^j+w_{k+1}^{j-1}-2w_k^{j-1}+w_{k-1}^{j-1}}{\tau^2}\right]\\
&\quad+\frac{\beta h}{24r_k}\left[\frac{w_{k+1}^{j+1}-w_{k-1}^{j+1}-2w_{k+1}^j+2w_{k-1}^j+w_{k+1}^{j-1}-w_{k-1}^{j-1}}{\tau^2}\right]\\
&\quad+\mathcal{O}\left(h^4+\tau^2\right),\quad k\in\theta_1, \qquad (3.2)
\end{aligned}$$

where $\theta_0=\left\{1,\ldots,\tilde{k}\right\}$, $\theta_1=\left\{\tilde{k}+1,\tilde{k}+2,\ldots,n\right\}$ and $p=p^j$ and τ is the variable z-step.

Denote

$$\sigma=\frac{\tau}{h^2},\ \lambda=24\beta\sigma,\ \mu_k^{\pm}=2\pm\frac{h}{r_k},\ \nu_k^{\pm}=1\pm\frac{h^2}{12r_k^2},\ \eta^{\pm}=1\pm\frac{2\beta}{\tau}.$$

In an effort to organize the scheme in a convenient manner, drop all truncation errors from (3.1), (3.2) and rearrange terms. We consequently arrive at the following *compact splitting algorithm* for the numerical solution of the subwavelength energy transfering problem (2.2)-(2.5),

$$Aw^{j+1}=Bw^j+Cw^{j-1}+p^{\,j},\quad j=1,2,3,\ldots, \qquad (3.3)$$

 ISBN: 978-84-617-8694-7

where $p, w \in \mathbb{C}^n$ and $A, B, C \in \mathbb{C}^{n\times n}$ are tridiagonal,

$$A = \begin{bmatrix} b_1 & (a_1+c_1) & & \\ a_2 & b_2 & c_2 & \\ \ddots & \ddots & \ddots & \\ & a_{n-1} & b_{n-1} & c_{n-1} \\ & & (a_n+c_n) & b_n \end{bmatrix}, \tag{3.4}$$

$$B = \begin{bmatrix} e_1 & (d_1+f_1) & & \\ d_2 & e_2 & f_2 & \\ \ddots & \ddots & \ddots & \\ & d_{n-1} & e_{n-1} & f_{n-1} \\ & & (d_n+f_n) & e_n \end{bmatrix}, \tag{3.5}$$

$$C = \begin{bmatrix} m_1 & (l_1+n_1) & & \\ l_2 & m_2 & n_2 & \\ \ddots & \ddots & \ddots & \\ & l_{n-1} & m_{n-1} & n_{n-1} \\ & & (l_n+n_n) & m_n \end{bmatrix}, \tag{3.6}$$

where

$$a_k = \begin{cases} \eta^-, & k\in\theta_0, \\ \mu_k^-\eta^-/2, & k\in\theta_1; \end{cases} \qquad b_k = \begin{cases} 10\eta^-, & k\in\theta_0, \\ 10\eta^-, & k\in\theta_1; \end{cases}$$

$$c_k = \begin{cases} \eta^-, & k\in\theta_0, \\ \mu_k^+\eta^-/2, & k\in\theta_1; \end{cases} \qquad d_k = \begin{cases} 4\beta\left(12\sigma - 1/\tau\right), & k\in\theta_0, \\ \lambda\nu_k^- - \dfrac{\lambda h}{2r_k}\nu_k^+ - \dfrac{2\beta}{\tau}\mu_k^-, & k\in\theta_1; \end{cases}$$

$$e_k = \begin{cases} -8\beta\left(12\sigma + 5/\tau\right), & k\in\theta_0, \\ -2\left(\lambda\nu_k^- + 20\beta/\tau\right), & k\in\theta_1; \end{cases} \qquad f_k = \begin{cases} 4\beta\left(12\sigma - 1/\tau\right), & k\in\theta_0, \\ \lambda\nu_k^- + \dfrac{\lambda h}{2r_k}\nu_k^+ - \dfrac{2\beta}{\tau}\mu_k^+, & k\in\theta_1; \end{cases}$$

$$g_k^j = \begin{cases} \tilde{g}(E_0^j), & k\in\theta_0, \\ 0, & k\in\theta_1; \end{cases} \qquad l_k = \begin{cases} \eta^+, & k\in\theta_0, \\ \mu_k^-\eta^+/2, & k\in\theta_1; \end{cases}$$

$$m_k = \begin{cases} 10\eta^+, & k\in\theta_0, \\ 10\eta^+, & k\in\theta_1; \end{cases} \qquad n_k = \begin{cases} \eta^+, & k\in\theta_0, \\ \mu_k^+\eta^+/2, & k\in\theta_1. \end{cases}$$

4 Asymptotic Stability

Consider an evolutional finite difference method with an amplification matrix M for solving an oscillatory problem associated with a high wave number κ. We say that the numerical

 ISBN: 978-84-617-8694-7

method is asymptotically stable if there exists a constant $d \in \mathbb{R}^+$ such that

$$\|M\| < 1 + \mathcal{O}\left(\kappa^{-d}\right), \quad \kappa \gg 1,$$

where $\|\cdot\|$ is an appropriate matrix norm and the constant $d > 0$ is the asymptotical stability index of the method [12, 14].

Theorem 4.1. *The compact splitting scheme* (3.3) *is unconditionally asymptotically stable with the index* $d = 1$.

Proof. Without loss of generality, we begin with our perturbation equation

$$\epsilon^{\,j+1} = A^{-1}B\epsilon^{\,j} + A^{-1}C\epsilon^{\,j-1}.$$

It follows that

$$\left\|\epsilon^{\,j+1}\right\| \;\leq\; \left(\left\|A^{-1}B\right\| + \left\|A^{-1}C\right\|\right)\left\|\epsilon^{\,j}\right\|.$$

Thus for the amplification matrix M, we have $\|M\| \leq \left\|A^{-1}B\right\| + \left\|A^{-1}C\right\|$.

Define

$$\tilde{A} = \begin{bmatrix}
10 & 1 & & & & & & \\
1 & 10 & 1 & & & & & \\
 & \ddots & \ddots & \ddots & & & & \\
 & & 1 & 10 & 1 & & & \leftarrow \left(\tilde{k}\right)^{th} \text{ row} \\
 & & & 1-\dfrac{h}{2r_{\tilde{k}+1}} & 10 & 1+\dfrac{h}{2r_{\tilde{k}+1}} & & \leftarrow \left(\tilde{k}+1\right)^{st} \text{ row} \\
 & & & & \ddots & \ddots & \ddots & \\
 & & & & 1-\dfrac{h}{2r_{n-1}} & 10 & 1+\dfrac{h}{2r_{n-1}} & \\
 & & & & & 1-\dfrac{h}{2r_n} & 10 &
\end{bmatrix}, \quad (4.1)$$

It is not difficult to see that

$$\left\|A^{-1}C\right\| = 1, \quad \left\|A^{-1}B\right\| \leq \left|\frac{1}{1+\frac{i}{\kappa\tau}}\right| \left|-\frac{i}{2\kappa}\right| \left\|\tilde{A}^{-1}\right\| \left\|\tilde{B}\right\|.$$

Since $\left|\left(1+\dfrac{i}{\kappa\tau}\right)^{-1}\right| < 1$, we conclude that

$$\left\|A^{-1}B\right\| < \frac{1}{2\kappa}\left\|\tilde{A}^{-1}\right\| \left\|\tilde{B}\right\| = \mathcal{O}\left(1/\kappa\right).$$

 ISBN: 978-84-617-8694-7

Thus

$$\|M\| \leq \left\|A^{-1}B\right\| + \left\|A^{-1}C\right\| < 1 + \mathcal{O}\left(1/\kappa\right), \quad \kappa \gg 1.$$

This completes our proof. ∎

The above proof follows for any desired matrix norm.

5 Example and Conclusion

Consider the problem (2.1)-(2.3) with $\kappa = 10^4$ and $z_0 = 100$. For a CFL number 0.01, we simulate the numerical solution w at the wave focusing location in Figures 5.1 and 5.2. The vector generated 3D figures clearly demonstrate the superior numerical convergence as suggested by the asymptotic stability of the compact splitting algorithm. The computational experiments are carried out on a high performance HP C3000BL HPC cluster system running CentOS 5. The cluster is comprised of 128 computer nodes, each with 16GB of RAM and dual quad-core Intel 2.6GHz processors giving a total of 1024 cores. An Infiniband ConnectX DDR network is used for message passing and networked storage. Shared storage capacity in the cluster is 123TB.

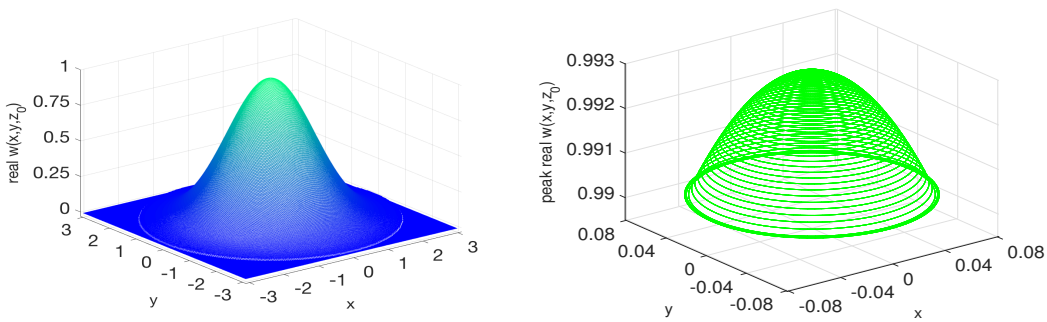

Fig. 5.1. Three-dimensional views of the real part of the focusing numerical solution $w(x, y, z_0) = w(r, z_0)$ (LEFT) and its enlarged inner solution (RIGHT).

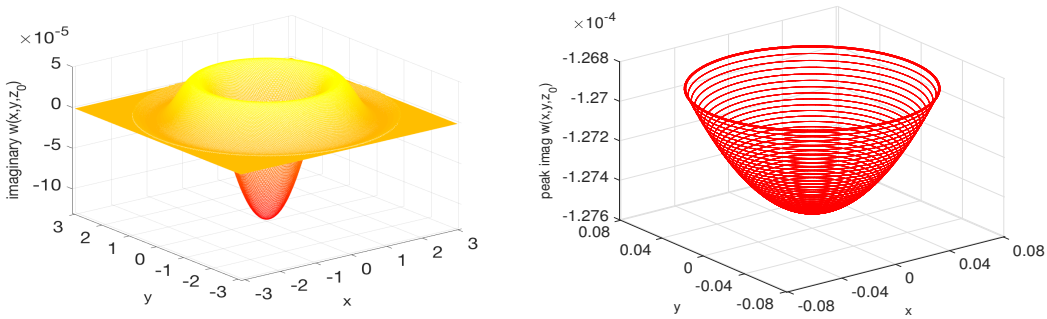

Fig. 5.2. Three-dimensional views of the imaginary part of the focusing numerical solution $w(x, y, z_0) = w(r, z_0)$ (LEFT) and its enlarged inner solution (RIGHT).

 ISBN: 978-84-617-8694-7

In summary, a splitting method for solving Helmholtz partial differential equations in subwavelength metal is developed on decomposed radially symmetric transverse fields successfully. The compact structures of the numerical method ensures higher accuracy and simplicity in nanostructured applications. Proper auxiliary expansions are utilized and discussed on decomposed domains. It is proven that the highly reliable and efficient compact splitting algorithm is asymptotically stable. The corresponding algorithms have been intensively used for numerous computational projects involving subwavelength metal optics and applications.

Smooth Cubic Pythagorean Hodograph Splines

Kryštof Kadlec[1] **and Zbyněk Šír**[1]

[1] *Faculty of Mathematics and Physics, Charles University, Prague*

emails: kadlec.krystof@gmail.com, zbynek.sir@mff.cuni.cz

Abstract

In this paper we describe how to control the transformations, reparameterizations and continuity of planar cubic Pythagorean Hodograph splines. More precisely we show how these features can be ensured by conditions on the curve preimage.

Key words: PH curve, spline, signed curvature, rotation

1 Introduction and preliminaries

Pythagorean hodograph (PH) curves (see [1, 3, 2, 4, 5] and the references cited therein), form a remarkable subclass of polynomial parametric curves. They have a piecewise polynomial arc length function and, in the planar case, rational offset curves. These curves provide an elegant solution of various difficult problems occurring in applications, in particular in the context of CNC (computer-numerical-control) machining. Our paper is devoted to the modification of the planar PH curves via their preimage and on the connection of two PH cubics in a smooth way.

A Bézier curve is called *Pythagorean Hodograph (PH)* if the length of its tangent vector, taken in the appropriate metric, depends in a polynomial way on the parameter. In particular in the planar case $\mathbf{p}(t) = [x(t), y(t)]$ is called *planar PH curve* if there exists a polynomial $\sigma(t)$ such that

$$x'(t)^2 + y'(t)^2 = \sigma^2(t). \tag{1}$$

The degree of $\sigma(t)$ equals $n-1$, where n is the degree of the PH curve. The curve $\mathbf{h}(t) = [x'(t), y'(t)]$ is called the *hodograph* of $\mathbf{p}(t)$.

The planar polynomial curve $\mathbf{p}(t)$ can be identified with complex valued polynomial $\mathbf{p}(t) = x(t) + iy(t)$. The hodograph $\mathbf{h}(t) = x'(t) + iy'(t)$ then satisfy the equation (1) if and

 ISBN: 978-84-617-8694-7

only if it is of the form $\mathbf{h}(t) = \lambda(t)\mathbf{w}(t)^2$, where $\mathbf{w}(t) = u(t) + iv(t)$ is a complex valued polynomial called *preimage*, [1, 6].

In order to study the $\mathcal{G}^2$ continuity we will need the notion of the signed curvature.

Definition 1.1 Let $\mathbf{c} : I \to \mathbb{R}^2$ be a regular parameterized curve. We define its *s*igned curvature at the point $t \in I$ by the formula

$$\kappa_z(t) = \frac{\det(c'(t),\, c''(t))}{\|\|c'(t)\|\|^3}. \tag{2}$$

The signed curvature is not changed by the orientation-preserving reparameterizations.

2 Controling PH curves via their preimage

In this section we will show how a PH curve can be transformed and reparameterized via its preimage. We will also provide the formula for the signed curvature based on the preimage.

Lemma 2.1 Let $\mathbf{p} : I \to \mathbb{R}^2$ be a PH curve nad $\mathbf{q} : I \to \mathbb{R}^2$ its preimage. Then $\mathbf{p}$ is regular if and only if $\forall t \in I : \mathbf{q}(t) \neq \mathbf{0}$.

Proof: Let the complex preimage is of the form $\mathbf{q}(t) = a(t) + ib(t)$. Suppose

$$\forall t \in I : \mathbf{q}(t) \neq \mathbf{0} \Leftrightarrow \forall t \in I : a(t) \neq 0 \vee b(t) \neq 0.$$

Thus for

$$\mathbf{h}(t) = q^2(t) = a^2(t) - b^2(t) + i2a(t)b(t)$$

we get $\forall t \in I : \mathbf{h}(t) \neq (0,0)$, because if for some $t_0 \in I : a(t_0) = b(t_0) \neq 0$, then $a(t_0)b(t_0) \neq 0$. If on the other hand for some $t_1 \in I : a(t_1)b(t_1) = 0$, then $a^2(t_1) - b^2(t_1) \neq 0$. As $\mathbf{p}'(t) = \mathbf{h}(t) \neq \mathbf{0} t \in I$, we obtain the regularity.
For the other implication consider the curve $\mathbf{p}$ with the hodograph

$$\mathbf{h}(t) = a^2(t) - b^2(t) + i2a(t)b(t),$$

which due to the regularity satisfies $\mathbf{h}(t) \neq \mathbf{0}, t \in I$. Then

$$\forall t \in I : a^2(t) - b^2(t) \neq 0 \vee 2a(t)b(t) \neq 0 \Leftrightarrow \forall t \in I : a(t) \neq 0 \vee b(t) \neq 0.$$

Thus we get

$$\forall t \in I : \mathbf{q}(t) = a(t) + ib(t) \neq \mathbf{0}.$$

□

Lemma 2.2 If the peimage is rotated clockwise by an angle α then the resulting PH curve is rotated by the angle 2α.

 ISBN: 978-84-617-8694-7

Proof: Rotation by the angle α can be realized by the multiplication with the complex unit $\cos\alpha + i\sin\alpha$. Suppose that the starting preimage is $\mathbf{q} = a + ib$ (we omit the parameter t on which the functions a, b depend) and obtain the rotated preimage

$$\begin{aligned}\mathbf{q}_r &= (a+ib)(\cos\alpha + i\sin\alpha) = \\ &= (a\cos\alpha - b\sin\alpha) + i(a\sin\alpha + b\cos\alpha) = c + id.\end{aligned}$$

Taking its square we obtain the rotated hodograph

$$\begin{aligned}&\mathbf{h}_r = (c^2 - d^2) + i(2cd) = \\ &= a^2\cos^2\alpha - 2ab\cos\alpha\sin\alpha + b^2\sin^2\alpha - a^2\sin^2\alpha - 2ab\sin\alpha\cos\alpha - \\ &- b^2\cos^2\alpha + i2(a^2\sin\alpha\cos\alpha + ab\cos^2\alpha - ab\sin^2\alpha - b^2\sin\alpha\cos\alpha) = \\ &= a^2\cos 2\alpha - 2ab\sin 2\alpha - b^2\cos 2\alpha + i(a^2\sin 2\alpha - b^2\sin 2\alpha + 2ab\cos(2\alpha) \\ &= ((a^2 - b^2) + i(2ab))(\cos 2\alpha + i\sin 2\alpha) = \mathbf{h}(\cos 2\alpha + i\sin 2\alpha).\end{aligned}$$

We thus obtain the starting hodograph rotated by the angle 2α. The same holds for the PH curve, as the integration commutes with the rotation. □

Translation can be realized by the integration constant. We have seen, that the rotation is obtained via rotating the preimage. The following lemma shows that the linear reparameterization of the preimage provides a scaled PH curve.

Lemma 2.3 Let the PH curve $\mathbf{p}$ has the r $\mathbf{q}$ and let $k \neq 0, l \in \mathbb{R}$. Then the linearly reparameterized preimage $\mathbf{q}(kt + l)$ provides the PH curve $\frac{1}{k}\mathbf{p}(kt + l)$.

Proof: We obtain this result by a direct use of the substitution in the integral. □

The following result is straightforward, too.

Lemma 2.4 Let $\mathbf{q}$ is the preimage of the PH curve $\mathbf{p}$. The $k\mathbf{q}, k \in \mathbb{R}$, is the preimage of the curve $k^2\mathbf{p}$.

Combining the two previous observation we get the following method for obtaining the pure reparameterization of the curve.

Proposition 2.5 Let $\mathbf{q}(t)$ be the preimage of the PH curve $\mathbf{p}(t)$ and k, $l \in \mathbb{R}, k > 0$. Then $\sqrt{k} \cdot \mathbf{q}(kt + l)$ is the preimage of the PH curve $\mathbf{p}(kt + l)$.

The signed curvature of the PH curve can be obtained from its preimage in the following way.

Proposition 2.6 Let a PH kivka
$\mathbf{p} : I \to \mathbb{R}^2$ has the preimage $\mathbf{q}$. Then the signed curvature of $\mathbf{p}$ can be expressed as

$$\kappa_z(t) = 2\frac{\mathrm{Im}(\bar{\mathbf{q}}(t)\mathbf{q}'(t))}{|\mathbf{q}(t)|^4}. \tag{3}$$

 ISBN: 978-84-617-8694-7

Proof: This formula can be found at [1] without the proof. Let us denote $\mathbf{h} = \mathbf{p}' = (x', y')$, $\mathbf{h} = \mathbf{q}^2$, thus $\mathbf{h}' = 2\mathbf{q}\mathbf{q}' = (x'', y'')$. using the formula (2) we get

$$\kappa_z = \frac{\det(\mathbf{p}',\, \mathbf{p}'')}{\|\mathbf{p}\|^3} = \frac{x'y'' - x''y'}{(x'^2 + y'^2)^{3/2}}.$$

Moreover

$$2\frac{\mathrm{Im}(\bar{\mathbf{q}}\mathbf{q}')}{|\mathbf{q}|^4} = \frac{\mathrm{Im}(2\mathbf{q}\mathbf{q}'\bar{\mathbf{q}}^2)}{|\mathbf{q}|^6} = \frac{\mathrm{Im}(\mathbf{h}'\bar{\mathbf{h}})}{|\mathbf{h}|^3} =$$
$$= \frac{\mathrm{Im}((x'' + iy'')(x' - iy'))}{(x'^2 + y'^2)^{3/2}} = \frac{x'y'' - x''y'}{(x'^2 + y'^2)^{3/2}} = \kappa_z.$$

□

3 Smooth joints of PH cubics

In the reminder of the paper we will restrict our investigations to the cubic PH curves. In particular we will consider the joint between two cubic PH curves and the sufficient end necessary conditions for the joint to be smooth. We will suppose that the curves are connected in the $\mathcal{C}^0$ way, which can be achieved by setting suitably the integration constants. We will use the following notation: Consider two PH cubics $\mathbf{p}_1$ a $\mathbf{p}_2$ with the linear preimages $\mathbf{q}_1$ and $\mathbf{q}_2$ of the form

$$\begin{gathered}\mathbf{q}_1(t) = \mathbf{w}_0(1-t) + \mathbf{w}_1 t, \mathbf{q}_2(t) = z_0(1-t) + z_1 t, \\ \mathbf{w}_0,\, \mathbf{w}_1,\, \mathbf{z}_0,\, \mathbf{z}_1 \in \mathbb{C}, \mathbf{w}_0 = w_{01} + iw_{02},\, \mathbf{w}_1 = w_{11} + iw_{12}.\end{gathered} \tag{4}$$

The following proposition gives the conditions for the $\mathcal{G}^1$ and $\mathcal{C}^1$ continuity.

Proposition 3.1 Let $\mathbf{p}_1$, $\mathbf{p}_2$ are PH cubics with the preimages of the form (4). The curves $\mathbf{p}_1$, $\mathbf{p}_2$ are connected in the $\mathcal{G}^1$ way if and only if $\mathbf{z}_0 = c\mathbf{w}_1, c \in \mathbb{R}, c \neq 0$.
In particular the curves are connected in the $\mathcal{C}^1$ way if and only if $c = \pm 1$.

Proof: Let $\mathbf{h}_1 = \mathbf{p}_1'$, $\mathbf{h}_2 = \mathbf{p}_2'$.
First suppose $\mathbf{z}_0 = c\mathbf{w}_1, c \in \mathbb{R}, c \neq 0$. Then

$$\mathbf{h}_1(t) = \mathbf{w}_0^2(1-t)^2 + \mathbf{w}_0\mathbf{w}_1 2t(1-t) + \mathbf{w}_1^2(1-t)^2,$$
$$\mathbf{h}_2(t) = c^2\mathbf{w}_1^2(1-t)^2 + c\mathbf{w}_1\mathbf{z}_1 2t(1-t) + \mathbf{z}_1^2(1-t)^2.$$

We thus have $\mathbf{p}_1'(1) = \mathbf{h}_1(1) = \mathbf{w}_1^2$ a $\mathbf{p}_2'(0) = \mathbf{h}_2(0) = c^2\mathbf{w}_1^2$. The tangent vectors thus have the same direction and orientation and we have the $\mathcal{G}^1$ continuity.

 ISBN: 978-84-617-8694-7

Moreover the reparameterization of $\mathbf{p}_2$ by the function $\phi(t) = t/c^2$ provides the $\mathcal{C}^1$ continuity. Denote

$$\mathbf{P}_0 = \frac{\mathbf{w}_0^2 + \mathbf{w}_0\mathbf{w}_1 + \mathbf{w}_1^2}{3}, \mathbf{P}_1 = \mathbf{P}_0 + \frac{c^2\mathbf{w}_1^2}{3},$$
$$\mathbf{P}_2 = \mathbf{P}_1 + \frac{c\mathbf{w}_1\mathbf{z}_1}{3}, \mathbf{P}_3 = \mathbf{P}_2 + \frac{\mathbf{z}_1^2}{3}.$$

It holds $\mathbf{p}_2(t) = \mathbf{P}_0(1-t)^3 + \mathbf{P}_1 3t(1-t)^2 + \mathbf{P}_2 3t^2(1-t) + \mathbf{P}_3 t^3$, tedy

$$(\mathbf{p}_2 \circ \phi)(t) = \mathbf{P}_0\left(1 - \frac{t}{c^2}\right)^3 + \mathbf{P}_1\frac{3t}{c^2}\left(1 - \frac{t}{c^2}\right)^2 + \mathbf{P}_2\frac{3t^2}{c^4}\left(1 - \frac{t}{c^2}\right) + \mathbf{P}_3\frac{t^3}{c^6}.$$

Differentiating we get

$$(\mathbf{p}_2 \circ \phi)'(t) = \mathbf{P}_0\left(-\frac{3}{c^2} + \frac{6t}{c^4} - \frac{3t^2}{c^6}\right) + 3\mathbf{P}_1\left(\frac{1}{c^2} - \frac{4t}{c^4} + \frac{3t^2}{c^6}\right) +$$
$$+ 3\mathbf{P}_2\left(\frac{2t}{c^4} - \frac{3t^2}{c^6}\right) + \mathbf{P}_3\frac{3t^2}{c^6},$$

and thus $(\mathbf{p}_2 \circ \phi)'(0) = -\frac{3\mathbf{P}_0}{c^2} + \frac{3\mathbf{P}_1}{c^2} = \mathbf{w}_1^2 = \mathbf{p}_1'(1)$.
For the inverse implication if the connection is $\mathcal{G}^1$ we have $\mathbf{p}_1'(1) = k\mathbf{p}_2'(0), k > 0$, and thus $\mathbf{h}_1(1) = \mathbf{w}_1^2 = k\mathbf{h}_2(0) = k\mathbf{z}_0^2$. Setting $c = \pm\sqrt{k} \neq 0$ we get the statement.
For $c = \pm 1$ there holds $\phi(t) = t/c^2 = t$, the reparameterization is thus the identity and we have the $\mathcal{C}^1$connection. □

The following proposition gives the conditions for the $\mathcal{G}^2$ and $\mathcal{C}^2$ continuity.

Proposition 3.2 Let $\mathbf{p}_1$, $\mathbf{p}_2$ are PH cubics with the preimages (4) and let $\mathbf{z}_0 = c\mathbf{w}_1, c \neq 0$. The curves $\mathbf{p}_1, \mathbf{p}_2$ are connected in the $\mathcal{G}^2$ way if and only if the point $\mathbf{z}_1$ is on the straight line

$$w_{12}x - w_{11}y + c^3(w_{01}w_{12} - w_{11}w_{02}) = 0.$$

The curves are connected in the $\mathcal{C}^2$ way if and only if $c = \pm 1$ and
$c(\mathbf{z}_1 - \mathbf{z}_0) = c(\mathbf{z}_1 - c\mathbf{w}_1) = \mathbf{w}_1 - \mathbf{w}_0$, tedy $\mathbf{z}_1 = c(2\mathbf{w}_1 - \mathbf{w}_0)$.

Proof: The $\mathcal{G}^1$ connection is ensured by the previous proposition. We must obtain the same signed curvature on both segments. Let us denote κ_1 (resp. κ_2) the signed curvature of the curve $\mathbf{p}_1$ (resp. $\mathbf{p}_2$). For $\mathbf{q}_1 = \mathbf{w}_0(1-t) + \mathbf{w}_1 t$ we get using 2.6

$$\kappa_1(t) = 2\frac{\mathrm{Im}(\bar{\mathbf{q}_1}(t)\mathbf{q}_1'(t))}{|\mathbf{q}_1(t)|^4} =$$
$$= \frac{2[(w_{01} + t(w_{11} - w_{01}))(w_{12} - w_{02}) - (w_{11} - w_{01})(w_{02} + t(w_{12} - w_{02}))]}{[(w_{01} + t(w_{11} - w_{01}))^2 + (w_{02} + t(w_{12} - w_{02}))^2]^2}$$

 ISBN: 978-84-617-8694-7

and for $\mathbf{q}_2 = c\mathbf{w}_1(1-t) + \mathbf{z}_1 t$, $\mathbf{z}_1 = [z_{11}, z_{12}]$ we get

$$\kappa_2(t) = 2\frac{\mathrm{Im}(\bar{\mathbf{q}_2}(t)\mathbf{q}_2'(t))}{|\mathbf{q}_2(t)|^4} =$$
$$= \frac{2[(cw_{11} + t(z_{11} - cw_{11}))(z_{12} - cw_{12}) - (z_{11} - cw_{11})(cw_{12} + t(z_{12} - cw_{12}))]}{[(cw_{11} + t(z_{11} - cw_{11}))^2 + (cw_{12} + t(z_{12} - cw_{12}))^2]^2}.$$

We require $\kappa_1(1) = \kappa_2(0)$, which leads to

$$\frac{2(w_{01}w_{12} - w_{11}w_{02})}{(w_{11}^2 + w_{12}^2)^2} = \frac{2c(w_{11}z_{12} - w_{12}z_{11})}{((cw_{11})^2 + (cw_{12})^2)^2},$$

which gives the condition for $\mathbf{z}_1$, namely

$$c^3(w_{01}w_{12} - w_{11}w_{02}) = w_{11}z_{12} - w_{12}z_{11}.$$

For the $\mathcal{C}^2$ continuity we must have $\mathbf{p}_1''(1) = \mathbf{p}_2''(0)$. There holds

$$\mathbf{p}_1''(1) = \mathbf{p}_2''(0) \Leftrightarrow \mathbf{h}_1'(1) = \mathbf{h}_2'(0) \Leftrightarrow 2\mathbf{w}_1(\mathbf{w}_1 - \mathbf{w}_0) = 2c\mathbf{w}_1(\mathbf{z}_1 - c\mathbf{w}_1) \Leftrightarrow$$
$$\Leftrightarrow (\mathbf{w}_1 - \mathbf{w}_0) = c(\mathbf{z}_1 - c\mathbf{w}_1), c = \pm 1.$$

□

4 Examples

Let us demonstrate the continuity results on several examples.

Example 4.1 *Let*

$$\mathbf{w}_0 = [1,\, 1],\ \mathbf{w}_1 = [0,\, -1],\ \mathbf{z}_0 = c\mathbf{w}_1 = [0,\, -3/2],\ \mathbf{z}_1 = [-1,\, 0], c = 3/2.$$

By Proposition 3.1 the resulting curves should be connected in the $\mathcal{G}^1$ way. Indeed

$$\mathbf{p}_2'(0) = (-9/4,\, 0) = c^2\mathbf{p}_1'(1) = \frac{9}{4}(-1, 0).$$

On Figure 1 there is the linear preimage $\mathbf{q}_1$, $\mathbf{q}_2$, and on Figure 2 the resulting PH curves. $\mathcal{C}^1$ connection is a special case of the $\mathcal{G}^1$ connection and is obtained by setting $c = \pm 1$. For $c = 1$ we get $\tilde{\mathbf{z}}_0 = [0, -1]$ and indeed $\tilde{\mathbf{p}}_2'(0) = \mathbf{p}_1'(1) = (-1, 0)$, see Figures 3 and 4. The preimage $\tilde{\mathbf{q}}_2$ has the control points $\tilde{\mathbf{z}}_0$, $\mathbf{z}_1$ and $\tilde{\mathbf{p}}_2$ is the resulting PH curve.

 ISBN: 978-84-617-8694-7

Example 4.2 *Let*

$$\mathbf{w}_0 = [1,\, 0],\, \mathbf{w}_1 = [2,\, 2],\, \mathbf{z}_0 = c\mathbf{w}_1 = [4,\, 4],\, \mathbf{z}_1 = [0,\, 8], c = 2.$$

For $\mathbf{z}_1$ *on the line* $x - y + 8 = 0$ *we get by 3.2 the* $\mathcal{G}^2$ *connectivity. On the figure 5 we see the preimage of the resulting PH along the the condition line (red). At the Figure 6 we see the resulting PH curves having at the joint points identical signed curvatures* $\kappa_{z1}(1) = \kappa_{z2}(0) = 1/16$.
In order to have the $\mathcal{C}^1$ *continuity let us set* $c = -1$, *and thus* $\tilde{\mathbf{z}}_0 = [-2,\, -2]$. *To obtain the* $\mathcal{G}^2$ *continuity the control point* $\mathbf{z}_1$ *must be on the line* $x - y - 1 = 0$. *If we set* $\mathbf{z}_1 = -2\mathbf{w}_1 + \mathbf{w}_0 = [-3,\, -4]$ *we obtain even the* $\mathcal{C}^2$ *continuity. We can see the results on Figures 7 and 8.*

5 Conclusion

We have solved the problem of the connection of order one and two for planar PH cubics. In the future we plan to investigate higher degree PH curves and express the connection results in the formalism of B-splines.

A Probabilistic Evolution Theoretical (PREVTH) Approach to Quantum Evolver Dynamical Equations for Singular Hamiltonians: Fluctuationlessness Approximation

Berfin Kalay[1] **and Metin Demiralp**[1]

[1] *Computational Science and Engineering Department, Informatics Institute, İstanbul Technical University*

emails: berfinkalay@gmail.com, metin.demiralp@gmail.com

Abstract

This work is devoted to the investigation of the Evolver Dynamics of a singular quantum system via Probabilistic Evolution Theoretical tools recently developed in our group studies. Even though the purpose is rather conceptuality we have also developed an approximation which is based on the fluctuationlessness theorem of multivariate functions. We have taken hydrogen-like systems as the target for constructing evolver dynamical equations. The system vector which is composed of operators involves either the position and momentum operator or position, momentum and Hamilton operator related operators as the basic entities and this gives expressions which are singular in position operator. On the other hand, the use of Hamiltonian powers instead of the inverse powers of position operator has facilitated the analysis especially for the use of ground state eigenfunction of the Hamiltonian as the initial wave function. We do not present any implementation because of the conceptual structure of the paper while we have reported how to use fluctuationlessness theorem to evaluate the expectation value evolutions.
Key words: PREVTH, Evolver Dynamics, Expectation Values, Mathematical Fluctuations, Uncertainty.

1 Introduction

Probabilistic Evolution Theory (PREVTH) has been recently developed in our group studies, [1–16] and has been quite well investigated for explicit autonomous ODE(s) with initial impositions. As we have done in our various works whose findings are reported until now,

we have attempted to use PREVTH in quantum expectation value dynamical equations arising from one of our main interests: quantum dynamical motions. We have employed Kronecker power series we proposed in last decade and Poisson Bracket algebra over the basic operators of the quantum system under consideration and obtained an analytical solution after using so-called space extensions, where the solution's vector components are determined thru rather simple recursions. Yet practical efficiency has not been provided and rather complicated cures are proposed in our group studies. All these urged us to develop the Evolver Dynamics which is somehow related to Heisenberg Picture of Quantum Mechanics. The coming sections detail this and related issues.

2 Introducing the Evolver Dynamics

In Schrödinger Picture, a quantum dynamical system can be described by the following partial differential equation which is known as time dependent Schrödinger equation and the accompanying initial imposition

$$i\hbar\frac{\partial\psi\left(\mathbf{x},t\right)}{\partial t}=\widehat{H}\left(\widehat{p},\widehat{q}\,\right)\psi\left(\mathbf{x},t\right),\qquad\psi\left(\mathbf{x},t_{0}\right)=\psi_{0}\left(\mathbf{x}\right)\tag{1}$$

where ψ denotes the wave function of the system, which is a function of position variable denoted by $\mathbf{x}$ and time is symbolized by t while $\hbar$ is the "Reduced Planck Constant" which is in fact the ratio of the universal Planck Constant to 2π. The initial moment of the system's evolution has been denoted by t_0 instead of 0 to give the possibility of using any initialization instant and therefore any desired subinterval for the evolution. Even though ψ_0 can be anything from the space of wave functions, we are going to confine ourselves to rather minimum uncertainty wave packets here for conciseness and brevity.

The expectation value dynamics avoids the use of wave function explicitly except its initial form and therefore the solution of the parabolic Schrödinger equations. In these type approaches, the transition operators are also frequently used and their investigation can be considered as "Transition Operator Picture" (even though this term is rather infrequently employed). This operator is defined as follows

$$\psi\left(\mathbf{x},t_{1}\right)=\widehat{T}\left(\widehat{p},\widehat{q},t_{1},t_{0}\right)\psi\left(\mathbf{x},t_{0}\right)\tag{2}$$

and connects the system's wave function values at two different time instants, t_0 and t_1. Transition operators for isolated systems (which do not interact with their environment) and interacted systems (having interactions with their environments) have of course different structures and the former case is analytically expressible. We do not intend to use different symbols or subscripts to this end but the Hamiltonian will reveal the difference.

 ISBN: 978-84-617-8694-7

The use of (2) in (1) implies that the transition operator $\widehat{T}$ will satisfy the following partial differential equation

$$i\hbar\frac{\partial\widehat{T}\left(\widehat{p},\widehat{q},t,t_0\right)}{\partial t}=\widehat{H}\left(\widehat{p},\widehat{q},t\right)\widehat{T}\left(\widehat{p},\widehat{q},t,t_0\right),\qquad\widehat{T}\left(\widehat{p},\widehat{q},t_0,t_0\right)=\widehat{I}\tag{3}$$

Transition Operator definition does not pretty much facilitate the investigation of quantum system evolution. However it helps us to construct the evolver dynamics. Beside Schrödinger Picture there is another and useful point of view which does not use wave function concept. It is a very well known theory and called "Heisenberg Picture". This picture uses an operator evolving in time for each given operator. This operator is produced by using a general superoperator.

We can now define

$$\mathbb{E}\left(\widehat{o}\right)(t)\equiv\widehat{T}\left(t,t_0\right)^{\dagger}\widehat{o}\,\widehat{T}\left(t,t_0\right)\tag{4}$$

where we call $\mathbb{E}\left(\widehat{o}\right)(t)$ "Evolver Operator of the Operator $\widehat{o}$" or "$\widehat{o}$'s Evolver Operator" while $\mathbb{E}$ which is in fact a superoperator mapping from the space of linear operators to the same space of linear operators since it defines a unitary transformation, is called "Evolver Superoperator".

Since $\widehat{o}$'s evolver operator is a function of t, we may investigate its time derivative and write

$$\begin{aligned}\frac{d\mathbb{E}\left(\widehat{o}\right)(t)}{dt}&=\frac{d\widehat{T}\left(t,t_0\right)^{\dagger}}{dt}\widehat{o}\,\widehat{T}\left(t,t_0\right)+\widehat{T}\left(t,t_0\right)^{\dagger}\widehat{o}\,\frac{d\widehat{T}\left(t,t_0\right)}{dt}\\&=\widehat{T}\left(t,t_0\right)^{\dagger}\left\{\widehat{H},\widehat{o}\right\}\widehat{T}\left(t,t_0\right)\end{aligned}\tag{5}$$

This result shows that time derivative of the image of a target operator $\widehat{o}$ under "Evolver Superoperator" takes us to the image of Poisson Bracket of that operator with the system Hamiltonian, under the same "Evolver Superoperator".

$$\frac{d\mathbb{E}\left(\widehat{o}\right)(t)}{dt}=\mathbb{E}\left(\left\{\widehat{H},\widehat{o}\right\}\right)\tag{6}$$

which is a general conclusion for any time independent operator $\widehat{o}$. The temporal variation of the operator $\widehat{o}$ changes the right hand side of (6) by adding the temporal derivative of $\widehat{o}$ to $\left\{\widehat{H},\widehat{o}\right\}$.

3 Constructing the PREVTH System Vector With No Hamiltonian Dependence

Now to explain how to construct evolver dynamics for a quantum system we are going to focus on a rather simple singular system, hydrogen-like system whose Hamiltonian can be

 ISBN: 978-84-617-8694-7

explicitly given below

$$\widehat{H} \equiv \frac{1}{2\mu}\widehat{p}^{\,2} - \alpha\widehat{q}^{\,-1} \tag{7}$$

where μ denotes the reduced mass parameter while $\widehat{p}$ and $\widehat{q}$ stand for momentum and position operators respectively whereas the scalar α is proportional to the atomic number of the system and contains also certain universal physical constants. We can naturally focus on the momentum and position operators and try to evaluate their Poisson Brackets with the system Hamiltonian. To this end we can use the following well-known properties of the Poission Bracket: (1) it is linear with respect to its both operands, (2) It is distributive on the products in one operand, (3) The leftmost or rightmost Hamilton operator factors in the operands can be factored out the Poisson Bracket. By using these features we can write the following equalities without giving the intermediate details

$$\begin{aligned} \left\{\widehat{H},\widehat{p}\right\} &= \alpha\left\{\widehat{p},\widehat{q}^{\,-1}\right\} = -\alpha\widehat{q}^{\,-2}, \\ \left\{\widehat{H},\widehat{q}\right\} &= \frac{1}{2\mu}\left\{\widehat{p}^{\,2},\widehat{q}\right\} - \alpha\left\{\widehat{q}^{\,-1},\widehat{q}\right\} = \frac{1}{\mu}\widehat{p} \end{aligned} \tag{8}$$

These equalities show that the set composed of momentum and position operators is not multinomially closed under the Poisson Bracket operation. Hence these are not appropriate for the PREVTH equations construction. To get at least multinomiality and beyond that conicality (second degree multinomial right hand sides) we need to consider the inverse of the position operator as a new basic operator. This is a space extension since the dimensionality of the basic operators is increased by one. However, momentum and position operator together with the reciprocal of the position operator does not provide the conicality and enforces us to increase the dimensionality. Until the conicality is obtained the basic operator set remains open under the action of the Poisson Bracket and we are further enforced to extend the space. After our all efforts we could have been able to show that the following system vector of operators provides the conicality.

$$\widehat{\mathbf{s}} \equiv [\,\widehat{s}_1 \;\; ... \;\; \widehat{s}_6\,] \equiv \left[\,\widehat{p} \;\; \widehat{q} \;\; \widehat{q}^{\,-1} \;\; \widehat{p}\,\widehat{q}^{\,-1} \;\; \widehat{q}^{\,-2} \;\; \widehat{q}^{\,-1}\widehat{p}\,\right] \tag{9}$$

The Poisson Bracket evaluations based on this structure can be given as follows

$$\begin{aligned} \left\{\widehat{H},\widehat{s}_1\right\} &= -\alpha\widehat{s}_3^2 & \left\{\widehat{H},\widehat{s}_2\right\} &= \tfrac{1}{\mu}\widehat{s}_1 \\ \left\{\widehat{H},\widehat{s}_3\right\} &= -\tfrac{1}{\mu}\widehat{s}_3\widehat{s}_4 & \left\{\widehat{H},\widehat{s}_4\right\} &= -\alpha\widehat{s}_3\widehat{s}_5 - \tfrac{1}{\mu}\widehat{s}_4^{\,2} \\ \left\{\widehat{H},\widehat{s}_5\right\} &= -\tfrac{1}{\mu}\widehat{s}_5\widehat{s}_4 - \tfrac{1}{\mu}\widehat{s}_6\widehat{s}_5 & \left\{\widehat{H},\widehat{s}_6\right\} &= -\tfrac{1}{\mu}\widehat{s}_6^{\,2} - \alpha\widehat{s}_3\widehat{s}_5 \end{aligned} \tag{10}$$

These equalities can be rewritten in the following concise format

$$\left\{\widehat{H},\widehat{\mathbf{s}}\right\} = \mathbf{F_1}\widehat{\mathbf{s}} + \mathbf{F_2}\widehat{\mathbf{s}}^{\otimes 2} \tag{11}$$

 ISBN: 978-84-617-8694-7

where $\mathbf{F}_1$ is desired to be proportional to 6×6 type identity matrix for getting analytical PREVTH solution while $\mathbf{F}_2$ stands for 6×36 type rectangular matrix. However $\mathbf{F}_1$ is not at that format which can be achieved by using an extra space extension by adding the operator element $\widehat{s}_7$ thru $\widehat{s}_7 \equiv a\widehat{I}$ where $\widehat{I}$ stands for the identity operator while a is arbitrary at this moment. This space extension is also known Constancy Adding Space Extension (CASE) whose original form was more comprehensive. After this CASE we can rewrite the above relevant equalities as follows

$$\widehat{\mathbf{s}} \equiv [\, \widehat{s}_1 \;\; ... \;\; \widehat{s}_7 \,] \equiv \left[\widehat{p} \;\; \widehat{q} \;\; \widehat{q}^{\,-1} \;\; \widehat{p}\widehat{q}^{\,-1} \;\; \widehat{q}^{\,-2} \;\; \widehat{q}^{\,-1}\widehat{p} \;\; a\widehat{I} \right] \tag{12}$$

$$\begin{aligned}
&\left\{\widehat{H}, \widehat{s}_1\right\} = \beta\widehat{s}_1 - \tfrac{\beta}{a}\widehat{s}_1\widehat{s}_7 - \alpha\widehat{s}_3^2 && \left\{\widehat{H}, \widehat{s}_2\right\} = \beta\widehat{s}_2 - \tfrac{\beta}{a}\widehat{s}_2\widehat{s}_7 + \tfrac{1}{a\mu}\widehat{s}_1\widehat{s}_7 \\
&\left\{\widehat{H}, \widehat{s}_3\right\} = \beta\widehat{s}_3 - \tfrac{\beta}{a}\widehat{s}_3\widehat{s}_7 - \tfrac{1}{\mu}\widehat{s}_3\widehat{s}_4 && \left\{\widehat{H}, \widehat{s}_4\right\} = \beta\widehat{s}_4 - \tfrac{\beta}{a}\widehat{s}_4\widehat{s}_7 - \alpha\widehat{s}_3\widehat{s}_5 - \tfrac{1}{\mu}\widehat{s}_4^{\,2} \\
&\left\{\widehat{H}, \widehat{s}_5\right\} = \beta\widehat{s}_5 - \tfrac{\beta}{a}\widehat{s}_5\widehat{s}_7 - \tfrac{1}{\mu}\widehat{s}_5\widehat{s}_4 - \tfrac{1}{\mu}\widehat{s}_6\widehat{s}_5 && \left\{\widehat{H}, \widehat{s}_6\right\} = \beta\widehat{s}_6 - \tfrac{\beta}{a}\widehat{s}_6\widehat{s}_7 - \tfrac{1}{\mu}\widehat{s}_6^{\,2} - \alpha\widehat{s}_3\widehat{s}_5 \\
&\left\{\widehat{H}, \widehat{s}_7\right\} = \beta\widehat{s}_7 - \tfrac{\beta}{a}\widehat{s}_7^{\,2}
\end{aligned} \tag{13}$$

where first six equalities of last formula turn out to be matching previous equalities while the seventh one becomes having zero right hand side when $\widehat{s}_7$ is replaced with $a\widehat{I}$. However we can write these 7 equalities in the following concise format

$$\left\{\widehat{H}, \widehat{\mathbf{s}}\right\} = \beta\,\widehat{\mathbf{s}} + \mathbf{F}\,\widehat{\mathbf{s}}^{\otimes 2} \tag{14}$$

where $\mathbf{F}$ is a rectangular matrix of 7×49 type. The nonzero elements of $\mathbf{F}$ are explicitly given below

$$\begin{aligned}
&F_{1,\,7} = -\tfrac{\beta}{a} && F_{1,\,17} = -\alpha && F_{2,14} = -\tfrac{\beta}{a} && F_{2,\,7} = \tfrac{1}{a\mu} \\
&F_{3,18} = -\tfrac{1}{\mu} && F_{3,21} = -\tfrac{\beta}{a} && F_{4,19} = -\alpha && F_{4,25} = -\tfrac{1}{\mu} \\
&F_{4,28} = -\tfrac{\beta}{a} && F_{5,32} = -\tfrac{1}{\mu} && F_{5,35} = -\tfrac{\beta}{a} && F_{5,40} = -\tfrac{1}{\mu} \\
&F_{6,19} = -\alpha && F_{6,41} = -\tfrac{1}{\mu} && F_{6,42} = -\tfrac{\beta}{a} && F_{7,49} = -\tfrac{\beta}{a}
\end{aligned} \tag{15}$$

The rectangular matrix ultimately obtained above is not unique because of two important reasons: (1) the employed space extension is based on the addition of new functions of original unknowns such that the additions are generally chosen linearly independent even though they are chosen functionally dependent on the existing unknowns, (2) the use of CASE brings very extensive flexibilites for the structuring of the matrix $\mathbf{F}$.

On the other hand the selection of the basic operators may change the $\mathbf{F}$ structuring depending on the preferences.

4 Constructing the PREVTH System Vector With Hamiltonian Dependence

The operator basis set we have used in the previous section contains the powers of finite region singularity in position operator explicitly. This may not be always desired and it preferred to hi de them in Hamiltonian and its powers for certain conveniences. In this section we are going to use Hamilton operator and its certain powers instead of position operator's reciprocal powers. Our investigations have shown that the following system vector's operator elements set is conically closed under the Poisson Bracket operation with the system Hamiltonian and also fits PREVTH format as CASE has been used to get that format

$$\widehat{\mathbf{s}} \equiv [\,\widehat{s}_1 \;\; ... \;\; \widehat{s}_{10}\,] \equiv \left[\,\widehat{p} \;\; \widehat{p}^{\,2} \;\; \widehat{H} \;\; \widehat{H}\,\widehat{p} \;\; \widehat{p}\,\widehat{H} \;\; \widehat{H}^{\,2} \;\; \widehat{p}^{\,3} \;\; \widehat{p}^{\,2}\,\widehat{H} \;\; \widehat{H}\,\widehat{p}^{\,2} \;\; a\widehat{I}\,\right] \tag{16}$$

This enables us to write the following equalities

$$\begin{aligned}
\left\{\widehat{H},\widehat{s}_1\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_2^2 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_3 + \tfrac{1}{2\mu\alpha}\widehat{s}_3\widehat{s}_2 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3^2 + \beta\widehat{s}_1 - \tfrac{\beta}{a}\widehat{s}_1\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_2\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_2\widehat{s}_7 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_2\widehat{s}_4 + \widehat{s}_4\widehat{s}_2\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_4 + \beta\widehat{s}_2 - \tfrac{\beta}{a}\widehat{s}_2\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_3\right\} &= \beta\widehat{s}_3 - \tfrac{\beta}{a}\widehat{s}_3\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_4\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_9\widehat{s}_2 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_4\widehat{s}_5 + \widehat{s}_6\widehat{s}_2\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_6 + \beta\widehat{s}_4 - \tfrac{\beta}{a}\widehat{s}_4\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_5\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_2\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_6 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_5 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_6 + \beta\widehat{s}_5 - \tfrac{\beta}{a}\widehat{s}_5\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_6\right\} &= \beta\widehat{s}_6 - \tfrac{\beta}{a}\widehat{s}_6\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_7\right\} &= -\tfrac{3}{4\mu^2\alpha}\widehat{s}_7^2 + \tfrac{1}{\mu\alpha}\widehat{s}_8\widehat{s}_2 + \tfrac{1}{2\mu\alpha}\widehat{s}_9\widehat{s}_2 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_9 + \tfrac{1}{2\mu\alpha}\widehat{s}_7\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_5\widehat{s}_7 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_5\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_8 - \tfrac{1}{\alpha}\widehat{s}_8\widehat{s}_3 \\
&\quad + \beta\widehat{s}_7 - \tfrac{\beta}{a}\widehat{s}_7\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_8\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_7\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_8\widehat{s}_5 + \widehat{s}_4\widehat{s}_8\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_6\widehat{s}_5 + \tfrac{1}{2\mu\alpha}\widehat{s}_7\widehat{s}_6 + \tfrac{1}{2\mu\alpha}\widehat{s}_5\widehat{s}_8 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_5\widehat{s}_6 + \beta\widehat{s}_8 - \tfrac{\beta}{a}\widehat{s}_8\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_9\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_9\widehat{s}_7 + \tfrac{1}{2\mu\alpha}\widehat{s}_9\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_6\widehat{s}_7 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_6\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_9 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_4\widehat{s}_6 + \beta\widehat{s}_9 - \tfrac{\beta}{a}\widehat{s}_9\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_{10}\right\} &= \beta\widehat{s}_{10} - \tfrac{\beta}{a}\widehat{s}_{10}^2
\end{aligned} \tag{17}$$

This structure can be rewritten in the following much more concise formula

$$\dot{\widehat{\mathbf{s}}}(t) = \beta\,\widehat{\mathbf{s}}(t) + \mathbf{F}\,\widehat{\mathbf{s}}(t)^{\otimes 2} \tag{18}$$

where $\mathbf{F}$ is an 11×121 type rectangular matrix with constant elements which may depend on certain system parameters beyond β and a. 54 non-zero elements of 1331 total elements

 ISBN: 978-84-617-8694-7

of $\mathbf{F}$ are explicitly given below

- $F_{1,10} = -\frac{\beta}{a}$, $F_{1,12} = -\frac{1}{4\alpha\mu^2}$, $F_{1,13} = \frac{1}{2\alpha\mu}$, $F_{1,22} = \frac{1}{2\alpha\mu}$, $F_{1,23} = -\frac{1}{\alpha}$;
- $F_{2,14} = \frac{1}{2\alpha\mu}$, $F_{2,17} = -\frac{1}{2\alpha\mu^2}$, $F_{2,20} = -\frac{\beta}{a}$, $F_{2,24} = -\frac{1}{\alpha}$ $F_{2,32} = \frac{1}{2\alpha\mu}$;
- $F_{3,30} = -\frac{\beta}{a}$;
- $F_{4,26} = -\frac{1}{\alpha}$, $F_{4,35} = \frac{1}{2\alpha\mu}$, $F_{4,40} = -\frac{\beta}{a}$, $F_{4,52} = \frac{1}{2\alpha\mu}$, $F_{4,82} = -\frac{1}{4\alpha\mu^2}$;
- $F_{5,16} = \frac{1}{2\alpha\mu}$, $F_{5,18} = -\frac{1}{4\alpha\mu^2}$, $F_{5,26} = -\frac{1}{\alpha}$, $F_{5,35} = \frac{1}{2\alpha\mu}$, $F_{5,50} = -\frac{\beta}{a}$;
- $F_{6,60} = -\frac{\beta}{a}$;
- $F_{7,18} = \frac{1}{2\alpha\mu}$, $F_{7,29} = -\frac{1}{\alpha}$, $F_{7,44} = -\frac{1}{\alpha}$, $F_{7,47} = \frac{1}{2\alpha\mu}$, $F_{7,64} = \frac{1}{2\alpha\mu}$, $F_{7,67} = -\frac{3}{4\alpha\mu^2}$, $F_{7,70} = -\frac{\beta}{a}$ $F_{7,72} = \frac{1}{\alpha\mu}$ $F_{7,73} = -\frac{1}{\alpha}$, $F_{7,82} = \frac{1}{2\alpha\mu}$;
- $F_{8,38} = \frac{1}{2\alpha\mu}$, $F_{8,46} = -\frac{1}{\alpha}$, $F_{8,48} = \frac{1}{2\alpha\mu}$, $F_{8,55} = -\frac{1}{\alpha}$, $F_{8,66} = \frac{1}{2\alpha\mu}$, $F_{8,68} = -\frac{1}{2\alpha\mu^2}$, $F_{8,75} = \frac{1}{2\alpha\mu}$, $F_{8,80} = -\frac{\beta}{a}$;
- $F_{9,36} = -\frac{1}{\alpha}$, $F_{9,38} = \frac{1}{2\alpha\mu}$, $F_{9,39} = \frac{1}{2\alpha\mu}$, $F_{9,54} = -\frac{1}{\alpha}$, $F_{9,57} = \frac{1}{2\alpha\mu}$, $F_{9,84} = \frac{1}{2\alpha\mu}$, $F_{9,87} = -\frac{1}{2\alpha\mu^2}$, $F_{9,90} = -\frac{\beta}{a}$;
- $F_{10,100} = -\frac{\beta}{a}$. (19)

where we have used the bullet symbol to mark rows of $\mathbf{F}$.

These equations apparently urge us to decompose $\mathbf{F}$ as follows

$$\mathbf{F} = \frac{\beta}{a}\mathbf{F}_{\frac{\beta}{a}} + \frac{1}{a}\mathbf{F}_{\frac{1}{a}} + F_R \tag{20}$$

where right hand side $\mathbf{F}$ matrices with subscripts do not depend on either β or a even though they vary with α and μ. We will use this decomposition in our companion paper [17] of this conference for optimization purposes. In the above analysis we have not focused on the position operator. However, it can be expressed in terms of the integral over the momentum evolver and since it is in principle evaluated through PREVTH solution there is no problem except the evaluation of an integral which is rather a straightforward task.

5 Probabilistic Evolution Theoretical Solution to the Equations of Evolver Dynamics

If both sides of (14) are premultiplied by the Hermitian conjugate of the transition operator and postmultiplied by the transition operator's itself then we can write

$$\dot{\widehat{\mathbf{S}}}(t) = \beta\,\widehat{\mathbf{S}}(t) + \mathbf{F}\,\widehat{\mathbf{S}}(t)^{\otimes 2}, \qquad \widehat{\mathbf{S}}\,(t_0) = \widehat{\mathbf{s}}, \qquad \widehat{\mathbf{S}}(t) \equiv \widehat{T}\,(t,t_0)^{\dagger}\,\widehat{\mathbf{s}}\,\widehat{T}\,(t,t_0) \tag{21}$$

where the first equation can be simplified through the following definitions and equations

$$\widehat{\mathbf{S}}(t) = \mathrm{e}^{\beta(t-t_0)}\boldsymbol{\xi}(t), \qquad u(t) \equiv \frac{\mathrm{e}^{\beta(t-t_0)}-1}{t}, \qquad \frac{d\boldsymbol{\xi}(u)}{du} = \mathbf{F}\boldsymbol{\xi}(u)^{\otimes 2}, \qquad \boldsymbol{\xi}\,(t_0) = \widehat{\mathbf{s}}. \tag{22}$$

The solution of this problem can be provided by PREVTH and can be written as follows

$$\boldsymbol{\xi}(u) = \sum_{j=0}^{\infty} \frac{u^j}{j!}\mathbf{T}_j\widehat{\mathbf{s}}^{\otimes(j+1)}, \qquad \widehat{\mathbf{S}}(t) = \mathrm{e}^{\beta(t-t_0)}\sum_{j=1}^{\infty}\frac{\mathrm{e}^{\beta(t-t_0)}-1}{\beta^j j!}\mathbf{T}_j\widehat{\mathbf{s}}^{\otimes(j+1)} \tag{23}$$

where $\widehat{\mathbf{s}}$ stands for the n-operator-element initial vector while $\mathbf{T}_j$'s (Telescope Matrices) are of $n \times n^{(j+1)}$ type and can be expressed in Monocular matrices defined below.

$$\mathbf{T}_j \equiv \prod_{k=1}^{j}\mathbf{M}_k \qquad j = 0,1,2,... \qquad \mathbf{M}_k \equiv \sum_{\ell=0}^{k-1}\mathbf{I}_n^{\otimes\ell}\otimes\mathbf{F}\otimes\mathbf{I}_n^{\otimes(k-1-\ell)}, \qquad k = 1,2,... \tag{24}$$

where $\mathbf{M}_k$ (Monocular Matrix) is of $n^k \times n^{(k+1)}$ type. Telescope matrices are cascaded form of them.

Telescope matrices are very sparse because of their above-given structures. This sparsity can be suppressed as much as possible by using the following "Squarified Telescope Matrices (SquTelMats)", $\mathbf{\Sigma}_j$s, and beyond them, more suppressed terms, $\mathbf{v}_j$ vectors. This takes us to the following vector recursion also.

$$\mathbf{v}_j = \sum_{k=0}^{j-1}\binom{j-1}{k}\lfloor\,\mathbf{F},\mathbf{v}_k\,\rceil\,\mathbf{v}_{j-k-1}, \quad j = 1,2,... \quad \mathbf{v}_0 = \widehat{\mathbf{s}}, \quad \mathbf{v}_j = \mathbf{\Sigma}_j(\widehat{\mathbf{s}})\widehat{\mathbf{s}} = \mathbf{T}_j\widehat{\mathbf{s}}^{\otimes j+1} \tag{25}$$

The squtelmat between $n \times n^2$ type $\mathbf{F}$ matrix and n element $\mathbf{y}$ vector can be explicitly defined as follows

$$\lfloor\mathbf{F},\mathbf{y}\rceil \equiv \sum_{j=1}^{n}\mathbf{y}_j\mathbf{F}_j, \qquad \mathbf{y} \equiv \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix}, \qquad \mathbf{F} = [\mathbf{F}_1\cdots\mathbf{F}_n] \tag{26}$$

The recursive equation of the squarification and the calculation of the squtelmats are detailed in [12–16].

 ISBN: 978-84-617-8694-7

$\mathbf{v}_k$ vectors depend on operator elements, basically the elements of $\widehat{\mathbf{s}}$ as can be noticed from (25). Hence, their expressions contain 11 operator elements and form kth degree multinomials in those operators. Since these operators are not totally commutative their expressions are quite cumbersome and the structural complications increases very rapidly as k grows. Hence, we do not give these structures explicitly even for a few small k values. Beyond that their evaluations via computer algebra systems is not easy because noncommutative algebra or very specific algorithms are needed for calculations.

6 Evaluating the Expectation Values at the Fluctuationlessness Limit

The expectation value of a given operator $\widehat{o}$ and its evolver $\mathbb{E}\,(\widehat{o})$ are defined as follows

$$\langle\, \widehat{o}\, \rangle \equiv \int_0^\infty dx \psi(x,t)^*\, \widehat{o}\, \psi(x,t), \qquad \langle\, \mathbb{E}\,(\, \widehat{o}\,)\, \rangle\,(t) \equiv \int_0^\infty dx \psi_0(x)^* \mathbb{E}\,(\widehat{o})\,(t) \psi_0(x) \tag{27}$$

where we have taken the domain of the position variable nonnegative real values consistently with our target system in this work. In our present case the system vector is composed of 11 operator elements when Hamiltonian involving operators are used instead of the reciprocal powers of the position operator. For each of these system operators we can write

$$\widehat{s}_j = \langle\, \widehat{s}_j\, \rangle\, \widehat{I} + \widehat{\phi}_j, \qquad j = 1, 2, ..., 11 \tag{28}$$

each of which is in fact the definition of the relevant fluctuation operator at the same time. As can be noticed immediately each fluctuation operator has vanishing expectation value. Now the expectation value of a multivariate analytic function depending on these system operators can be approximated by replacing its each argument operator with its expectation value. This is known as the "Fluctuationlessness Theorem" and enables us to get the conclusion "The expectation value of an operators product is equal to the product of relevant operator's expectation values at the fluctuationlessness limit". By using this fact we can rewrite the rightmost equation of (23) after using the rightmost equality of (25) and then evaluating the expectation values of both sides in the resulting equality as follows

$$\left\langle \widehat{\mathbf{S}}(t) \right\rangle = \mathrm{e}^{\beta(t-t_0)} \sum_{j=1}^{\infty} \frac{\mathrm{e}^{\beta(t-t_0)} - 1}{\beta^j j!} \langle \mathbf{v}_j \rangle \tag{29}$$

which needs to be combined with the following equality which can be produced from (25).

$$\langle \mathbf{v}_j \rangle = \sum_{k=0}^{j-1} \binom{j-1}{k} \lfloor\, \mathbf{F}, \langle \mathbf{v}_k \rangle\, \rceil\, \langle \mathbf{v}_{j-k-1} \rangle\,, \quad j = 1, 2, ... \quad \langle \mathbf{v}_0 \rangle = \langle \widehat{\mathbf{s}} \rangle \tag{30}$$

 ISBN: 978-84-617-8694-7

This recursion exactly matches the recursion obtained via PREVTH for 11 ODEs where the unknown vector is the expectation value of the system Evolver Vector, $\widehat{\mathbf{S}}(t)$, and the initial vector is the expectation value of the system vector $\widehat{\mathbf{s}}$ composed of the system operator expectation values. We do not intend to get into details of this issues since they are available through some of our publications.

7 Focusing on the Initial Wave Packet

We have not specifically consider the structure of the initial wave function until now even though the use of Hamiltonian instead of reciprocal powers of the position operator has been implicitly or, more or less, explicitly implying the Hamiltonian eigenfunctions as the initial wave function. If the initial wave function matches one of the eigenfunction of the considered system's Hamiltonian then the evolver of a considered temporally invariant operator does not change, remains temporally constant. Our specific Hamiltonian has both discrete (bound states) and continuous (scattering states) spectra and the union of eigenfunctions for these spectra forms a complete basis set for representing any given initial wave function. Hence, the eigenfunction case for initial wave function is not so interesting in this sense.

If the initial wave function is not expressible in linear combinations of finitely many eigenfunctions of the Hamilton operator then the expectation value of an operator may not be expanded to a temporal Maclaurin series unless the initial wave function's images under all nonnegative integer powers of the Hamilton operator remains in the function space where the wave functions lie. This however may require an essential singularity in the initial wave function at the Hamiltonian's singular point with respect to the position operator. For example an exponential function of a linear combination of x and $1/x$ with negative combination coefficients can be considered to this end.

What we have told above also imply that the the convergence properties of the PREVTH series quite strongly depends on the initial wave function structure. This convergence is also affected by the level of the uncertainty in the system operators expectation values and therefore the uncertainty in the initial wave function. We do not intend to get into the details of these issues here. We are conducting studies on these issues and planning to report them when done.

8 Concluding Remarks

This work is devoted the first time construction of what we call Evolver Dynamical Equations. We have used hydrogen-like systems as the sample target systems and constructed two different set of equations by using two different operator basis set which is conically closed under the Poisson Bracket operation with the system Hamiltonian with the special PREVTH conicality. We have also given certain details of the fluctuation free expectation

 ISBN: 978-84-617-8694-7

value evaluation. Many important part of this study is based on the Probabilistic Evolution Theory (PREVTH) recently developed in our group studies whose relevant publications can be found in the scientific literature.

We have introduced two arbitrary constant in our formulations. These parameters can be optimised to extend the convergence properties of PREVTH solution to larger domain. This is given in our another paper, where the introduction possibilities of some other flexibilities for optimisation will be mentioned, in this conference.

Abstract

This is somehow a companion paper to our another contribution relevant to the evolver dynamical equations construction for a quantum system whose Hamiltonian has a singular point in finite domain of the position operator, in this conference. We focus on again the hydrogen-like systems as sample target and take the operator basis set which involves Hamilton operator's positive integer powers instead of position operator's integer reciprocal powers. We optimise β and a parameters appearing in the PREVTH format to extend the convergence properties validity region to larger domains. We propose to use exponential weight function which has essential singularities in both 0 and infinite values of the position variable. This weight's parameters are also optimised to suppress the uncertainty such that the smoothest element of the basis function set to represent the initial wave function becomes the least oscillating basis function. Even though the fluctuation expansion is also possible we do not involve discussions to this end since it complicates the presentation unnecessarily too much.

Key words: Evolver dynamics, Expectation values, Singular Hamiltonian, Mathematical fluctuation theory.

1 Probabilistic Evolution Theoretical Introduction

In our another contribution [1] to this conference, which is somehow companion to this paper, we have developed a new method based on the Heisenberg picture of quantum mechanics and combined with the Probabilistic Evolution Theory (PREVTH) [2–15], recently-developed in our group studies. We called the method "Evolver Dynamics in Probabilistic

Evolution Theoretical Perspective". Evolver is a unitary superoperator producing a linear operator from another but given operator and is the unknown of the Heisenberg Picture equations. It uses the interaction representation operator connecting the wave function of the considered system at a time instant to the same function but at a different time instant. It satisfies the Schrödinger equation with the unit operator initial imposition.

In the companion paper we have focused on hydrogen-like systems Which are composed of two electrically charged particles (mathematically point objects) mutually interacting through a Coulomb force. The Hamiltonian of such a system can be expressed as follows

$$\widehat{H} \equiv \frac{1}{2\mu}\widehat{p}^{\,2} - \alpha\widehat{q}^{\,-1} \tag{1}$$

where μ denotes the system's reduced mass whose reciprocal is equal to the sum of particles' mass reciprocals. This is in fact a reduced Hamiltonian which is obtained after (i) separating the mass center coordinates and related Hamiltonian part, (ii) then passing through the spherical coordinates constructed on the relative coordinates system which assumes that one of the particles is as if motionless. The operators $\widehat{p}$ and $\widehat{q}$ respectively stand for the momentum and position operators which are defined through the following equalities.

$$\widehat{p}f(x) \equiv -i\hbar\frac{\partial f(x)}{\partial x}, \qquad \widehat{q}f(x) \equiv xf(x), \qquad x \in [0,\infty) \tag{2}$$

where we call x position variable (note that we have used different symbols for position operator and position variable). Hamilton operator for this system has singularity at $x = 0$ as can be seen immediately.

PREVTH aims to use a system operator vector $\widehat{\mathbf{s}}$ which has finite number, say n, operator elements such that each element's Poisson Bracket with the system Hamiltonian is a second degree multinomial. To this end various types of space extensions are used as long as the set of these elements is multinomially closed under the Poisson Bracketing operation. The conicality (second degree multinomiality) is in such a way that we can write

$$\left\{\widehat{H}, \widehat{\mathbf{s}}\right\} = \beta\widehat{\mathbf{s}} + \mathbf{F}\widehat{\mathbf{s}}^{\otimes 2} \tag{3}$$

where β is an arbitrary scalar at the moment while $\widehat{\mathbf{s}}$ may have some finite number of operator elements. This finite number may be varying depending on how the space extensions are used. In other words this form is not unique in dimension even though there are a lot of signals for the existence of minimum dimensional space extension. In the companion of this paper we have shown that 7 operator elements can remain conically closed under Poisson Bracketing such that the linear term coefficient is proportional to identity matrix (PREVTH format) when we have used momentum and position operators together with certain integer powers of position operator reciprocal. We have also constructed another similar operator basis set which contains certain positive integer powers of momentum and

 ISBN: 978-84-617-8694-7

Hamilton operators together with the position operator. In this case the system vector of operator elements has 11 elements whose explicit structures are given below (we prefer to focus on this case since the singularity is somehow hidden in the Hamiltonian)

$$\widehat{\mathbf{s}} \equiv [\, \widehat{s}_1 \;\; ... \;\; \widehat{s}_{10} \,] \equiv \left[\widehat{p} \;\; \widehat{p}^{\,2} \;\; \widehat{H} \;\; \widehat{H}\,\widehat{p} \;\; \widehat{p}\,\widehat{H} \;\; \widehat{H}^{\,2} \;\; \widehat{p}^{\,3} \;\; \widehat{p}^{\,2}\,\widehat{H} \;\; \widehat{H}\,\widehat{p}^{\,2} \;\; a\widehat{I} \right] \tag{4}$$

This leads us to construct the following equalities

$$\begin{aligned}
\left\{\widehat{H},\widehat{s}_1\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_2^2 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_3 + \tfrac{1}{2\mu\alpha}\widehat{s}_3\widehat{s}_2 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3^2 + \beta\widehat{s}_1 - \tfrac{\beta}{a}\widehat{s}_1\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_2\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_2\widehat{s}_7 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_2\widehat{s}_4 + \widehat{s}_4\widehat{s}_2\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_4 + \beta\widehat{s}_2 - \tfrac{\beta}{a}\widehat{s}_2\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_3\right\} &= \beta\widehat{s}_3 - \tfrac{\beta}{a}\widehat{s}_3\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_4\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_9\widehat{s}_2 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_4\widehat{s}_5 + \widehat{s}_6\widehat{s}_2\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_6 + \beta\widehat{s}_4 - \tfrac{\beta}{a}\widehat{s}_4\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_5\right\} &= -\tfrac{1}{4\mu^2\alpha}\widehat{s}_2\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_6 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_5 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_6 + \beta\widehat{s}_5 - \tfrac{\beta}{a}\widehat{s}_5\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_6\right\} &= \beta\widehat{s}_6 - \tfrac{\beta}{a}\widehat{s}_6\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_7\right\} &= -\tfrac{3}{4\mu^2\alpha}\widehat{s}_7^2 + \tfrac{1}{\mu\alpha}\widehat{s}_8\widehat{s}_2 + \tfrac{1}{2\mu\alpha}\widehat{s}_9\widehat{s}_2 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_3\widehat{s}_9 + \tfrac{1}{2\mu\alpha}\widehat{s}_7\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_5\widehat{s}_7 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_5\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_2\widehat{s}_8 - \tfrac{1}{\alpha}\widehat{s}_8\widehat{s}_3 \\
&\quad + \beta\widehat{s}_7 - \tfrac{\beta}{a}\widehat{s}_7\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_8\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_7\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\left(\widehat{s}_8\widehat{s}_5 + \widehat{s}_4\widehat{s}_8\right) \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_6\widehat{s}_5 + \tfrac{1}{2\mu\alpha}\widehat{s}_7\widehat{s}_6 + \tfrac{1}{2\mu\alpha}\widehat{s}_5\widehat{s}_8 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_5\widehat{s}_6 + \beta\widehat{s}_8 - \tfrac{\beta}{a}\widehat{s}_8\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_9\right\} &= -\tfrac{1}{2\mu^2\alpha}\widehat{s}_9\widehat{s}_7 + \tfrac{1}{2\mu\alpha}\widehat{s}_9\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_6\widehat{s}_7 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_6\widehat{s}_4 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_8 + \tfrac{1}{2\mu\alpha}\widehat{s}_4\widehat{s}_9 \\
&\quad - \tfrac{1}{\alpha}\widehat{s}_4\widehat{s}_6 + \beta\widehat{s}_9 - \tfrac{\beta}{a}\widehat{s}_9\widehat{s}_{10} \\
\left\{\widehat{H},\widehat{s}_{10}\right\} &= \beta\widehat{s}_{10} - \tfrac{\beta}{a}\widehat{s}_{10}^2
\end{aligned} \tag{5}$$

which can be rewritten in much more concise formula as follows

$$\dot{\widehat{\mathbf{s}}}(t) = \beta\,\widehat{\mathbf{s}}(t) + \mathbf{F}\,\widehat{\mathbf{s}}(t)^{\otimes 2} \tag{6}$$

where $\mathbf{F}$ is an 11×121 type rectangular matrix whose 54 non-zero elements of 1331 total

 ISBN: 978-84-617-8694-7

elements are explicitly given below

$$
\begin{aligned}
&\bullet\ F_{1,10}=-\frac{\beta}{a},\quad F_{1,12}=-\frac{1}{4\alpha\mu^2},\quad F_{1,13}=\frac{1}{2\alpha\mu},\quad F_{1,22}=\frac{1}{2\alpha\mu},\quad F_{1,23}=-\frac{1}{\alpha};\\
&\bullet\ F_{2,14}=\frac{1}{2\alpha\mu},\quad F_{2,17}=-\frac{1}{2\alpha\mu^2},\quad F_{2,20}=-\frac{\beta}{a},\quad F_{2,24}=-\frac{1}{\alpha}\quad F_{2,32}=\frac{1}{2\alpha\mu};\\
&\bullet\ F_{3,30}=-\frac{\beta}{a};\\

&\quad F_{9,84}=\frac{1}{2\alpha\mu},\quad F_{9,87}=-\frac{1}{2\alpha\mu^2},\quad F_{9,90}=-\frac{\beta}{a};\\
&\bullet\ F_{10,100}=-\frac{\beta}{a}.
\end{aligned}
\tag{7}
$$

where the bullet symbol has been used to mark rows of $\mathbf{F}$.

These equations imply the following decomposition

$$\mathbf{F}=\frac{\beta}{a}\mathbf{F}_{\frac{\beta}{a}}+\frac{1}{a}\mathbf{F}_{\frac{1}{a}}+\mathbf{F}_R \tag{8}$$

where right hand side subscripted $\mathbf{F}$ matrices do not depend on PREVTH parameters, either β or a. Dependence on given α and μ parameters are existing as expected.

In the last formula here, a is an arbitrary constant at this moment while $\widehat{s}_{11}$ definition has been introduced to the operator definitions to provide the very specific linear structure in (3). This is based on the facts that (i) the degree of any operator pre or post multiplied by $\widehat{s}_{11}$ is increased by one. This enables us to push any desired first degree operator to the second degree operators, (ii) the square of $\widehat{s}_{11}$ is proportional to itself, (iii) any operator

 ISBN: 978-84-617-8694-7

inserted to first degree operators can be balanced by adding its product with an appropriate multiple of $\widehat{s}_{11}$. All these enable us to write

$$\widehat{T}\left(t,t_0\right)^{\dagger}\left\{\widehat{H},\widehat{\mathbf{s}}\right\}\widehat{T}\left(t,t_0\right)=\beta\,\widehat{\mathbf{S}}(t)+\mathbf{F}\,\widehat{\mathbf{S}}(t)^{\otimes 2},\qquad \widehat{\mathbf{S}}(t)\equiv\widehat{T}\left(t,t_0\right)^{\dagger}\,\widehat{\mathbf{s}}\,\widehat{T}\left(t,t_0\right). \tag{9}$$

This implies

$$\dot{\widehat{\mathbf{S}}}(t)=\beta\,\widehat{\mathbf{S}}(t)+\mathbf{F}\,\widehat{\mathbf{S}}(t)^{\otimes 2},\qquad \widehat{\mathbf{S}}(t)\equiv\widehat{T}\left(t,t_0\right)^{\dagger}\,\widehat{\mathbf{s}}\,\widehat{T}\left(t,t_0\right) \tag{10}$$

where $\psi\left(\mathbf{x},t\right)=\widehat{T}\left(\widehat{p},\widehat{q},t,t_0\right)\psi\left(\mathbf{x},t_0\right)$ and

$$i\hbar\frac{\partial\widehat{T}\left(\widehat{p},\widehat{q},t,t_0\right)}{\partial t}=\widehat{H}\left(\widehat{p},\widehat{q},t\right)\widehat{T}\left(\widehat{p},\widehat{q},t,t_0\right),\qquad \widehat{T}\left(\widehat{p},\widehat{q},t_0,t_0\right)=\widehat{I}. \tag{11}$$

The last equation has been obtained from the Schrödinger equation which is a linear parabolic partial differential equation in temporal and spatial coordinates. However, we do not want to use the wave function to determine the expectation values of the observables related to the system under consideration and this is the main reason why we develop evolver dynamics.

The solutions of the PREVTH equations for evolver dynamics in (10) is the basic goal of PREVTH and we can write the solution as follows

$$\widehat{\mathbf{S}}\left(u(t)\right)=\left(1+\beta u(t)\right)\sum_{j=0}^{\infty}\frac{1}{j!}u(t)^{j}\mathbf{v}_j\left(\widehat{\mathbf{S}}_0\right),\qquad u(t)\equiv\frac{\mathrm{e}^{\beta(t-t_0)}-1}{\beta} \tag{12}$$

where $\mathbf{v}_j$ vectors satisfy the following recursion

$$\mathbf{v}_j\left(\widehat{\mathbf{S}}_0\right)=\sum_{k=0}^{j-1}\binom{j-1}{k}\left\lfloor\mathbf{F},\mathbf{v}_k\left(\widehat{\mathbf{S}}_0\right)\right\rceil\mathbf{v}_{j-1-k}\left(\widehat{\mathbf{S}}_0\right),\quad j=1,2,3,...\qquad \mathbf{v}_0\left(\widehat{\mathbf{S}}_0\right)\equiv\widehat{\mathbf{S}}_0 \tag{13}$$

and we have used the squarified telescope matrix (SquTelMat) notation which is defined as follows

$$\left\lfloor\mathbf{F},\mathbf{v}_k\left(\widehat{\mathbf{S}}_0\right)\right\rceil\equiv\sum_{\ell=1}^{7}v_{\ell}^{(k)}\mathbf{F}_{\ell},\qquad \mathbf{F}\equiv\left[\,\mathbf{F}_1\;\;...\;\;\mathbf{F}_7\,\right]^{T},\qquad \mathbf{v}_k\equiv\left[\,v_1^{(k)}\;\;...\;\;v_7^{(k)}\,\right]^{T} \tag{14}$$

On the other hand, $\widehat{\mathbf{S}}_0$ is equal to $\widehat{\mathbf{S}}(0)$ and therefore to $\widehat{\mathbf{s}}$.

Now each $\widehat{s}_i$ $(i=1,2,...,11)$ operator can be written in terms of relevant fluctuations as follows $\widehat{s}_i\equiv\langle\widehat{s}_i\rangle\,\widehat{I}+\widehat{\phi}_i,\qquad i=1,2,3,...,7$ which are definitions of the related fluctuation operators at the same time and imply that the expectation values of all fluctuation operators vanish. The fluctuationlessness theorem dictates us that the expectation value of a multivariate function depending on certain operators is equal to the image of all those

 ISBN: 978-84-617-8694-7

operator's expectation values under that multivariate function at the zero fluctuation limit. This enables us to replace (12) with its following fluctuationless counterpart.

$$\mathbf{v}_j\left(\langle\widehat{\mathbf{s}}\rangle\right)=\sum_{k=0}^{j-1}\binom{j-1}{k}\left\lfloor\mathbf{F},\mathbf{v}_k\left(\langle\widehat{\mathbf{s}}\rangle\right)\right\rceil\mathbf{v}_{j-1-k}\left(\langle\widehat{\mathbf{s}}\rangle\right),\quad j=1,2,3,...;\quad \mathbf{v}_0\left(\langle\widehat{\mathbf{s}}\rangle\right)\equiv\langle\widehat{\mathbf{s}}\rangle \tag{15}$$

where we have replaced $\widehat{\mathbf{S}}_0$ with its equivalent, $\widehat{\mathbf{s}}$.

2 Optimization of Fundamental PREVTH Parameters

As we have seen in the previous section, β and a constants are arbitrary parameters appearing in the PREVTH equations relevant to evolver dynamics. Hence the determination of these parameters under certain conditions gains a lot of importance. We consider the convergence of the PREVTH solution as most important issue and we can try to choose β and a in such a way that the convergence rules in a largest domain. This can be accomplished via optimization. We can write the following inequality from (12) to this end

$$\left\|\sum_{j=0}^{\infty}\frac{1}{j!}u(t)^j\mathbf{v}_j\left(\widehat{\mathbf{s}}\right)\right\|\leq\sum_{j=0}^{\infty}\frac{1}{j!}\left(u(t)^*u(t)\right)^{\frac{j}{2}}\left\|\mathbf{v}_j\right\| \tag{16}$$

where we have used Frobenious vector norm definition which is submultiplicative. The right hand side can be enlarged by replacing the norm of the vector $\mathbf{v}_j$ with a bound b_j which is valid for all nonnegative integer j values. That is, $\|\mathbf{v}_j\|\leq b_j,(j=0,1,2,...)$ On the other hand we can write the following formulae from (13)

$$\begin{aligned}\left\|\left\lfloor\mathbf{F},\left\langle\,\mathbf{v}_k\left(\widehat{\mathbf{s}}\right)\right\rangle\right\rceil\left\langle\,\mathbf{v}_{j-1-k}\left(\widehat{\mathbf{s}}\right)\right\rangle\right\|&=\left\|\mathbf{F}\left(\left\langle\,\mathbf{v}_k\left(\widehat{\mathbf{s}}\right)\right\rangle\otimes\left\langle\,\mathbf{v}_{j-1-k}\left(\widehat{\mathbf{s}}\right)\right\rangle\right)\right\|\\&\leq\|\mathbf{F}\|\left\|\mathbf{v}_j\right\|\left\|\mathbf{v}_{j-k-1}\right\|\leq\rho\left(\mathbf{F}\right)b_kb_{j-k-1},\qquad j=1,2,3,...\;\;k=0,1,2,...,j-1\end{aligned} \tag{17}$$

where $\rho\left(\mathbf{B}\right)$ stands for the spectral radius (that is, maximum singular value) of $\mathbf{F}$. Since b_j is defined via an inequality its choice is somehow at our disposal. So it is quite reasonable to impose the following equality which can be derived from (15)

$$\frac{b_j}{(j-1)!}=\rho\left(\mathbf{F}\right)\sum_{k=0}^{j-1}\frac{b_k}{k!}\frac{b_{j-k-1}}{(j-k-1)!},\qquad j=1,2,3,... \tag{18}$$

which is in fact a recursion to determine b_js. For the solution we can use the generating function method. If we multiply the both sides of this equation by z^j where z is a scalar variable and then sum over all positive integer j values we can write

$$\sum_{j=1}^{\infty}z^j\frac{b_j}{(j-1)!}=\rho\left(\mathbf{F}\right)\sum_{j=1}^{\infty}\sum_{k=0}^{j-1}z^j\frac{b_k}{k!}\frac{b_{j-k-1}}{(j-k-1)!},\quad j=1,2,3,...;\quad b_0=\left\|\left\langle\widehat{\mathbf{s}}\right\rangle\right\| \tag{19}$$

 ISBN: 978-84-617-8694-7

which can also be rewritten in the following concise form

$$\frac{dG(z)}{dz} = \rho\left(\mathbf{F}\right) G(z)^2, \qquad G(0) = \| \langle \widehat{\mathbf{s}} \rangle \|, \qquad G(z) \equiv \sum_{j=0}^{\infty} \frac{b_j}{j!} z^j \tag{20}$$

whose unique solution is as follows

$$G(z) = \frac{\| \langle \widehat{\mathbf{s}} \rangle \|}{1 - \rho\left(\mathbf{F}\right) \| \langle \widehat{\mathbf{s}} \rangle \| z}. \tag{21}$$

If we now use bound for v_j in (16) and replace z by $\sqrt{(u(t)^* u(t))}$ then (16) can be rewritten as follows

$$\left\| \sum_{j=0}^{\infty} \frac{1}{j!} u(t)^j \mathbf{v}_j\left(\widehat{\mathbf{s}}\right) \right\| \leq G\left(\sqrt{u(t)^* u(t)}\right) = \frac{\| \langle \widehat{\mathbf{s}} \rangle \|}{1 - \rho\left(\mathbf{F}\right) \| \langle \widehat{\mathbf{s}} \rangle \| \sqrt{u(t)^* u(t)}}. \tag{22}$$

which brings the following condition on time

$$\rho\left(\mathbf{F}\right) \| \langle \widehat{\mathbf{s}} \rangle \| \sqrt{u(t)^* u(t)} < 1. \tag{23}$$

The left hand side expression at the left of this inequality depends on β and a and therefore can be optimised to diminish this expression as much as possible. To this end, we need to find the functional dependences of this expression on these parameters to get results precise as much as possible. We can write first

$$| \langle \widehat{\mathbf{s}} \rangle | = \sqrt{\nu^2 + |a|^2} < \nu + |a|, \qquad \nu^2 \equiv \sum_{j=1}^{10} | \langle \widehat{s}_j \rangle |^2 \tag{24}$$

where the entities between single vertical pipe symbols denote the complex modulus of the relevant scalar entity. In fact all $\widehat{s}_j$ operators which are self-adjoint have real valued expectation values. All these expectation values will depend on which structure is used for the initial wave function. a does not appear in the first 10 elements of system vector. In this formula we have assumed that the unknown scalar a can take complex values also.

On the other hand, the spectral radius of the $\mathbf{F}$ matrix is also a norm (induced, spectral norm) and therefore urges us to write

$$\rho\left(\mathbf{F}\right) = \frac{|\beta|}{|a|} \rho\left(\mathbf{F}_{\frac{\beta}{a}}\right) + \frac{1}{|a|} \rho\left(\mathbf{F}_{\frac{1}{a}}\right) + \rho\left(\mathbf{F}_R\right), \qquad \rho\left(\mathbf{F}_{\frac{\beta}{a}}\right) = 1, \qquad \rho\left(\mathbf{F}_{\frac{1}{a}}\right) = \frac{1}{\mu} \tag{25}$$

where β and a are unknown scalars as we stated previously and we have skipped the intermediate details of rightmost two equalities.

 ISBN: 978-84-617-8694-7

We can also write the following formulae for the temporal entity $u(t)$

$$\begin{aligned}\sqrt{(u(t)^{*}u(t))} &= |u(t) = \left|\frac{\mathrm{e}^{\beta(t-t_0)}-1}{\beta}\right| = \left|\sum_{j=1}^{\infty}\frac{\beta^{j-1}}{j!}(t-t_0)^j\right| < \sum_{j=1}^{\infty}\frac{|\beta|^{j-1}}{j!}T^j \\ &< \frac{\mathrm{e}^{|\beta|}-1}{|\beta|}, \qquad t\in[\,t_0,t_0+T\,] \end{aligned} \tag{26}$$

where the positive constant T denotes the evolution time duration.

Entire analysis of this section until now urges us to define the following cost functional

$$J(\beta,a)\equiv\left[\left(|\beta|+\frac{1}{\mu}\right)\frac{1}{|a|}+\rho\left(\mathbf{F}_R\right)\right](\nu+|a|)\,\frac{\mathrm{e}^{|\beta|}-1}{|\beta|}, \qquad t\in[\,t_0,t_0+T\,] \tag{27}$$

whose less than one values for some T values correspond to the convergence of PREVTH solution. However, this depends on β and a and can be minimized with respect to these parameters. For this minimization J must be separately differentiated with respect to these parameters and then each resulted equation should be set equal to zero. This gives two coupled algebraic equations which are quite nonlinear and therefore can not be solved analytically even though various numerical procedures to get the solution can be used to this end.

Despite we have assumed that the parameters β and a can take complex values, the above analysis involves only complex moduli of these parameters. This is because of the pessimism in the construction of the above cost functional. We have used in fact quite loose bounds in this construction such that only the complex moduli appeared in the results and therefore all phase related terms have been somehow rounded off. The utilization of much more tight bounds through rigorous analyses will bring the dependences on phases also, beside the moduli. However, this is a quite cumbersome procedure and we do not intend to get into further details of this issue.

3 Further Convergence Maximization Possibilities

The analysis in the previous section is based on the PREVTH parameters since they are the only arbitrary entities to be optimised in the PREVTH solution. However, it is also possible to introduce further arbitrarinesses into the rectangular matrix $\mathbf{F}$. One important thing to this end is the commutativity of the system operators. A careful look at (4) reveals that, the first, second, and, third powers of the momentum operator are mutually commutative. At the same time the first and second powers of the Hamilton operator are also commutative. Beyond that $\widehat{s}_{11}$ is commutative with all remaining operators. All these mean the existence of totally 14 commutativity relations. The commutativity between any given two operators, $\widehat{o}_1$ and $\widehat{o}_2$, enables us to write $c\,(\widehat{o}_1\widehat{o}_2-\widehat{o}_2\widehat{o}_1)=0$ where c is an arbitrary

 ISBN: 978-84-617-8694-7

coefficient. This permits us to add this kind vanishing entities with different c coefficients and different operator pairs to the right hand side of each equation in (5). This enters totally 154 arbitrary c coefficients in the structure of $\mathbf{F}$, and therefore, of $\mathbf{F}_R$. Thus, there is a possibility to suppress the spectral norm of this matrix. This optimisation is based on the optimisation of a quadratic form in cs. However, we do not intend to get into details of this issue here furthermore.

4 Basis Function Set for Representing Initial Wave Function

In last two sections we have not specified the structure of the initial wave function. One way to choose initial wave function is to use eigenfunctions of the system Hamiltonian. However, the expectation values of integer reciprocal powers can not be evaluated through these eigenfunctions as long as the integer power of the position operator remains greater than or equal to -2. On the other hand, the cases where the initial wave function is one of the eigenfunctions corresponds to the separation of the temporal and spatial dependences and is very well-known. Hence, the profits coming from PREVTH utilisation may not be considered so much important and therefore is not so interesting in the PREVTH point of view.

The other way to use a different basis set is to take the singularity in the Hamiltonian to the consideration. Since the Hamiltonian is singular at both 0 and ∞ for x, the function whose image under Hamiltonian must have some specific behavior at these singularities. Otherwise the image function becomes having singularities at these values of the position variable. As told above, Hamiltonian eigenfunctions do not give singularities at these points. However, they are insufficient to evaluate the expectation values of the greater than two powers of the position operator reciprocal. So, in this case, we intend to construct such a basis set that the expectation values of all powers (positive and nonpositive) can be evaluated through these basis functions. This enforces us to use a weight function and insert such a behaviour to this weight that all negative and nonnegative powers in expectation values can be suppressed by this weight function. We can write the following structure which is composed of the weight function alone for the initial wave function as a first step to be taken for the set construction.

$$\psi_0(x) \equiv cx^{-\frac{1}{4}} \mathrm{e}^{-\left(\frac{\nu_1}{2x}+\frac{\nu_2}{2}x\right)+i\nu_3 x}, \qquad x \in [0,\infty) \tag{28}$$

where c and νs are positive parameters and we need to find the values of these parameters in such a way that this function should have unit norm and can be able to produce the given expectation values of the position and momentum operators. This leaves one parameter unknown and we can connect that parameter to the standard deviation to get uniqueness. For normalization we need to evaluate the modulus square integral of this function's except

 ISBN: 978-84-617-8694-7

the c factor. We can write

$$\int_0^\infty dx x^{-\frac{1}{2}} \mathrm{e}^{-\left(\frac{\nu_1}{x}+\nu_2 x\right)} = 2\mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}} \int_0^\infty dx \mathrm{e}^{-\left(\frac{\sqrt{\nu_1}}{x}-\sqrt{\nu_2}x\right)^2} = 2\sqrt{\nu_1}\sqrt{\nu_2}\mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}}$$
$$\times \int_0^\infty dx \mathrm{e}^{-\sqrt{\nu_1}\sqrt{\nu_2}\left(\frac{1}{x}-x\right)^2} = 2\sqrt{\nu_1}\sqrt{\nu_2}\mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}} \int_0^\infty dx \frac{1}{x^2} \mathrm{e}^{-\sqrt{\nu_1}\sqrt{\nu_2}\left(\frac{1}{x}-x\right)^2} \quad (29)$$

where the last equality implies

$$\int_0^\infty dx \mathrm{e}^{-\sqrt{\nu_1}\sqrt{\nu_2}\left(\frac{1}{x}-x\right)^2} = \frac{1}{2}\int_0^\infty d\left(x-\frac{1}{x}\right) \mathrm{e}^{-\sqrt{\nu_1}\sqrt{\nu_2}\left(\frac{1}{x}-x\right)^2} = \frac{\sqrt{\pi}}{4\left(\nu_1\nu_2\right)^{\frac{1}{4}}} \quad (30)$$

which can be combined with (29) to give

$$\int_0^\infty dx x^{-\frac{1}{2}} \mathrm{e}^{-\left(\frac{\nu_1}{x}+\nu_2 x\right)} = \frac{\sqrt{\pi}}{2}\left(\nu_1\nu_2\right)^{\frac{1}{4}} \mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}} \quad (31)$$

This integral therefore can be considered as a generating function and enables us to write the following formulae

$$\int_0^\infty dx x^{j-\frac{1}{2}} \mathrm{e}^{-\left(\frac{\nu_1}{x}+\nu_2 x\right)} = (-1)^j \frac{\partial^j}{\partial \nu_1^j}\left\{\frac{\sqrt{\pi}}{2}\left(\nu_1\nu_2\right)^{\frac{1}{4}} \mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}}\right\}, \qquad j=0,1,2,... \quad (32)$$

$$\int_0^\infty dx x^{-j-\frac{1}{2}} \mathrm{e}^{-\left(\frac{\nu_1}{x}+\nu_2 x\right)} = (-1)^j \frac{\partial^j}{\partial \nu_2^j}\left\{\frac{\sqrt{\pi}}{2}\left(\nu_1\nu_2\right)^{\frac{1}{4}} \mathrm{e}^{-2\sqrt{\nu_1}\sqrt{\nu_2}}\right\}, \qquad j=0,1,2,... \quad (33)$$

These equalities are sufficient to evaluate expectation values of all power involving terms. This means that we can also construct a set of polynomials in the position variable's non-negative powers or in its reciprocal powers as a basis set to represent initial wave function. There are of course certain properties facilitating this construction. This issue is under an intense study of us even though we do not report certain further informations. We are planning to tell more issues in the presentations and the possible extended publication.

5 Concluding Remarks

In our two contrubutions to this conference we have constructed evolver dynamics somehow based on the Heisenberg Picture of Quantum Mechanics. We have obtained the super ODEs on operators, the right hand sides of which has a Probabilistic Evolution Theory (PREVTH) specific conicality by using certain type space extensions. This has been accomplished in the previous paper.

This paper is basically devoted to the PREVTH parameter optimisation and the convergence of PREVTH solution has also been revisited. The initial function representation

 ISBN: 978-84-617-8694-7

which is a very important issue in our analysis has also been considered. A specific basis set has been proposed such that its weight function's modulus square can be evaluated analytically. Beyond that all polynomial factors can also be imported to the analytic integration such that integrations can be performed by using partial differentiation on a generating function appearing in the modulus square integral of the weight function.

We have proposed the fluctuation free evaluations for approximation. However, quantum mechanics of our singular systems depend on fluctuation terms beyond that the fluctuationlessness terms. Howeever we have not intended to deal fluctuation expansion here even though that extension seems to be quite straightforward and we are planning to report our future results on this issue as soon as possible.

Abstract

This paper presents an improved method for smoothed particle hydrodynamics (SPH) within a nested Lagrangian domain of fluid particles. In the previous method, ghost particles, generated around fluid particles using Poisson-disk sampling method, transfer necessary physical quantities of the outer domain to the fluid. Using this technique, the local fluid motion is reproduced which agrees with the results simulated with full SPH. However, the computational cost for generation of ghost particles are non-negligible. In order to reduce the cost, we develop a patch-based sampling method to generate ghost particles. In our approach, the ghost particles are generated locally around each fluid particle for computational efficiency and corresponding physical quantities are determined using the local ghost particles. Furthermore, we introduce a new technique that determines physical quantities of ghost particles to transfer information from the outer domain to the local fluid particles.

Key words: smoothed particle hydrodynamics, fluid simulation

1 Introduction

In this paper, we propose an efficient method of local smoothed particle hydrodynamics (SPH). Particle tracking is a typical and important problem in environmental fluid engineering [1] and the local SPH is designed specifically to the problem [2]. The formulation of the local SPH is based on the conventional SPH which we refer to as full SPH (See Figure

 ISBN: 978-84-617-8694-7

1 for comparison of full SPH and local SPH) in this paper and works under an assumption that global physical quantities of outer fluid flow are given *a priori*. In this formulation, the global quantities are transferred to local fluid particles of the nested Lagrangian domain, using so called ghost particles that are temporally allocated around the local fluid particles. The ghost particles are generated at every time step of SPH based on the technique of Poisson-disk sampling (PDS) so that they surround the fluid particles. This ghost particle generation process is time consuming and is often a bottleneck of speed in practical computation. In order to address this problem, we present a new method to transfer the physical quantities from the outer domain to the fluid particles. In our approach, the ghost particles are generated around each fluid particle individually. This method does not require globally consistent ghost particles and can be performed with lower computational cost.

PDS is a method to generate randomly distributed points following some statistical properties [3]. Many fast PDS techniques have been developed for CPU [4] and GPU [5], and also adopted to fluid simulation with SPH [6]. In our local SPH context, although PDS can generate appropriate ghost particles around the fluid, it is not efficient to operate on the fly. In order to avoid inefficient generation of the particles, we develop patch-based ghost particle sampling.

SPH is a particle-based fluid simulation method, and a review of recent studies is found in [7]. In this paper, we adopt δ-SPH [8, 9] to simulate weakly compressible flow based on the Euler equations and continuity equation. Since the physical quantities evaluated in SPH are generally not equal to those obtained by analytical solutions or other methods, if the physical quantities obtained with such ways are used as outer flow, local SPH does not work correctly. In order to avoid this situation, we introduce a new technique that determines physical quantities of ghost particles appropriately.

2 Improved ghost particles

The previous method uses PDS to generate ghost particles around local fluid particles. This appropriately reproduces local fluid motion and reduces computational cost compared to full SPH. However the computational time of ghost particle generation is not negligible. For more efficient computation, we propose here a new sampling method.

We generate ghost particles around each fluid particle by applying a precomputed patch to the fluid particle, then removing the samples that are too close to fluid particles. The effects of the ghosts at the fluid particle is determined individually using only the ghost particles around the fluid particle after removal. This approach is more efficient than the previous method [2] in the sense that globally consistent ghost particles are not required.

As a precomputation process, many patches are prepared using PDS around one dummy fluid particle. We distribute sampled particles within the kernel effective radius from the dummy, yet outside a minimal distance of any particles of αl (α is a user defined parameter).

 ISBN: 978-84-617-8694-7

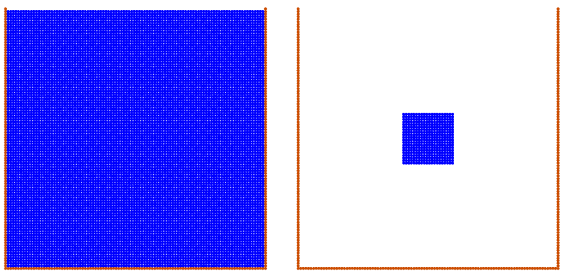

Figure 1: Full SPH (Left) and local SPH (Right). The blue particles indicate the fluid and the blown particles are the wall. The particles are arranged with initial spacing l.

Since the distances from the fluid particle to the samples are known before actual simulation, we avoid the distance evaluation during the simulation.

In order to transfer outer physical quantities to the fluids, we copy the velocity and pressure of the outer domain to each ghost particle and evaluate the i-th ghost's density as $\rho_i^t = \frac{p_i^t}{c_0^2} + \rho_0$, where ρ is the density, p the pressure, c_0 the sound speed and t is time. The density ρ_i^t is then used for the density diffusive term in δ-SPH while the other terms are evaluated with rest density for weak compressibility. This technique naturally passes the outer information to the fluids using only δ-SPH formulation.

3 Results

We compare the proposed method and the previous method [2] with two dimensional static water test case as shown in right hand side of Figure 1. The fluid particles are arranged in square and 20 particles are used for each edge (totally 400 fluid particles).

In this test case, the previous method takes 5.99ms per time step, while the proposed one takes 1.58ms. As shown in Figure 2, the errors are less than initial spacing l in both methods even after 1M time steps, and our new method has less errors for long time simulation. This means that our method works appropriately and faster than the previous one.

Abstract

A four-dimensional mathematical model is presented and analyzed, which describes the hypothalamus-pituitary-adrenal (HPA) axis with the influence of the GR concentration and includes general feedback functions. Due to the fact that the involved processes are not instantaneous, distributed time delays are incorporated, providing a more realistic modeling approach, since the whole past history of the variables is taken into account. Sufficient conditions for the local asymptotic stability of the equilibrium points are obtained and the occurrence of Hopf bifurcations is investigated, accounting for the appearance of limit cycles which successfully model the ultradian rhythm of the HPA axis. Numerical simulations reflect the importance of the theoretical results.

Key words: HPA axismathematical model distributed time delay stability bifurcation numerical simulation

1 Introduction

One of the most important self-regulated dynamic feedback neuroendocrine systems, which helps the body respond to stress, is the hypothalamuspituitaryadrenal (HPA) axis [6]. It consists of three regions: the hypothalamus, pituitary and adrenal glands, along with a set of direct influences and positive and negative feedback interactions. Both physical and psychological stressors (e.g. infection, dehydration, anticipation, fear) activate the hypothalamus

 ISBN: 978-84-617-8694-7

to release corticotropin-releasing hormone (CRH), which induces the corticotropin (ACTH) production in the pituitary. Then, ACTH is transported by the blood to the adrenal cortex, where it stimulates the production of cortisol (CORT), which in turn suppresses the production of both CRH and ACTH.

Mathematical modeling has been successfully applied in the study of metabolic and endocrine processes [3]. Several mathematical models of the HPA axis have been recently explored [2, 3, 6, 9, 10, 13, 14, 16, 17, 18, 20, 21, 22]. Oscillatory solutions of the mathematical models of the HPA axis should reflect the circadian as well as ultradian rhythm of hormone levels [5]. The ultradian rhythm is seen as an inherent behavior of the HPA axis, while the circadian rhythm is regarded as an external input to the axis [2]. Additionally, it is important to emphasize that time delays unavoidably exist in the HPA axis, due to the transportation of the hormones among the three glands, therefore, it is mandatory to incorporate them in the mathematical model.

The "minimal model" of the HPA axis, consisting of a system of three coupled, nonlinear differential equations, with the hormones CRH, ACTH and cortisol as variables, has been developed in [22]. No oscillatory behavior has been observed in this minimal model if time delays are not taken into consideration [2, 22]. This model has been recently generalized in [13], including memory terms in the form of distributed delays and fractional-order derivatives, which are linked with generating oscillatory solutions.

In this paper, we investigate a four-dimensional model of the HPA axis which includes distributed time delays. General distributed delays are helpful to reflect the whole past history of the variables, proving to be more realistic and more accurate in real world applications than discrete time delays [7]. Distributed delay models appear in a wide range of applications such as hematopoiesis [1], population biology [8], neural networks [11].

2 Mathematical model of HPA with distributed delays

In formulating the mathematical model which describes the variation in time of the concentrations of the three hormones CRH, ACTH and CORT, the following sequence of typical events is considered. CRH is secreted from the hypothalamus and released into the portal blood vessel of the hypophyseal stalk, and then transported to the anterior pituitary where it stimulates the secretion of ACTH, with an average time delay τ_1. Then, in the cortex of the adrenal glands, ACTH stimulates the secretion of the stress hormone cortisol with the average time delay τ_2. Cortisol has a negative feedback effect on the hypothalamus and the pituitary, expressed by two feedback functions f_1 and f_2, affecting the synthesis and release of CRH and ACTH, respectively. On one hand, cortisol inhibits the secretion of CRH through glucocorticoid receptors (GRs) situated in the hypothalamus [15], with an average time delay τ_{31}. On the other hand, cortisol also performs a negative feedback on the secretion of ACTH through GRs situated in the pituitary, with an average time delay

 ISBN: 978-84-617-8694-7

τ_{32}. The hormone concentrations of CRH, ACTH and cortisol are depleted through the rate constants w_1, w_2 and w_3, respectively.

Denoting the hormone concentrations, for simplicity, by $CRH(t) = x_1(t)$, $ACTH(t) = x_2(t)$, $CORT(t) = x_3(t)$, $GR(t) = x_4(t)$, the following system of differential equations with distributed delays is considered:

$$\begin{cases} \dot{x}_1(t) = f_1\left(\int_{-\infty}^{t} x_3(s)h_{31}(t-s)ds\right) - w_1x_1(t), \\ \dot{x}_2(t) = f_2\left(x_4(t)\int_{-\infty}^{t} x_3(s)h_{32}(t-s)ds\right)\int_{-\infty}^{t} x_1(s)h_1(t-s)ds - w_2x_2(t), \\ \dot{x}_3(t) = k_3\int_{-\infty}^{t} x_2(s)h_2(t-s)ds - w_3x_3(t), \\ \dot{x}_4(t) = f_3\left(x_4(t)\int_{-\infty}^{t} x_3(s)h_{34}(t-s)ds\right) - w_4x_4(t), \end{cases} \tag{1}$$

where all the first terms on the right hand side represent production and all the second terms represent depletion of hormones. The constant k_3 as well as the elimination constants w_1, w_2, w_3, w_4 are positive.

The functions $f_1, f_2 : [0,\infty) \to (0,\infty)$, which represent the negative feedback from CORT on CRH and ACTH, respectively, are assumed to be strictly decreasing, smooth and bounded on $[0,\infty)$. In particular, the results presented in this paper are also applicable when Hill functions are being used in the expression of the feedback functions [2, 22]:

$$f_1(u) = k_1\left(1 - \eta\frac{u^{\alpha_1}}{c^{\alpha_1}+u^{\alpha_1}}\right) \quad , \quad f_2(u) = k_2\left(1 - \mu\frac{u^{\alpha_2}}{c^{\alpha_2}+u^{\alpha_2}}\right), \tag{2}$$

with $\alpha_1, \alpha_2 \geq 1$, $k_1, k_2 > 0$, $\eta, \mu \in (0,1)$, $c > 0$. It is easy to verify that functions (2) satisfy all the properties mentioned above. However, it may be possible to model the negative feedback using different types of functions f_1 and f_2. In this paper, our aim is to obtain general results which will also be applicable to other choices of negative feedback functions, besides functions (2), often used in the literature.

The function $f_3 : [0,\infty) \to (0,\infty)$, which represents the positive feedback from CORT on the GR production is strictly increasing, smooth and bounded on $[0,\infty)$. In particular, it can also be considered as a Hill function of the form:

$$f_3(u) = k_4\left(1 + \xi\frac{u^{\alpha_3}}{c^{\alpha_3}+u^{\alpha_3}}\right), \tag{3}$$

with $\alpha_3 \geq 1$, $k_4 > 0$, $\xi \in (0,1)$, $c > 0$.

In system (1), the delay kernels $h_1, h_2, h_{31}, h_{32}, h_{34} : [0,\infty) \to [0,\infty)$ are probability density functions representing the probability that a particular time delay occurs. They are assumed to be bounded, piecewise continuous and satisfy

$$\int_0^{\infty} h(s)ds = 1. \tag{4}$$

 ISBN: 978-84-617-8694-7

The average delay of a delay kernel $h(t)$ is given by

$$\tau = \int_0^\infty sh(s)ds < \infty.$$

Two important classes of delay kernels often used in the literature, are worth mentioning:

- Dirac kernels: $h(s) = \delta(s - \tau)$, where $\tau \geq 0$, equivalent to a discrete time delay:

$$\int_{-\infty}^{t} x(s)h(t-s)ds = \int_0^\infty x(t-s)\delta(s-\tau)ds = x(t-\tau).$$

- Gamma kernels: $h(s) = \dfrac{s^{p-1}e^{-s/\beta}}{\beta^p\Gamma(p)}$, where $p, \beta > 0$, with the average delay $\tau = p\beta$.

In the mathematical modeling of real world phenomena, the exact distribution of time delays is generally unavailable, and hence, general kernels may provide better results [4, 23]. The analysis of models which include particular classes of delay kernels (e.g. weak Gamma kernels with $p = 1$ or strong Gamma kernels with $p = 2$) may reveal the more realistic effect of distributed delays on the system's dynamics, compared to discrete delays.

Initial conditions associated with system (1) are of the form:

$$x_i(s) = \varphi_i(s), \quad \forall\, s \in (-\infty, 0],\ i = 1, 2, 3, 4,$$

where φ_i are bounded continuous functions defined on $(-\infty, 0]$, with values in $[0, \infty)$.

3 Local stability analysis

The existence of an equilibrium point of system (1) is provided by the following:

Proposition 1. *The equilibrium states of system (1) are of the form*

$$E = \left(\frac{f_1(x_0)}{w_1}, \frac{w_3x_0}{k_3}, x_0, \frac{1}{x_0}f_2^{-1}\left(\frac{w_1w_2w_3}{k_3}\frac{x_0}{f_1(x_0)}\right)\right). \tag{5}$$

where $x_0 \in \left[0, \dfrac{k_1k_2k_3}{w_1w_2w_3}\right]$ *with* $k_i = f_i(0)$, $i = 1, 2$, *is a solution of the equation*

$$f_3\left(f_2^{-1}\left(\frac{w_1w_2w_3}{k_3}\frac{x}{f_1(x)}\right)\right) = \frac{w_4}{x}f_2^{-1}\left(\frac{w_1w_2w_3}{k_3}\frac{x}{f_1(x)}\right). \tag{6}$$

In what follows, we provide necessary and sufficient conditions for the local asymptotic stability of an equilibrium point E and the occurrence of limit cycles in a neighborhood of E (due to Hopf bifurcations) that can explain the ultradian rhythm. Considering general

 ISBN: 978-84-617-8694-7

delay kernels, we first obtain delay independent sufficient conditions for the local asymptotic stability of the equilibrium point E, which may prove to be useful if the time delays in system (1) cannot be accurately estimated.

The characteristic equation of the linearized system at the equilibrium point E is:

$$\begin{aligned}&(z+w_1)(z+w_2)(z+w_3)(z+\tilde{w_4})+a(w_4-\tilde{w_4})(z+w_1)H_2(z)H_{34}(z)+\\&+b(z+\tilde{w_4})H_1(z)H_2(z)H_{31}(z)+a(z+w_1)(z+\tilde{w_4})H_2(z)H_{32}(z)=0,\end{aligned}\tag{7}$$

where $H_i(z)=\int_0^\infty e^{-zs}h_i(s)ds$ represent the Laplace transforms of the delay kernels h_i, $i\in\{1,2,31,32,34\}$ and

$$a=-\frac{k_3}{w_1}f_1(x_0)f_2'(x_0r_0)r_0=-w_2w_3\frac{x_0r_0f_2'(x_0r_0)}{f_2(x_0r_0)}>0,\tag{8}$$

$$b=-k_3f_1'(x_0)f_2(x_0r_0)=-w_1w_2w_3\frac{x_0f_1'(x_0)}{f_1(x_0)}>0,\tag{9}$$

$$\tilde{w_4}=w_4-x_0f_3'(x_0r_0)<w_4.\tag{10}$$

The following inequalities will be useful for the theoretical analysis:

(I_0) $\tilde{w_4}>0$ and
$(w_1+\tilde{w_4})(w_2+\tilde{w_4})(w_3+\tilde{w_4})\geq(\tilde{w_4}-w_1)(\tilde{w_4}-w_4)(w_1+w_2+w_3+\tilde{w_4})$;

(I_1) $a(w_1+w_4)+b\leq(w_1+w_2)(w_2+w_3)(w_1+w_3)$;

(I_2) $\dfrac{aw_4}{\tilde{w_4}}+\dfrac{b}{w_1}<w_2w_3$;

$(\overline{I_2})$ $\dfrac{aw_4}{\tilde{w_4}}+\dfrac{b}{w_1}\geq w_2w_3$.

Theorem 1 (Local asymptotic stability)**.**

1. *In the non-delayed case, if inequality (I_1) is satisfied, then the equilibrium point E of system (1) is locally asymptotically stable.*

2. *For any delay kernels $h_i(t)$, $i\in\{1,2,31,32,34\}$, if inequality (I_2) holds, then the equilibrium point E of system (1) is locally asymptotically stable.*

Corollary 1. *For any delay kernels $h_i(t)$, $i\in\{1,2,31,32,34\}$, if the equilibrium point E of system (1) is unstable, then inequality $(\overline{I_2})$ holds. In other words, inequality $(\overline{I_2})$ is a necessary condition for the occurrence of bifurcations in system (1).*

 ISBN: 978-84-617-8694-7

4 Bifurcation analysis

For simplicity, we further assume that

$$H_{32}(z) = H_{34}(z) = H_1(z)H_{31}(z),$$

and we denote

$$H(z) = H_2(z)H_{32}(z) = H_2(z)H_{34}(z) = H_1(z)H_2(z)H_{31}(z).$$

In fact, $H(z)$ is the Laplace transform of the convolution of the delay kernels h_2 and h_{32} defined as

$$h(t) = \int_0^t h_2(s)h_{32}(t-s)ds,$$

with the mean

$$\tau = \int_0^\infty sh(s)ds = \tau_2 + \tau_{32}, \tag{11}$$

where τ_2 and τ_{32} represent the average delays of the kernels h_2 and h_{32} respectively.

Therefore, the characteristic equation (7) becomes

$$(z+w_1)(z+w_2)(z+w_3)(z+\tilde{w_4}) + [a(z+w_1)(z+w_4) + b(z+\tilde{w_4})]H(z) = 0,$$

which can be rewritten as:

$$H(z)^{-1} = Q(z), \tag{12}$$

where

$$Q(z) = -\frac{a(z+w_1)(z+w_4) + b(z+\tilde{w_4})}{(z+w_1)(z+w_2)(z+w_3)(z+\tilde{w_4})}.$$

The properties of the function $Q(z)$ are given in the following Lemma.

Lemma 1. *The function*

$$\omega \mapsto |Q(i\omega)| = \sqrt{\frac{(b\tilde{w_4} + aw_1w_4 - a\omega^2)^2 + \omega^2(a(w_1+w_4)+b)^2}{(\omega^2+w_1^2)(\omega^2+w_2^2)(\omega^2+w_3^2)(\omega^2+\tilde{w_4}^2)}}$$

is strictly decreasing on $[0,\infty)$ *and the equation*

$$|Q(i\omega)| = 1$$

has a unique positive real root ω_0 *if and only if inequality* $(\overline{I2})$ *is satisfied.*

Moreover, the following inequality holds:

$$\Im\left(\frac{Q'(i\omega)}{Q(i\omega)}\right) > 0 \qquad \forall\, \omega > 0.$$

For the bifurcation analysis, we focus our attention on the following two cases: (1) all delay kernels are Dirac kernels; (2) all delay kernels are Gamma kernels.

 ISBN: 978-84-617-8694-7

4.1 Dirac kernels

If all the delay kernels are Dirac kernels: $h_1(t) = \delta(t-\tau_1)$, $h_2(t) = \delta(t-\tau_2)$, $h_{31}(t) = \delta(t-\tau_{31})$, $h_{32}(t) = \delta(t-\tau_{32})$, $h_{34}(t) = \delta(t-\tau_{34})$ where $\tau_1, \tau_2, \tau_{31}, \tau_{32}, \tau_{34} \geq 0$ satisfy the property

$$\tau_2 + \tau_{32} = \tau_2 + \tau_{34} = \tau_1 + \tau_2 + \tau_{31} = \tau > 0, \tag{13}$$

then, the characteristic equation (12) becomes:

$$e^{\tau z} = Q(z). \tag{14}$$

Choosing τ as bifurcation parameter and following the same proof as in [13], we have:

Theorem 2 (Hopf bifurcations in the case of Dirac kernels)**.** *Assume that inequalities* (I_0), (I_1) *and* $(\overline{I_2})$ *are satisfied. For any* $p \in \mathbb{Z}^+$*, consider*

$$\tau_p = \frac{\arccos\left[\Re(Q(i\omega_0))\right] + 2p\pi}{\omega_0}, \tag{15}$$

where $\omega_0 > 0$ *is given by Lemma 1. The equilibrium point* E *is asymptotically stable if any only if* $\tau \in [0, \tau_0)$*. For any* $p \in \mathbb{Z}^+$*, at* $\tau = \tau_p$*, system (1) undergoes a Hopf bifurcation at the equilibrium point* E*.*

4.2 Gamma kernels

If the delay kernels are Gamma kernels: $h_1(t) = \dfrac{t^{n_1-1}e^{-t/\beta}}{\beta^{n_1}(n_1-1)!}$, $h_2(t) = \dfrac{t^{n_2-1}e^{-t/\beta}}{\beta^{n_2}(n_2-1)!}$, $h_{31}(t) = \dfrac{t^{n_{31}-1}e^{-t/\beta}}{\beta^{n_{31}}(n_{31}-1)!}$, $h_{32}(t) = \dfrac{t^{n_{32}-1}e^{-t/\beta}}{\beta^{n_{32}}(n_{32}-1)!}$, $h_{34}(t) = \dfrac{t^{n_{34}-1}e^{-t/\beta}}{\beta^{n_{34}}(n_{34}-1)!}$, where $\beta > 0$ and $n_1, n_2, n_{31}, n_{32}, n_{34} \in \mathbb{Z}^+ \setminus \{0\}$ satisfy:

$$n_2 + n_{32} = n_2 + n_{34} = n_1 + n_2 + n_{31} = n \geq 2,$$

the characteristic equation (7) is:

$$(\beta z + 1)^n = Q(z). \tag{16}$$

Choosing β as bifurcation parameter, as in [13], the following result holds:

Theorem 3 (Hopf bifurcations in the case of Gamma kernels)**.** *Assume that inequalities* (I_0), (I_1) *and* $(\overline{I_2})$ *are satisfied. Let* ω_n *denote the largest real root of the equation*

$$T_n\left(\frac{1}{|Q(i\omega)|^{1/n}}\right) = \frac{\Re(Q(i\omega))}{|Q(i\omega)|} \tag{17}$$

 ISBN: 978-84-617-8694-7

from the interval $(0, \omega_0)$*, where* T_n *is the Chebyshev polynomial of the first kind of order* n*, and consider*

$$\beta_n = \frac{1}{\omega_n}\sqrt{|Q(i\omega_n)|^{2/n} - 1}. \tag{18}$$

The equilibrium point E *is asymptotically stable if* $\beta \in (0, \beta_n)$*. At* $\beta = \beta_n$*, system (1) undergoes a Hopf bifurcation at the equilibrium point* E*.*

5 Numerical simulations

For numerical simulations, the literature values of the elimination constants are considered: $w_1 = 0.17329$ min^{-1}, $w_2 = 0.034831$ min^{-1}, $w_3 = 0.0090726$ min^{-1} and $w_4 = 0.01$ min^{-1} [21].

The equilibrium point E of the system consists of the 24-h mean values of the hormones: $\bar{x}_1 = 7.659$ pg/ml, $\bar{x}_2 = 21$ pg/ml, $\bar{x}_3 = 3.055$ ng/ml [5] and $\bar{x}_4 = 1$ pg/ml.

The feedback functions f_1, f_2 and f_3 are considered as in eqs. (2) and (3), with $\alpha_1 = \alpha_2 = 5$, $\alpha_3 = 7$, $\eta = \mu = 1$, $\xi = 0.75$, $k_1 = 12.364$ pg/(ml $\cdot$ min), $k_2 = 0.88969$ min^{-1}, $k_4 = 0.0058368$ min^{-1} and $c = 2$ ng/ml. Moreover, $k_3 = 1.31985$ min^{-1}.

According to [3], we assume the mean delay $\tau_1 = 0$. Recently, it has been shown that humans show fast HPA negative feedback [19], suggesting that both GR (glucocorticoid receptors) and MR (mineralocorticoid receptors) are involved in this mechanism, with GR effecting a rapid nongenomic feedback at the level of the anterior pituitary and MR sensing higher glucocorticoid levels while levels are still rising [12]. This is in accordance with our numerical simulations (Figs. 1,2), which show that for small values (less than 10 min) of the average time delays $\tau_2, \tau_{31}, \tau_{32}, \tau_{34}$, oscillatory behavior occurs in system (1), with different types of distributed delays.

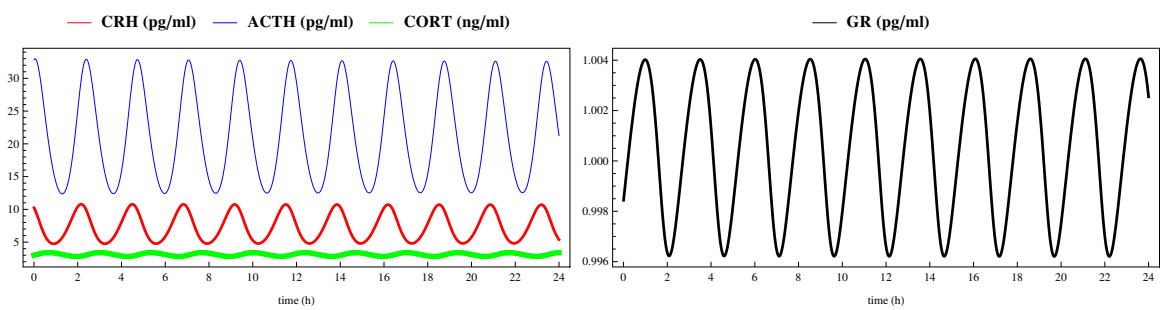

Figure 1: Stable periodic orbit of system (1) with Dirac kernels (discrete delays $\tau_1 = 0$, $\tau_2 = 7.5$ (min), $\tau_{31} = \tau_{32} = \tau_{34} = 8$ (min)) due to the Hopf bifurcation taking place when the bifurcation parameter τ exceeds the critical value $\tau_0 = 14.81$ (min).

 ISBN: 978-84-617-8694-7

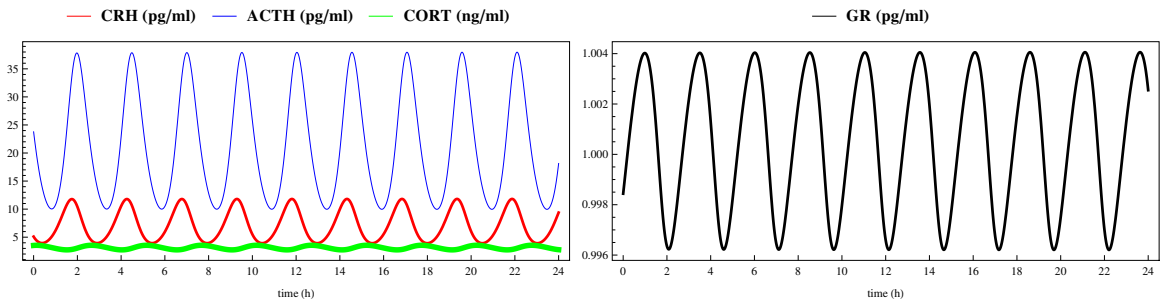

Figure 2: Stable periodic orbit of system (1) with strong Gamma kernels ($n_1 = 0$, $n_2 = n_{31} = n_{32} = n_{34} = 2$, $\beta = 4.5$ (min), mean delays: $\tau_2 = \tau_{31} = \tau_{32} = \tau_{34} = 9$ (min)) due to the Hopf bifurcation taking place when the bifurcation parameter β exceeds the critical value $\beta_4 = 4.07056$ (min).

6 Conclusions

This paper presents an analysis of a four-dimensional mathematical model describing the hypothalamus-pituitary-adrenal axis with the influence of the GR concentration, considering general feedback functions to account for the interactions within the HPA axis. Due to the fact that the involved processes are not instantaneous, distributed delays have been included. This is a more realistic approach to the modeling of the biological processes, as it takes into account the whole past history of the variables, efficiently capturing the vital mechanisms of the HPA system. Sufficient conditions have been obtained for the local asymptotic stability of the equilibrium point and the occurrence of Hopf bifurcations has been investigated. Numerical simulations reflect the importance of the theoretical results and are in accordance with experimental findings.

As a direction for future research, a fractional-order formulation of the mathematical model will be analyzed.

Abstract

In recent years, many authors have tried to find at least a fixed point for multi-valued quasi-contractions whose contractivity constants α belonged to the interval $(0, 1)$. Up to now, efforts in this direction when $\alpha \in (\frac{1}{2}, 1)$ either have failed or have been lessened to a lighter version. The main result of current research gives a partial positive answer to the above-mentioned problem by adding a necessary and sufficient condition in order to guarantee the existence of strict fixed points for quasi-contractive multi-valued mappings. Ultimately, some examples and results obtain which have a closed relation to quasi-contractions mappings.

Key words: Strict fixed point, fixed point, Quasi-contraction, Pompeiu-Hausdorff metric, Multi valued mapping
MSC 2000: AMS 47H10, 47H08, 54C60.

1 Introduction

In 2011, Wardowski published a paper [11] where he introduced fixed point results for multi-valued contractive mappings in normal cone metric spaces. In 2011, Amini-Harandi

managed to prove a result on the existence of fixed points in the set of multi-valued quasi-contractive mappings in metric spaces by using Rezapour *et al.*'s technique which had been given in [8]. But, like Kadelburg *et al.* [5], he could only prove it for $\alpha \in (0, \frac{1}{2})$ [1]. In 2012, Rezapour *et al.* [4] introduced quasi-contractive type multi-valued mappings and they demonstrated that the main result of Amini-Harandi also held in the set of quasi-contractive type multi-valued mappings.

In what follows, the following notions are needed to achieve the goal. From now on, let (X, d) be a metric space and let $\mathcal{CB}(X)$ be the family of all nonempty, closed, bounded subsets of X. Let $T : X \to \mathcal{CB}(X)$ be a multi-valued mapping on X. A point $x \in X$ is called a *fixed point* of T if $x \in Tx$, and it is called a *strict fixed point of* T if $Tx = \{x\}$. We denote by $Fix(T)$ (respectively, by $SFix(T)$) the family of all fixed points (respectively, the family of all strict fixed points) of T. Obviously, $SFix(T) \subseteq Fix(T)$. Some authors call *endpoints* to strict fixed points (for instance, see [9] and [10]). From our point of view, the nomenclature "*strict fixed point*" is more appropriate, so we will use it throughout this paper.

A multi-valued mapping $T : X \to \mathcal{CB}(X)$ is said to be a *multi-valued quasi-contractive mapping* whenever there exists $\alpha \in (0, 1)$ such that

$$\mathcal{H}(Tx, Ty) \leq \alpha\, M(x, y) \quad \textit{for all } x, y \in X,$$

where

$$M(x, y) = \max\{\, d(x, y),\, d(x, Tx),\, d(y, Ty),\, d(x, Ty),\, d(y, Tx)\,\}.$$

In recent years, many authors (such as Amini-Harandi, Rezapour *et al.*, and Kadelburg *et al.*) have introduced some fixed point theorems for multi-valued quasi-contractions whose contractivity constants α belonged to the interval $\left(\frac{1}{2}, 1\right)$. However, Amini-Harandi pointed out, it is not clear whether such results also hold when $\alpha \in \left(0, \frac{1}{2}\right)$, Up to now, efforts in this direction either have failed or they have been lessened to a lighter version. The main result of the current research gives a partial positive answer to the above-mentioned problem by adding a necessary and sufficient condition in order to guarantee existence of strict fixed points of quasi-contractive multi-valued mappings. This problem has remained open for many years. Moreover, some important results have obtained in this direction.

Theorem 1.1. *Let (X, d) be a complete metric space and let $T : X \to \mathcal{CB}(X)$ be a multi-valued quasi-contraction for some $\alpha \in (0, \frac{1}{2})$. Then T has a fixed point.*

Immediately, he proposed the following question.

Question 1.2. *[**Amini Harandi's Conjecture**] Does the conclusion of Theorem 1.1 remain true for any $\alpha \in [\frac{1}{2}, 1)$*

In this manuscript, we give a partial positive answer.

 ISBN: 978-84-617-8694-7

2 A Partial Positive Answer

In this section, we introduce a necessary and sufficient condition for guaranteeing existence of strict fixed points of quasi-contractive multi-valued mappings, which gives a partial positive answer to Question 1.2.

The following definition plays a crucial role to continue.

Definition 2.1. *([6, Moradi, Khojasteh]) A multi-valued mapping $T : X \to \mathcal{CB}(X)$ has* approximate strict fixed point property *if*

$$\inf \{ \mathcal{H}(\{x\}, Tx) : x \in X \} = 0. \tag{1}$$

Theorem 2.2. *Let (X, d) be a complete metric space and let $T : X \to \mathcal{CB}(X)$ be a multi-valued mapping such that*

$$\mathcal{H}(Tx, Ty) \leq \alpha \max \{ d(x, y),\, d(x, Tx),\, d(y, Ty),\, d(x, Ty),\, d(y, Tx) \}, \tag{2}$$

for all $x, y \in X$, where $0 \leq \alpha < 1$. Then T has a strict fixed point in X, if and only if, T has the approximate strict fixed point property. In such case, $SFix(T) = Fix(T)$ and T has a unique (strict) fixed point.

Corollary 2.3. *Let (X, d) be a complete metric space and let $T : X \to \mathcal{CB}(X)$ be a multi-valued mapping such that*

$$\mathcal{H}(Tx, Ty) \leq \alpha \max \left\{ d(x, y),\, d(x, Tx),\, d(y, Ty),\, \frac{d^2(y, Tx) + d^2(x, Ty)}{d(y, Tx) + d(x, Ty)} \right\},$$

for all $x, y \in X$, where $0 \leq \alpha < 1$. Then T has a unique strict fixed point in X, if and only if, T has the approximate strict fixed point property. In such a case, $SFix(T) = Fix(T)$.

Corollary 2.4. *Let (X, d) be a complete metric space and let $f : X \to X$ be a mapping such that*

$$d(fx, fy) \leq \alpha \max \left\{ d(x, y),\, d(x, fx),\, d(y, fy),\, \frac{d^2(y, fx) + d^2(x, fy)}{d(y, fx) + d(x, fy)} \right\},$$

for all $x, y \in X$, and $0 \leq \alpha < \frac{1}{2}$. Then T has the approximate fixed point property in X, that is,

$$\inf \{ d(x, fx) : x \in X \} = 0$$

Corollary 2.5. *Let (X, d) be a complete metric space and let $f : X \to X$ be a mapping such that*

$$d(fx, fy) \leq \alpha \max \left\{ d(x, y),\, d(x, fx),\, d(y, fy),\, \frac{d^2(y, fx) + d^2(x, fy)}{d(y, fx) + d(x, fy)} \right\}, \tag{3}$$

for all $x, y \in X$, $0 \leq \alpha < \frac{1}{2}$. Then T has a unique fixed point.

 ISBN: 978-84-617-8694-7

3 Some Consequences

In this section, we present some new fixed point results in the set of multi-valued mappings which generalize the results introduced by Nadler [7], Ćirić [2], and Daffer and Kaneko [3]. The following theorem is our first main result.

Theorem 3.1. *Let (X,d) be a complete metric space and let $T: X \to \mathcal{CB}(X)$ be a multi-valued mapping such that*

$$\mathcal{H}(Tx,Ty) \leq \alpha \max\left\{ d(x,y),\, d(x,Tx),\, d(y,Ty),\, c\cdot\frac{d^2(y,Tx)+d^2(x,Ty)}{d(y,Tx)+d(x,Ty)} \right\}, \qquad (4)$$

for all $x,y \in X$, where $\frac{1}{2} \leq c < 1$ and $0 \leq \alpha < \frac{1}{4c^2}$. Then at least one of the following conditions holds:

(i). T has a fixed point

(ii). T^2 has a fixed point (that is, there exists $z \in X$ such that $z \in T^2 z$, where $T^2 z = \bigcup_{\omega \in Tz} T\omega$).

The following consequences are obtained by replacing the contractivity condition by a stronger one.

Corollary 3.2. *Let (X,d) be a complete metric space and let $T: X \to \mathcal{CB}(X)$ be a multi-valued mapping such that*

$$\mathcal{H}(Tx,Ty) \leq \alpha \max\left\{ d(x,y),\, d(x,Tx),\, d(y,Ty),\, c\sqrt{\frac{d^2(y,Tx)+d^2(x,Ty)}{2}} \right\}, \qquad (5)$$

for all $x,y \in X$ where $\frac{1}{2} \leq c < 1$ and $0 \leq \alpha < \frac{1}{4c^2}$. Then at least one of the following conditions holds:

(i). T has a fixed point,

(ii). T^2 has a fixed point.

Corollary 3.3. *Let (X,d) be a complete metric space and let $T: X \to \mathcal{CB}(X)$ be two multi-valued mapping such that*

$$\mathcal{H}(Tx,Ty) \leq \alpha \max\left\{ d(x,y),\, d(x,Tx),\, d(y,Ty),\, \frac{d^2(y,Tx)+d^2(x,Ty)}{d(y,Tx)+d(x,Ty)} \right\}, \qquad (6)$$

for all $x,y \in X$, where $0 \leq \alpha < \frac{1}{2}$. Then T has a fixed point.

We also have found two suitable examples to show that the new class of contractions which have been introduced in Theorem 3.1 or Corollary 2.5 is a non-empty set.

Recursion Based Sensitivity Coefficient Determination for Probabilistic Evolution Theoretical (PREVTH) Solutions to Explicit Autonomous Ordinary Differential Equations

Melike Ebru KIRKIN[1] and Metin DEMİRALP[2]

[1] *Computational Science and Engineering Department, Informatics Institute, İstanbul Technical University, Maslak, 34469, İstanbul, Türkiye (Turkey)*

emails: ebrkirkin@itu.edu.tr, metin.demiralp@gmail.com

Abstract

Probabilistic Evolution Theory (PREVTH) has been recently developed in our group studies [1–17] and it stands as one of most effective methods used for the solution of explicit autonomous ordinary differential equations. Its most recent form is based on a rather simple recursion between so-called Squarified Telescope Matrices or between the images of initial vector under these matrices. The initial vector elements can be considered as parameters to the solutions and the sensitivities of the solution vector to these parameters can be utilized for robustness investigations. The partial derivatives can be used to this end, and for each derivative a different recursion can be constructed simply partial differentiating the PREVTH vector recursion accordingly. This work is devoted to this issue and a sample target system (Henon-Heiles system) has been taken to the focus.

Key words: Ordinary Differential Equation, Probabilistic Evolution Theory, Constancy Adding Space Extension, Telescope Matrices, Squarification, Henon Heiles, Recursion between Vectors.

1 Introduction

Even though the Probabilistic Evolution Theory (PREVTH) has been developed for the first order autonomous explicit ODEs, this is not a great limitation since (1) all higher-than-first order ODEs can be converted to a set of first order ODEs whose number of unknown is higher than the original ODEs, (2) any nonautonomy can be converted to autonomy by defining a new unknown function which is identical to the time variable, t. This leaves us

 ISBN: 978-84-617-8694-7

with no loss of generality. Under this situation we can write the ODEs to be solved via following equations

$$\dot{\mathbf{x}}(t) = \mathbf{f}\left(x_1(t), ..., x_n(t)\right), \qquad \mathbf{x}(0) = \mathbf{a} \tag{1}$$

where t stands for "time" and the right hand side does not explicitly depend on time because of autonomy. The unknown functions are the elements of the vector $\mathbf{x}(t)$ while $\mathbf{a}$ vector's elements denote the initial values of the unknown functions.

The right hand side of first equation in (1) is assumed to be analytic in unknown functions. Hence it can be expanded to a multivariate Taylor series which is not preferable to use because of its quite complicated multiindex structure. Instead we can use the Kronecker power series defined as follows in our group studies [5–7].

$$\mathbf{f}\left(\mathbf{x}(t)\right) = \sum_{j=0}^{\infty} \mathbf{F}_j \mathbf{x}(t)^{\otimes j} \tag{2}$$

where $\mathbf{F}_j$ stands for a constant matrix of $n \times n^j$, which can be constructed from the vector function $\mathbf{f}$. The Kronecker product of two entities ($\mathbf{A}$ and $\mathbf{B}$), matrix and/or vector, and, the Kronecker power are defined as follows

$$\left[\, \mathbf{A} \otimes \mathbf{B} \,\right]_{i,j} \equiv \left[\, \mathbf{A} \,\right]_{i,j} \mathbf{B}, \qquad \mathbf{x}(t)^{\otimes j} \equiv \mathbf{x}(t) \otimes \cdots \otimes \mathbf{x}(t) \tag{3}$$

If the right hand side function vector $\mathbf{f}$ has a special structure such that the addition of new functions depending on the unknown functions as new elements to unknown function set then the new right hand side vector function can take a multinomial form which can be reduced to a second degree right hand side function by new unknown additions (space extension) [12, 13]. So under these conditions one can write

$$\dot{\mathbf{x}}(t) = \mathbf{F}_0 + \mathbf{F}_1 \mathbf{x}(t) + \mathbf{F}_2 \mathbf{x}(t)^{\otimes 2} \tag{4}$$

where $\mathbf{F}_0$ is an $n \times 1$ type vector while $\mathbf{F}_1$ and $\mathbf{F}_2$ are $n \times n$ and $n \times n^2$ type matrices. Beyond that, $\mathbf{x}$ is a vector of n elements and is composed of unknown functions. If we attempt to extend the space by adding an unknown constant as a new additional function (this procedure is called "Constancy Adding Space Extension" CASE) then the constant term $\mathbf{F}_0$ in (4) can be removed while $\mathbf{F}_1$ can be converted to $\beta \mathbf{I}_n$ where β is an arbitrary parameter. All these mean that the following vector ODE and accompanying initial condition become valid for our original equation

$$\dot{\mathbf{x}}(t) = \beta \mathbf{I}_n \mathbf{x}(t) + \mathbf{F} \mathbf{x}(t)^{\otimes 2}, \qquad \mathbf{x}(0) = \mathbf{a} \tag{5}$$

This can be further simplified by using the following definitions

$$\mathbf{x}(t) = e^{\beta t} \boldsymbol{\xi}(t), \qquad u(t) \equiv \frac{\mathrm{e}^{\beta t} - 1}{\beta} \tag{6}$$

 ISBN: 978-84-617-8694-7

to get

$$\frac{d\boldsymbol{\xi}(u)}{du} = \mathbf{F}\boldsymbol{\xi}(u)^{\otimes 2}, \qquad \boldsymbol{\xi}(0) = \mathbf{a} \tag{7}$$

whose analytic solution and the related form of $\mathbf{x}(t)$ can be written as follows in accordance with PREVTH.

$$\boldsymbol{\xi}(u) = \sum_{j=0}^{\infty} \frac{u^j}{j!} \mathbf{T}_j \mathbf{a}^{\otimes j+1}, \qquad \mathbf{x}(t) = e^{\beta t} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta t} - 1}{\beta} \right)^j \mathbf{T}_j \mathbf{a}^{\otimes j+1} \tag{8}$$

where $\mathbf{a}$ stands for the initial vector with n given elements as we stated before and this equation obtained after the use of "Constancy Additional Space Extension" which is detailed in [18, 21]. In this formula $\mathbf{T}_j$'s are called as "Telescope Matrices" which are of $n \times n^{(j+1)}$ type. Their explicit structures are given thru below equalities

$$\mathbf{T}_j \equiv \prod_{k=1}^{j} \mathbf{M}_k, \qquad j = 0, 1, 2, ... \qquad \mathbf{M}_k \equiv \sum_{\ell=0}^{k-1} \mathbf{I}_n^{\otimes \ell} \otimes \mathbf{F} \otimes \mathbf{I}_n^{\otimes (k-1-\ell)}, \qquad k = 1, 2, ... \tag{9}$$

where the matrix factor, $\mathbf{M}_k$ is called "Monocular Matrix" and is of $n^k \times n^{(k+1)}$ type. They are cascaded to produce telescope matrices as expressed above.

Telescope matrices have abundantly many of zero elements and hence are very sparse. In order to suppress the sparsity as much as possible, the following "Squarified Telescope Matrices (SquTelMats)" denoted by $\mathbf{S}_j$'s can be brought to scene as follows

$$\mathbf{T}_j \mathbf{a}^{\otimes j+1} \equiv \mathbf{S}_j(\mathbf{a})\mathbf{a} \qquad j = 0, 1, 2, ... \tag{10}$$

The following recursion between squarified telescope matrices hold

$$\mathbf{S}_j = \sum_{k=0}^{j-1} \binom{j-1}{k} \lfloor\, \mathbf{F}, \mathbf{S}_k \mathbf{a} \,\rceil\, \mathbf{S}_{j-k-1}, \qquad j = 1, 2, ... \qquad \mathbf{S}_0 = \mathbf{I} \tag{11}$$

where the squtelmat between $n \times n^2$ type $\mathbf{F}$ matrix and n element $\mathbf{y}$ vector is explicitly defined below

$$\lfloor \mathbf{F}, \mathbf{y} \rceil \equiv \sum_{j=1}^{n} \mathbf{y}_j \mathbf{F}_j, \qquad \mathbf{y} \equiv \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix}, \qquad \mathbf{F} = [\mathbf{F}_1 \cdots \mathbf{F}_n] \tag{12}$$

The recursion equation of the squarification and the calculation of the squtelmats are detailed in [18–23]. The above recursion amongst squtelmats has a computational complexity which is much more than the computational complexity of the following vector recursion

 ISBN: 978-84-617-8694-7

which can be obtained from the postmultiplication of the both sides in the above squtelmat recursion with the initial vector.

$$\mathbf{v}_j = \mathbf{S}_j(\mathbf{a})\mathbf{a}, \qquad \mathbf{v}_j = \sum_{k=0}^{j-1} \binom{j-1}{k} \lfloor\, \mathbf{F}, \mathbf{v}_k \,\rceil\, \mathbf{v}_{j-k-1}, \qquad j = 1, 2, ... \qquad \mathbf{v}_0 = \mathbf{a} \tag{13}$$

This recursion is expected to be implemented much more rapidly than the relevant matrix recursion and our implementations confirm this point.

2 Sensitivity Coefficients

The use of the above $\mathbf{v}$ vectors enable us to rewrite the PREVTH solution as follows

$$\mathbf{x}(t) = \mathrm{e}^{\beta t} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta t} - 1}{\beta} \right)^j \mathbf{v}_j(\mathbf{a}) \tag{14}$$

We have nothing further to do with this formula and the above recursion but just to use. However, there is an important question about the parameterization of the PREVTH ODEs and relevant solutions together with the above recursion: "How do the solution vector elements of PREVTH solution changes when the parameters in the equations change?". Parameters can come from the right hand function or initial vector structure. We can investigate these changes simply by evaluate the first partial derivative of the solution with respect to those parameters. We call these derivatives "Sensitivity Coefficients". For simplicity we are going to focus on the sensitivity coefficients with respect to the initial vector elements in this work.

If we denote the parameter, with respect to which we are going to evalaute sensitivity coefficient by σ then we can write

$$\mathbf{F} = \mathbf{F}(\sigma), \qquad \mathbf{v}_j = \mathbf{v}_j(\sigma), \qquad \mathbf{a} = \mathbf{a}(\sigma) \tag{15}$$

where σ dependence of $\mathbf{v}$ vectors are in fact thru a few channel, from F and $\mathbf{a}$ dependencies. The partial differentiation of above vector recursion with respect to σ produces

$$\begin{aligned} \frac{\partial \mathbf{v}_j}{\partial \sigma} \;=\; & \sum_{k=0}^{j-1} \binom{j-1}{k} \left(\left\lfloor \mathbf{F}, \frac{\partial \mathbf{v}_k}{\partial \sigma} \right\rceil \mathbf{v}_{j-k-1} + \lfloor \mathbf{F}, \mathbf{v}_k \rceil \frac{\partial \mathbf{v}_{j-k-1}}{\partial \sigma} \right) \\ & + \sum_{k=0}^{j-1} \binom{j-1}{k} \left\lfloor \frac{\partial \mathbf{F}}{\partial \sigma}, \mathbf{v}_k \right\rceil \mathbf{v}_{j-k-1}, \qquad \frac{\partial \mathbf{v}_0}{\partial \sigma} = \frac{\partial \mathbf{a}}{\partial \sigma} \end{aligned} \tag{16}$$

$$\frac{\partial \mathbf{x}}{\partial \sigma} = \mathrm{e}^{\beta t} \sum_{j=0}^{\infty} \frac{1}{j!} \left(\frac{\mathrm{e}^{\beta t} - 1}{\beta} \right)^j \frac{\partial \mathbf{v}_j}{\partial \sigma} \tag{17}$$

 ISBN: 978-84-617-8694-7

In the case where σ is taken as a_ℓ we can write

$$\frac{\partial \mathbf{V}_0}{\partial \mathbf{a}_1} = \mathbf{e}_\ell, \qquad \ell = 1, 2, 3, ..., n \tag{18}$$

where $\mathbf{e}_\ell$ stands for the ℓth standard unit vector whose only nonzero element is 1 and is positioned on the ℓth position.

3 Implementations

The following four ODEs can be written for Henon-Heiles system which is given by [24, 25]

$$\dot{x}_1 = x_2, \qquad \dot{x}_2 = -x_1 - 2x_1x_3, \qquad \dot{x}_3 = x_4, \qquad \dot{x}_4 = -x_3 - x_1^2 + x_3^2 \tag{19}$$

which are conical at the right hand side genuinely. However, the first degree terms do not have a scalar matrix (identity matrix scaled by a scalar) coefficient. On the other hand, the use of CASE (Constancy Additional Space Extension) adds a constant function with an arbitrary value to the unknowns and therefore makes a space extension by a constant. This creates 5-unknown ODEs whose right hand side $\mathbf{F}_1^{(aug)}$ matrix is now $\beta\mathbf{I}_5$ and the other matrix, 5×25 type $\mathbf{F}_2^{(aug)}$ has unknown parameters like β and the constant coming from CASE. Those parameters are determined to get a minimum norm form the 5×25 type rectangular. After this optimization β and the CASE constant are found as zero while the new form of 5×25 type $\mathbf{F}_2^{(aug)}$ becomes having only 4 nonzero elements which are explicitly given below

$$\left[F_2^{(aug)} \right]_{2,3} = -1, \qquad \left[F_2^{(aug)} \right]_{2,9} = -1, \qquad \left[F_2^{(aug)} \right]_{4,1} = -1, \qquad \left[F_2^{(aug)} \right]_{4,11} = 1. \tag{20}$$

The accompanying initial conditions in the implementations of this section have been taken as follows

$$\mathbf{x}(0) = \mathbf{a} \equiv [\ 0.1 \quad 0.2 \quad 0.3 \quad 0.4\ ]^T \tag{21}$$

In the first implementation the general σ variable has been taken as a_1 and approximants formed by 2, 3, 4, 5, 6 and 10 terms truncations are plotted in the same graphics separately for the first, second, third, and, fourth components of the 5 element PREVTH solution. These are evaluated by using the vector recursion above and the fifth element which in fact corresponds to zero function has not been shown. The variation of the approximants are given throughout the interval $[\,0, 1\,]$. The convergence is at easily noticable level as seen from the plots.

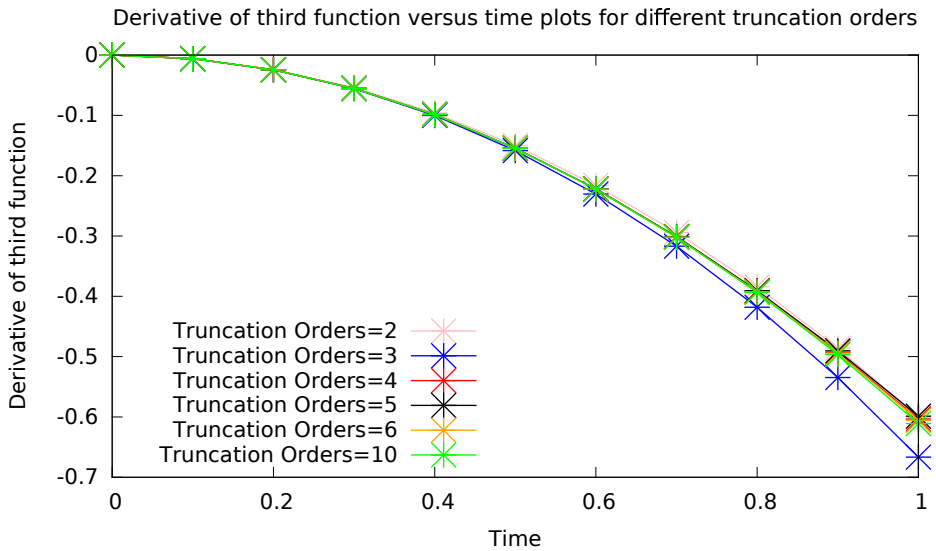

Figure 3: Derivative of the third PREVTH solution vector component with respect to the first element of the initial vector

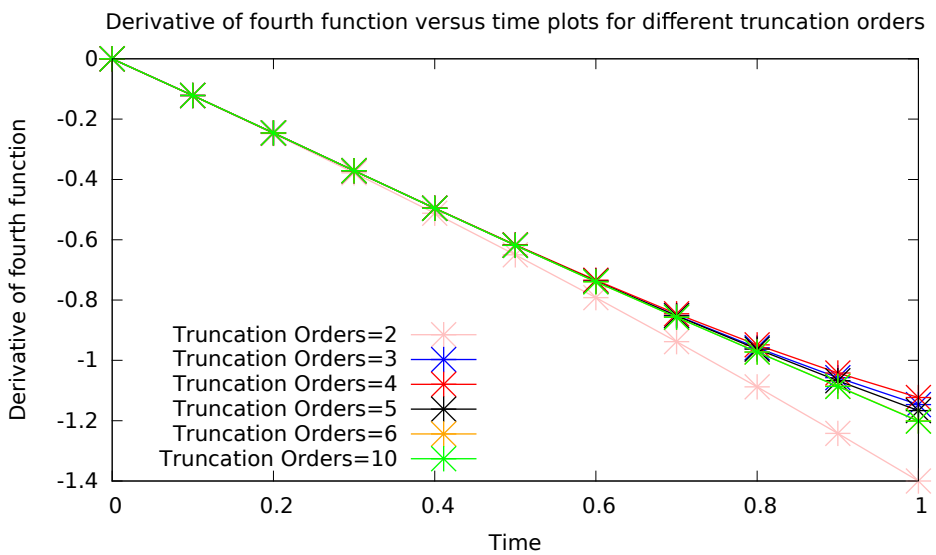

Figure 4: Derivative of the fourth PREVTH solution vector component with respect to the first element of the initial vector

For these truncations the absolute errors between certain truncation approximants can

 ISBN: 978-84-617-8694-7

also be given in the following graphics.

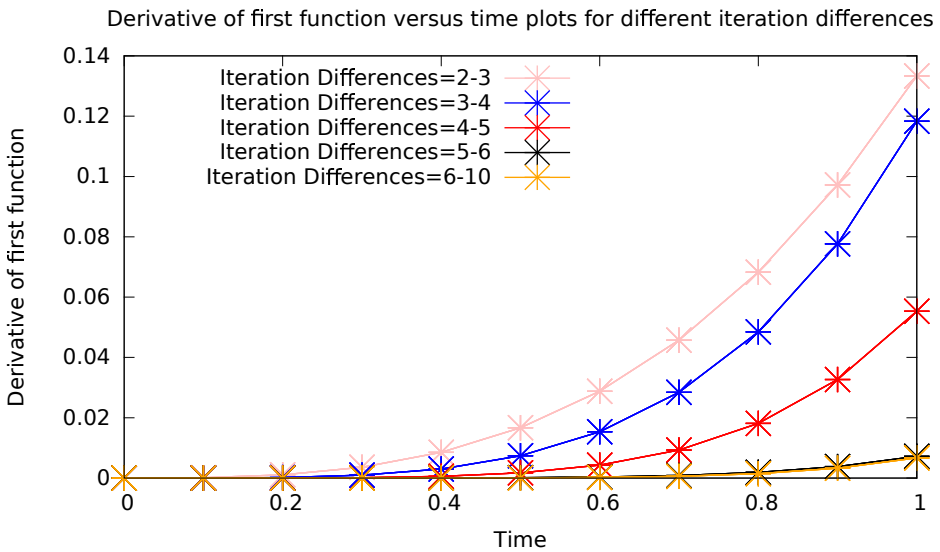

Figure 5: Truncation approximant comparisons for the derivative of the first PREVTH solution vector component with respect to the first element of the initial vector

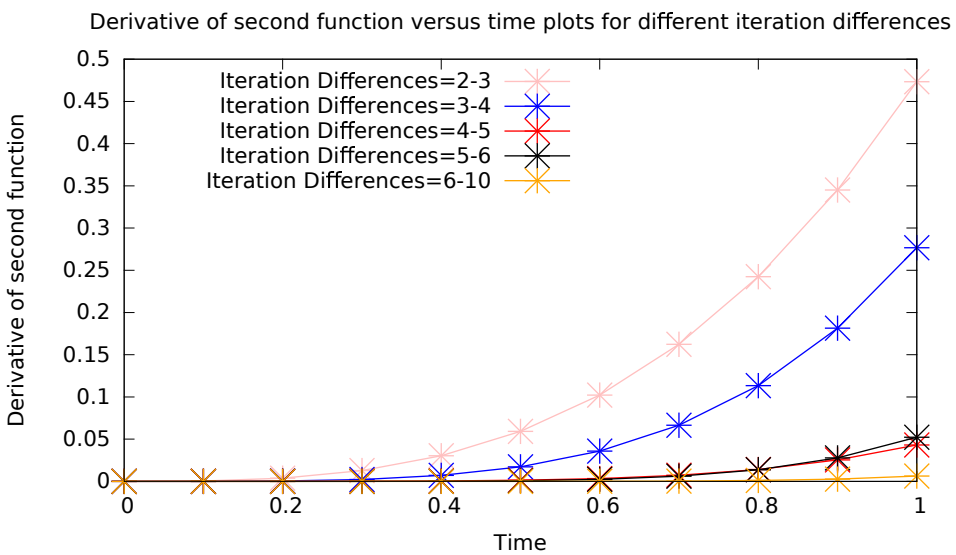

Figure 6: Truncation approximant comparisons for the derivative of the second PREVTH solution vector component with respect to the first element of the initial vector

 ISBN: 978-84-617-8694-7

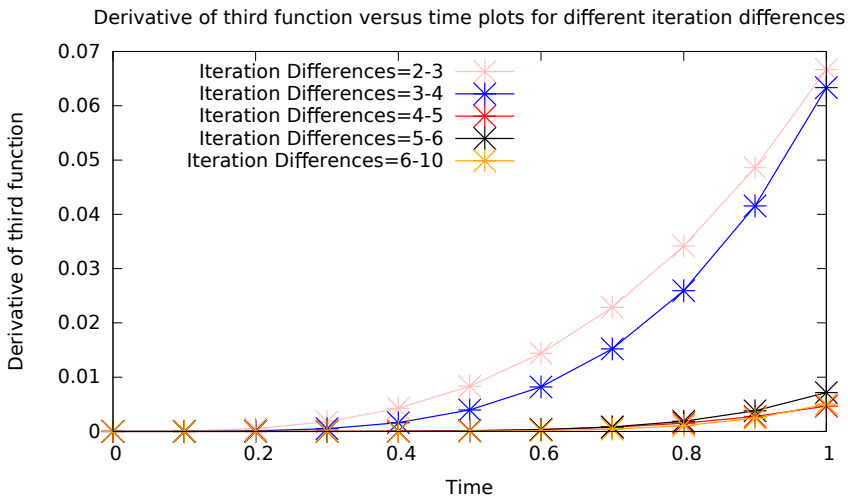

Figure 7: Truncation approximant comparisons for the derivative of the third PREVTH solution vector component with respect to the first element of the initial vector

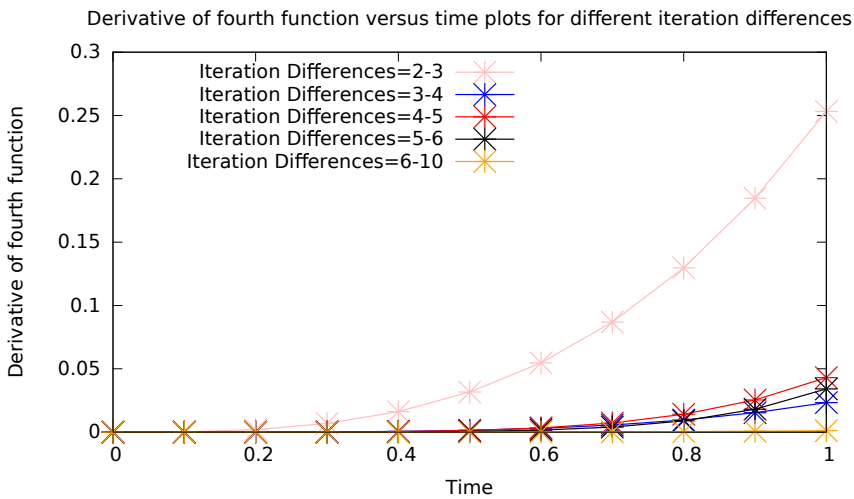

Figure 8: Truncation approximant comparisons for the derivative of the fourth PREVTH solution vector component with respect to the first element of the initial vector

 ISBN: 978-84-617-8694-7

Even though we have evaluated the derivatives of the PREVTH solution vector elements with respect to all elements of the initial vector, we have reported only the partial derivatives with respect to the first element of the initial vector because of the typographical room insufficency. However, the convergence behavior of all cases seem to be almost same and the rather lower truncation order approximants seem to be sufficent for moderate qualities.

Conclusion

In this work we have attempted to evaluate certain sensitivity coefficients by using PREVTH solutions accompanied by a recently developed recursion. Our all implementations support what we expect theoretical aspects of PREVTH. The sensitivity equations are in fact linear and facilitates the solution techniques. We intend to continue our studies towards this direction in our future works.

Abstract

In this paper, we are concentrated on solving Delta equation for a class of non-linear option pricing models. The unknown solution is the first spatial derivative of the option value - Greek Delta. We develop and analyze monotone finite difference method for the model problem. Some basic properties of the numerical scheme are established. To improve the efficiency of the computations, two-grid method is used.

Key words: Delta Greek, Delta equation, finite difference scheme, monotonicity, convergence, two-grid method

1 Introduction and possing the problem

We consider Black-Scholes equation with non-linear volatility term

$$\frac{\partial V}{\partial t} + \frac{1}{2}\sigma^2\left(S, t, \frac{\partial^2 V}{\partial S^2}\right) S^2 \frac{\partial^2 V}{\partial S^2} + (r-q)S\frac{\partial V}{\partial S} - rV, \quad S > 0, \quad 0 \le t \le T, \tag{1}$$

where the solution $V = V(S,t)$ depends on the time variable t and the underlying asset price S. The other parameters are: $r > 1$ is the interest rate, $q \ge 0$ is the dividend yield rate, T is the maturity. Such modifications of the classical option pricing equation, model for instance, presence of constant transaction costs (Leland [4]), non-constant transactions costs (see e.g. Ševčovič and Žitňanská [5]), imperfect replication and investor's preferences (cf. Barles and Soner [2]), etc.

The so called Greeks, representing the sensitivity of the price of derivatives, are very important tools in mathematical engineering. In particular Greek Delta - the first spatial

 ISBN: 978-84-617-8694-7

derivative of the option value, measure the rate of change of the option value with respect to changes in the underlying asset's price.

Let $W = \frac{\partial V}{\partial S}$. Applying time inversion $t = T - t$ and differentiating (1) with respect to S, we derive Delta equation

$$\frac{\partial W}{\partial t} - \frac{1}{2}\frac{\partial}{\partial S}\left[\sigma^2\left(S, t, \frac{\partial W}{\partial S}\right) S^2 \frac{\partial W}{\partial S}\right] + qW - (r-q)S\frac{\partial W}{\partial S} = 0, \ (S,t) \in (0, S_{\max}) \times (0,T), \quad (2)$$

The semi-infinite domain is truncated by large enough computational interval $[0, S_{\max}]$. The problem is completed with initial and boundary conditions, which depends on the type of the option. Let $H(x) = 1_{[0,\infty)}(x)$ stands for the Heaviside function and g_1', g_2^W, g_3^W are known functions. The initial conditions for some popular options are

$$g_1'(S) = \begin{cases} H(S-K) & \text{for Vanilla call,} \\ -H(K-S) & \text{for Vanilla put,} \\ H(S-K_1) - 2H(S-K) + H(S-K_2) & \text{for Butterfly Spread,} \end{cases} \quad (3)$$

The corresponding boundary conditions for (2): g_2^W at $S = 0$ and g_3^W at $S = S_{\max}$, are

$$g_2^W = \begin{cases} 0 & \text{for Vanilla call,} \\ -1 & \text{for Vanilla put,} \\ 0 & \text{for Butterfly Spread,} \end{cases} \qquad g_3^W = \begin{cases} 1 & \text{for Vanilla call,} \\ 0 & \text{for Vanilla put,} \\ 0 & \text{Butterfly Spread.} \end{cases} \quad (4)$$

The aim of this work is to construct and investigate appropriate and efficient numerical method for solving the model problem (2)-(4).

In the papers [6, 7] a numerical approach for computing the Delta Greek and the option price of the Black-Scholes-Barenblatt equation is developed. In our previous paper [3] a first order upwind numerical method is constructed for solving (2)-(4).

2 Numerical method

Finite difference discretization. We define non-uniform meshes in space and time. The space step is $h_i = S_{i+1} - S_i$, $i = 0, 1, \ldots, M-1$, $S_0 = 0$, $S_M = S_{\max}$ and time step $\triangle t_n = t_{n+1} - t_n$, $n = 0, 1, \ldots, N-1$. Let $\hbar_0 = h_0/2$, $\hbar_i = (h_{i-1} + h_i)/2$, $i = 1, 2, \ldots, M-1$, $\hbar_M = h_{M-1}/2$ and the numerical solution at point (S_i, t^n) is denoted by W_i^n.

Using upwind scheme, combined with 'maximal use of central differencing' [8] for the convection term, we construct the weighted ($\theta \in [0,1]$) discretization of (2). For $i = 1, 2, \ldots, M-1$, $n = 0, 1, \ldots, N-1$ we have

$$\begin{aligned} \frac{W_i^{n+1} - W_i^n}{\triangle t_n} - \frac{\theta}{2\hbar_i}\Big[& S_{i+1/2}^2 \widehat{\sigma}_{i+1/2}^{2,n+1} (W_S)_i^{n+1} - S_{i-1/2}^2 \widehat{\sigma}_{i-1/2}^{2,n+1} (W_{\bar{S}})_i^{n+1}\Big] \\ & - \theta(r-q)^+ S_i [\chi_i^+ (W_S)_i^{n+1} + (1-\chi_i^+)(W_{\mathring{S}})_i^{n+1}] \\ & + \theta(r-q)^- S_i [\chi_i^- (W_{\bar{S}})_i^{n+1} + (1-\chi_i^-)(W_{\mathring{S}})_i^{n+1}] + q\theta W_i^{n+1} \end{aligned} \quad (5)$$

 ISBN: 978-84-617-8694-7

$$= \frac{(1-\theta)}{2\hbar_i}\left[S^2_{i+1/2}\widehat{\sigma}^{2,n}_{i+1/2}(W_S)^n_i - S^2_{i-1/2}\widehat{\sigma}^{2,n}_{i-1/2}(W_{\bar{S}})^n_i\right]$$
$$+(1-\theta)(r-q)^+S_i[\chi^+_i(W_S)^n_i + (1-\chi^+_i)(W_{\mathring{S}})^n_i]$$
$$-(1-\theta)(r-q)^-S_i[\chi^-_i(W_{\bar{S}})^n_i + (1-\chi^-_i)(W_{\mathring{S}})^{n+1}_i] + q(1-\theta)W^n_i,$$

where $(W_S)^n_i = (W^n_{i+1} - W^n_i)/h_i$, $(W_{\bar{S}})^n_i = (W_S)^n_{i-1}$, $(W_{\mathring{S}})^n_i = (h_{i-1}(W_S)^n_i + h_i(W_{\bar{S}})^n_i)/2\hbar_i$,

$$\widehat{\sigma}^{2,n+1}_{i+1/2} := \sigma^2\left(S_{i+1/2}, t_{n+1}, (W_S)^{n+1}_i\right), \quad \widehat{\sigma}^{2,n+1}_{i-1/2} := \sigma^2\left(S_{i-1/2}, t_{n+1}, (W_{\bar{S}})^{n+1}_i\right),$$

$$\chi^+_i = \begin{cases} 0, & h_i < \dfrac{S^2_{i-1/2}\widehat{\sigma}^{2,n+1}_{i-1/2}}{(r-q)^+S_i}, \\ 1, & \text{otherwise}, \end{cases} \quad \chi^-_i = \begin{cases} 0, & h_{i-1} < \dfrac{S_{i+1/2}\widehat{\sigma}^{2,n+1}_{i+1/2}}{(r-q)^-}, \\ 1, & \text{otherwise}. \end{cases}$$

The finite difference scheme is completed with boundary and initial conditions

$$W^n_0 = g^W_2(t_n),\ W^n_M = g^W_3(t_n),\ n = 1, \ldots, N, \quad W^0_i = g'_1(S_i),\ i = 0, \ldots, M. \tag{6}$$

Convergence. On the base of the results in [1] for a second order non-linear PDE, from stability, monotonicity and consistency of the numerical discretization follows convergence of the numerical solution to the viscosity solution.

Lemma 1. (Stability) *If the following restriction is fulfilled*

$$\begin{aligned} \triangle t_n \leq & \frac{1}{1-\theta}\left(\frac{1}{2\hbar_i h_{i-1}}S^2_{i-1/2}\widehat{\sigma}^{2,n}_{i-1/2} + \frac{1}{2\hbar_i h_i}S^2_{i+1/2}\widehat{\sigma}^{2,n}_{i+1/2}\right. \\ & +(r-q)^-S_i\left[\frac{\chi^-_i}{h_{i-1}} + \frac{(1-\chi^-_i)h_i}{2\hbar_i}\left(\frac{h_i}{h_{i-1}} - \frac{h_{i-1}}{h_i}\right)\right] \\ & \left.+(r-q)^+S_i\left[\frac{\chi^+_i}{h_i} + \frac{(1-\chi^+_i)h_{i-1}}{2\hbar_i}\left(\frac{h_{i-1}}{h_i} - \frac{h_i}{h_{i-1}}\right)\right] + q\right)^{-1}, \end{aligned} \tag{7}$$

then the solution of the discretization (5), (6) *satisfies the estimate*

$$\|W^{n+1}\|_\infty \leq \max\{\|g'_1\|_\infty, \|g^W_3\|_\infty, \|g^W_3\|_\infty\}.$$

Lemma 2. (Monotonicity) The discretization (5), (6), $\theta = 1$ is monotone, if

$$h_i \leq \frac{S^2_{i-1/2}}{S_i|r-q|}\min\left\{\frac{1}{(1-\chi^-_{i+1})}\frac{\partial(\widehat{\sigma}^{2,n+1}_{i+3/2}U^{n+1}_{i+3/2})}{\partial U^{n+1}_{i+3/2}}, \frac{1}{(1-\chi^+_i)}\frac{\partial(\widehat{\sigma}^{2,n+1}_{i-1/2}U^{n+1}_{i-1/2})}{\partial U^{n+1}_{i-1/2}}\right\}. \tag{8}$$

Lemma 3. *The discretization* (5), (6) *is consistent.*

Theorem 1. *Let the conditions of Lemmas 1 - 3 are fulfilled. Then the solution of* (5), (6), $\theta = 1$, *converges to the viscosity solution* as $(|h|, \triangle t) \to (0^+, 0^+)$, where $|h| = \max\limits_{0\leq i\leq M} h_i$ and $\triangle t = \max\limits_{0\leq n\leq N-1} \triangle t_n$.

Abstract

In this work we consider a system of weakly coupled semi-linear parabolic equations of optimal portfolio in a regime-switching model in the case of exponential utility function, proposed by A.R. Valdez and T. Vargiolu [8]. We develop efficient finite difference method for 2D case. For the approximation of the convection term we implement van Leer flux limiter technique and for the discretization of the mixed derivatives we apply different stencils, depending on the sign of the correlation. We prove comparison principle and convergence for the approximated solution.

Key words: Regime-switching model, system of semi-linear parabolic PDE, exponential non-linearity, finite difference scheme, flux limiter, convergence

1 Introduction and model formulation

Following the regime-switching model in [8], we consider the PDE system

$$C_t^k + rSC_S^k + \tfrac{1}{2}\mathrm{tr}(\overline{S}\sum_k \sum_k^T \overline{S} C_{SS}^k) + \frac{e^{-r(T-t)}}{\alpha}\left[\sum_{j=1}^m (e^{-\alpha\phi(C^k - C^j)} - 1)\lambda^{kj} - \tfrac{1}{2}z_k^2\right] = rC^k, \quad C^k(T) = 0. \tag{1}$$

Here $C(t,S) := (C^k(t,S))_{k=1,\dots,m} \in C_b^{1,2}([0,T]\times B, \mathbb{R}^m)$, $B = (0,\infty)^d$, r is the risk-free interest rate, $\phi(t) := e^{r(T-t)}$, $\alpha > 0$, $\mu_k = \mu_k(t,S) : [0,T]\times B \subset \mathbb{R}^d \to \mathbb{R}^d$, $\sum_k \sum_k^T$ are locally Lipschitz and bounded, $\sum_k = \sum_k(t,S) : [0,T]\times B \subset \mathbb{R}^d \to \mathbb{R}^{d\times d}$ is nonsingular for all (t,S), $\sum_k^{-1}\mu_k$ and $\lambda^{kj} : [0,T]\times B \to [0,\infty)$, $\lambda^{kj} \in C_b^1([0,T]\times B)$ are bounded on $\Omega_T = [0,T]\times B$, for all $k,j = 1,\dots,m$, $\mathbf{1}$ is the d-dimensional unit column vector,

 ISBN: 978-84-617-8694-7

$\overline{S} := \mathrm{diag}(S)$, $S = (S_1, S_2, \ldots, S_d)$, C^k_S is the gradient with respect to S, C^k_{SS} is the Hessian matrix with entries $C^k_{S_iS_j}$, $i, j = 1, 2, \ldots, d$ and functions z^2_k are defined by

$$z^2_k(t, S) := (\mu_k(t, S) - r\mathbf{1})^T \left(\sum_k(t, S) \sum^T_k(t, S)\right)^{-1} (\mu_k(t, S) - r\mathbf{1}).$$

A simpler regime-switching model (represented by a parabolic-ODE system) in the case of exponential utility is derived in [6]. For solving this market model, in [1, 2, 7] are constructed and analyzed efficient finite difference schemes. In our previous work [3] a scalar case of problem (1) is studied.

We consider two-dimensional case of (1) with more general terminal conditions $C^k(T, S) = C^k_0(S)$, $k = 1, 2$. The semi-infinite domain B is truncated by large enough computational region $[0, S_{1\max}] \times [0, S_{2\max}]$, imposing natural boundary conditions. Next, we apply the logarithmic change of the space variables $x_i = \ln S_i$. As a result $[0, S_{i\max}]$ transforms to the semi-infinite domain $(-\infty, \ln S_{i\max}]$. Then, this domain is truncated by large enough computational domain $D = D_1 \times D_2$, $D_i = [L^-_i, L^+_i]$, $L^+_i = \ln S_{i\max}$ and $L^-_i < 0$, $L^+_i > 0$ are real numbers. For $i = 1, 2$ we define the function δ_i

$$\delta_i = \begin{cases} 0, & x_i = L^{\pm}_i, \\ 1, & \text{otherwise}, \end{cases} \qquad \delta^2_i = \delta_i.$$

In order to obtain an initial-value problem we invert the time, setting $\tau := T - t$. Let $\sum_k \sum^T_k = \{\sigma^k_{il}\}^{2,2}_{i,l=1} \geq 0$ and denote $2\rho^k_{il} = \sigma^k_{il} + \sigma^k_{li}$, $k = 1, 2$. Finally, the resulting problem for $(\tau, x) \in Q_T = (0, T] \times D_1 \times D_2$, is

$$C^k_\tau - \delta_1 \left(r - \frac{1}{2}\sigma^k_{11}\right) C^k_{x_1} - \delta_2 \left(r - \frac{1}{2}\sigma^k_{22}\right) C^k_{x_2} + rC^k$$

$$- \frac{1}{2}\left(\delta_1\sigma^k_{11}C^k_{x_1x_1} + 2\delta_1\delta_2\rho^k_{12}C^k_{x_1x_2} + \delta_2\sigma^k_{22}C^k_{x_2x_2}\right) = \frac{e^{-r\tau}}{\alpha}\left(\sum_{j=1}^{m}(e^{-\alpha\phi(C^k - C^j)} - 1)\lambda^{kj} - \frac{1}{2}z^2_k\right) \quad (2)$$

$$C^k(0, x) = C^k_0(e^x), \quad x \in D_1 \times D_2.$$

We prove comparison principle for the differential problem (2).

2 Numerical method

We consider uniform mesh in space $\overline{\omega}_h = \overline{\omega}_{h_1} \times \overline{\omega}_{h_2}$ with mesh step size h_i in x_i direction

$$\overline{\omega}_{h_i} = \left\{x_{i,j_i} : x_{i,j_i} = L^-_i + (j_i - 1)h_i,\ j_i = 1, \ldots, N_i, \quad h_i = (L^+_i - L^-_i)/(N_i - 1)\right\}$$

and non-uniform mesh ω_τ in time with time increments $\triangle\tau^n$, i.e. $\tau^{n+1} = \tau^n + \triangle\tau^n$, $n = 0, 1, \ldots, N_\tau$. The numerical solution at grid nodes from $Q^h_T = \omega_\tau \times \overline{\omega}_h$ is denoted by

 ISBN: 978-84-617-8694-7

$C^k_{j_1,j_2} := C^k(\tau^n, x_{1j_1}, x_{2j_2})$ and $\widehat{C}^k_{j_1,j_2} := C^k(\tau^{n+1}, x_{1j_1}, x_{2j_2})$. Further, we use the following notations for the derivative approximations

$$C^k_{t_{j_1,j_2}} = \frac{\widehat{C}^k_{j_1,j_2} - C^k_{j_1,j_2}}{\triangle\tau^n}, \quad C^k_{\overline{x}_1 j_1,j_2} = \frac{C^k_{j_1,j_2} - C^k_{j_1-1,j_2}}{h_1}, \quad C^k_{x_1 j_1,j_2} = C^k_{\overline{x}_1 j_1+1,j_2},$$

$$C^k_{\overline{x}_2 j_1,j_2} = \frac{C^k_{j_1,j_2} - C^k_{j_1,j_2-1}}{h_2}, \quad C^k_{x_2 j_1,j_2} = C^k_{\overline{x}_2 j_1,j_2+1}, \quad C^k_{\overline{x}_s x_p} = (C^k_{\overline{x}_s})_{x_p},\ s,p = \{1,2\},$$

$$(C^k)^-_{x_1x_2} = \frac{1}{2}[C^k_{\overline{x}_1 x_2} + C^k_{x_1 \overline{x}_2}], \quad (C^k)^+_{x_1x_2} = \frac{1}{2}[C^k_{x_1x_2} + C^k_{\overline{x}_1\,\overline{x}_2}], \quad (C^k)^\pm = \max\{0, \pm C^k\}.$$

In order to approximate the model problem (2), we use different stencils for the approximation of the mixed derivative, depending on the sign of ρ^k_{12} and for convection term we implement van Leer flux limiter technique [5]. For the exponential term we apply Newton-like linearization. The resulting weighted ($\theta_1, \theta_2, \theta_3 \in [0,1]$) numerical scheme is

$$\begin{aligned}
&C^k_t - \theta_1\delta_1[(A^k_1)^+(\widehat{\Lambda}^k_1)^+\widehat{C}^k_{x_1} - (A^k_1)^-(\widehat{\Lambda}^k_1)^-\widehat{C}^k_{\overline{x}_1}] \\
&\quad - \theta_1\delta_2[(A^k_2)^+(\widehat{\Lambda}^k_2)^+\widehat{C}^k_{x_2} - (A^k_2)^-(\widehat{\Lambda}^k_2)^-\widehat{C}^k_{\overline{x}_2}] + r\theta_2\widehat{C}^k + \theta_3\sum_{j=1}^m e^{-\alpha\widehat{\phi}(C^k-C^j)}(\widehat{C}^k - \widehat{C}^j)\widehat{\lambda}^{kj} \\
&\quad - \frac{1}{2}\theta_2\left(\delta_1\sigma^k_{11}\widehat{C}^k_{\overline{x}_1x_1} + 2\delta_1\delta_2(\rho^k_{12})^+(\widehat{C}^k)^+_{x_1x_2} - 2\delta_1\delta_2(\rho^k_{12})^-(\widehat{C}^k)^-_{x_1x_2} + \delta_2\sigma^k_{22}\widehat{C}^k_{\overline{x}_2x_2}\right) \qquad (3) \\
&= (1-\theta_1)\delta_1[(A^k_1)^+(\Lambda^k_1)^+C^k_{x_1} - (A^k_1)^-(\Lambda^k_1)^-C^k_{\overline{x}_1}] \\
&\quad + (1-\theta_1)\delta_2[\left((A^k_2)^+(\Lambda^k_2)^+C^k_{x_2} - (A^k_2)^-(\Lambda^k_2)^-C^k_{\overline{x}_2}\right)] + \mathcal{F}^m_1 + \mathcal{F}^m_2 - r(1-\theta_2)C^k \\
&\quad + \frac{1-\theta_2}{2}\left(\delta_1\sigma^k_{11}C^k_{\overline{x}_1x_1} + 2\delta_1\delta_2(\rho^k_{12})^+(C^k)^+_{x_1x_2} - 2\delta_1\delta_2(\rho^k_{12})^-(C^k)^-_{x_1x_2} + \delta_2\sigma^k_{22}C^k_{\overline{x}_2x_2}\right),
\end{aligned}$$

coupled with initial conditions $C^k(0,x_1,x_2) = C^k_0(e^{x_1}, e^{x_2})$, $(x_1,x_2) \in \overline{\omega}_h$. The following notations are used in (3)

$$(\Lambda^k_i)^+ = 1 + \frac{1}{2}\Phi((\theta^k_{j_i+1/2})^{-1}) - \frac{1}{2}\Phi(\theta^k_{j_i+3/2}), \quad (\Lambda^k_i)^- = 1 + \frac{1}{2}\Phi(\theta^k_{j_i+1/2}) - \frac{1}{2}\Phi((\theta^k_{j_i-1/2})^{-1}),$$

$$\Phi(\theta^k) = \frac{|\theta^k| + \theta^k}{1 + |\theta^k|}, \quad \theta^k_{j_i+1/2} = \frac{C^k_{x_i j_1,j_2}}{C^k_{\overline{x}_i j_1,j_2}}, \quad i = 1,2,$$

$$\mathcal{F}^m_1 = (1-\theta_3)\frac{e^{-r\tau^n}}{\alpha}\left[\sum_{j=1}^m (e^{-\alpha\phi(C^k-C^j)} - 1)\lambda^{kj} - \frac{1}{2}z^2_k\right],$$

$$\mathcal{F}^m_2 = \theta_3\frac{e^{-r\tau^{n+1}}}{\alpha}\left[\sum_{j=1}^m [(1 + \alpha\widehat{\phi}(C^k - C^j))e^{-\alpha\widehat{\phi}(C^k-C^j)} - 1]\widehat{\lambda}^{kj} - \frac{1}{2}\widehat{z}^2_k\right].$$

Now, if $|\rho^k_{12}|(\sigma^k_{22})^{-1} \le h_1h_2^{-1} \le \sigma^k_{11}|\rho^k_{12}|^{-1}$, then the coefficient matrix of the system (3) is an M-matrix.

 ISBN: 978-84-617-8694-7

Further, for a mild time step restriction, we prove negativity preserving property and convergence in maximal discrete norm of the solution of (3).

Various numerical experiments confirm computational efficiency of the proposed method and validate the theoretical statements.

Abstract

In this paper, we investigate and prove common random fixed point theorems in cone random metric spaces for weakly compatible mappings satisfying implicit relations.

Key words: Random Fixed Point, Cone Random Metric Spaces, Implicit Relation
MSC 2000: 47H10, 54H25

1 Introduction

Random fixed point theorems is stochastic generalizations of classical fixed point theorems. The study of random fixed points form a central topic in this area. Random fixed point theorems for random contraction mappings on separable complete metric spaces were first proved by Špaček [1] and Hanš [2]. Subsequently, Bharucha-Reid [3] proved the stochastic version of the well-known Banachs and Schauders fixed point theorem and hence random fixed point theory and applications have been developed rapidly in recent years, see [4, 5, 6, 7]. In 2007, Huang and Zhang [8] defined the cone metric spaces. They also described the

 ISBN: 978-84-617-8694-7

convergence of sequences and introduced the notion of completeness in cone metric spaces and proved some fixed point theorems of contractive mappings on complete cone metric space. In 2008, Rezapour and Hamlbarani [9], showed that there are no normal cones with normal constant $M < 1$, and for each $k > 1$ there are cones with normal constant $M > k$, by providing non-normal cones and omitting the assumption of normality. Random fixed point results in cone random metric spaces are stochastic generalization of deterministic fixed point results in cone metric space. Several other authors see [10, 11, 12] studied the existence of random fixed points and common random fixed points of mappings satisfying contractive type conditions in setting cone random metric spaces. Recently, Rashwan and Hammad [12] a common random fixed point for four weakly compatible mappings on a nonempty separable closed subset of cone random metric spaces. In this paper, we prove common random fixed point theorems for weakly compatible mapping vai implicit relation.

2 Preliminaries

Definition 2.1. *[10] Let $(\mathcal{E}, \tau)$ be a topological vector space. A subset p of $\mathcal{E}$ is called a cone if the following conditions satisfied:*

(c_1) p is closed, nonempty and $p \neq \{0\}$;

(c_2) $a, b \in \mathbb{R}$, $a, b \geq 0$ and $x, y \in p \Rightarrow ax + by \in p$;

(c_3) If $x \in p$ and $-x \in p \Rightarrow x = 0$.

For a given cone $p \subset \mathcal{E}$ we define a partial ordering $\preceq$ with respect to p by $x \preceq y$ if $y - x \in p$. We shall write $x \prec y$ to indicate that $x \preceq y$ but $x \neq y$, while $x \ll y$ will stand for $y - x \in p^{\circ}$, where p° indicate to the interior of p.

Definition 2.2. *[8, 14] Let X be a nonempty set and the mapping the mapping $d : X \times X \to \mathcal{E}$ satisfies:*

(d_1) $0 \leq d(x, y)$ for all $x, y \in X$ and $d(x, y) = 0 \Leftrightarrow x = y$;

(d_2) $d(x, y) = d(y, x)$ for all $x, y \in X$;

(d_3) $d(x, y) \leq d(x, z) + d(z, y)$; $x, y, z \in X$.

Then d is called a cone metric [8] or K-metric [14] on X and (X, d) is called a cone metric space [8].
The concept of a cone metric space is more general than that of a metric space, because each metric space is a cone metric space where $\mathcal{E} = \mathbb{R}$ and $p = [0, +\infty)$.

 ISBN: 978-84-617-8694-7

Definition 2.3. *Let (X, d) be a cone metric space. We say that $\{x_n\}$ is:*

(i) a Cauchy sequence if for every ε in $\mathcal{E}$ with $0 \ll \varepsilon$, then there is an $\mathbb{N}$ such that for all $n, m > \mathbb{N}$, $d(x_n, x_m) \ll \varepsilon$;

(ii) a convergent sequence if for every ε in $\mathcal{E}$ with $0 \ll \varepsilon$, then there is an $\mathbb{N}$ such that for all $n > \mathbb{N}$, $d(x_n, x) \ll \varepsilon$ for some fixed x in X.

A cone metric space X is said to be complete if every Cauchy sequence in X is convergent in X.

Definition 2.4. *Let (Ω, Σ) be a measurable space with Σ- a sigma algebra of subsets of Ω and $\mathcal{M}$ be a nonempty subset of a metric space $X = (X, d)$. Let $2^{\mathcal{M}}$ be the family of nonempty subsets of $\mathcal{M}$ and $C(\mathcal{M})$ the family of all nonempty closed subsets of $\mathcal{M}$. A mapping $G : \Omega \to 2^{\mathcal{M}}$ is called measurable if for each open subset U of $\mathcal{M}$, $G^{-1}(U) \in \Sigma$, where $G^{-1}(U) = \{\omega \in \Omega : G(\omega) \cap U \neq \emptyset\}$*

Definition 2.5. *A mapping $\xi : \Omega \to \mathcal{M}$ is called measurable selector of a measurable mappings $G : \Omega \to 2^{\mathcal{M}}$ if ξ is measurable and $\xi(\omega) \in G(\omega)$ for each $\omega \in \Omega$.*

Definition 2.6. *The mapping $T : \Omega \times \mathcal{M} \to X$ is called a random operator if for each fixed $x \in \mathcal{M}$, the mapping $T(\cdot, x) : \Omega \to X$ is measurable.*

Definition 2.7. *A random operator $T : \Omega \times \mathcal{M} \to X$ is called continuous random operator if for each fixed $x \in \mathcal{M}$ and $\omega \in \Omega$, the mapping $T(\omega, \cdot) : \Omega \to X$ is continuous.*

Definition 2.8. *A measurable mappings $\xi : \Omega \to \mathcal{M}$ is a random fixed point of a random operator $T : \Omega \times \mathcal{M} \to X$ if $T(\omega, \xi(\omega)) = \xi(\omega)$ for each $\omega \in \Omega$.*

Definition 2.9. *Let $\mathcal{M}$ be a nonempty set and the mapping $d : \Omega \times \mathcal{M} \to p$, where p is a cone, $\omega \in \Omega$ be a selector, satisfy the following conditions:*

(i) $d(x(\omega), y(\omega)) \geq 0$ and $d(x(\omega), y(\omega)) = 0 \Leftrightarrow x(\omega) = y(\omega)$ for all $x(\omega), y(\omega) \in \Omega \times \mathcal{M}$,

(ii) $d(x(\omega), y(\omega)) = d(y(\omega), x(\omega))$ for all $x, y \in \mathcal{M}$, $\omega \in \Omega$ and $x(\omega), y(\omega) \in \Omega \times \mathcal{M}$,

(iii) $d(x(\omega), y(\omega)) \leq d(x(\omega), z(\omega)) + d(z(\omega), y(\omega))$ for all $x, y, z \in \mathcal{M}$ and $\omega \in \Omega$ be a selector,

(iv) for any $x, y \in \mathcal{M}, \omega \in \Omega, d(x(\omega), y(\omega))$ is nonincreasing and left continuous.

Then d is called cone random metric on $\mathcal{M}$ and $(\mathcal{M}, d)$ is called a cone random metric space.

 ISBN: 978-84-617-8694-7

Definition 2.10. *Random operators $T, S : \Omega \times X \to X$ are weakly compatible if $T(S(\xi(\omega))) = S(T(\xi(\omega)))$ provided that $T(\xi(\omega)) = S(\xi(\omega))$ for every $\omega \in \Omega$.*

Definition 2.11. *[15] Let F_6 be the family of all continuous mappings $F(t_1, t_2, t_3, t_4, t_5, t_6) : \mathbb{R}_+^6 \to \mathbb{R}$ with $t_3 + t_4 \neq 0$ satisfying the following condition:*
(F_1) there exists $0 \leq h < 1$ such that for all $u, v, w \geq 0$ with

(F_a) $F(u, v, v, u, w, 0) \leq 0$ or

(F_b) $F(u, v, u, v, 0, 0) \leq 0$
we have $u \leq hv$.

3 Main result

Theorem 3.1. *Let (X, d) be a complete cone random metric space with respect to a cone $\mathcal{P}$ and let $\mathcal{M}$ be nonempty separable closed subset of X. Assume that S, T, f, and g be four continuous random operators defined on $\mathcal{M}$ such that $\omega \in \Omega$, $S(\omega, \cdot), T(\omega, \cdot), f(\omega, \cdot), g(\omega, \cdot) : \Omega \times \mathcal{M} \to \mathcal{M}$ satisfying the following conditions:*

(i) $S(\omega, X) \subseteq g(\omega, X)$ and $T(\omega, X) \subseteq f(\omega, X)$,

(ii) the pairs $\{S, f\}$ and $\{T, g\}$ are random weakly compatible mappings,

(iii)

$$\begin{aligned} &F(d(S(x(\omega)), T(y(\omega))), d(f(x(\omega)), g(y(\omega))), d(f(x(\omega)), S(x(\omega))), \\ &d(g(y(\omega)), T(y(\omega))), d(f(x(\omega)), T(y(\omega))), d(S(x(\omega)), g(y(\omega)))) \leq 0 \end{aligned} \tag{1}$$

for all $x(\omega), y(\omega) \in \Omega \times X$ and $F \in F_6$.
Satifies (F_1) if $d(f(x(\omega)), S(x(\omega))) + d(g(y(\omega)), T(y(\omega))) \neq 0$, or $d(S(x(\omega)), T(x(\omega))) = 0$ if $d(f(x(\omega)), S(x(\omega))) + d(g(y(\omega)), T(y(\omega))) = 0$.
Then the four random mapping have unique common random fixed point in X.

Proof. For each $x_0(\omega), x_1(\omega) \in \Omega \times X$ and $n = 1, 2, 3, \ldots$, we choose $y_1(\omega), y_2(\omega) \in \Omega \times X$ such that

$$y_1(\omega) = S(x_0(\omega)) = g(x_1(\omega))$$

and

$$y_2(\omega) = T(x_1(\omega)) = f(x_2(\omega))$$

In general we construct a sequence of measurable mappings $x_n(\omega), y_n(\omega) : \Omega \to X$ defined by

$$y_{2n+1}(\omega) = S(x_{2n}(\omega)) = g(x_{2n+1}(\omega)) \tag{2}$$

 ISBN: 978-84-617-8694-7

$$y_{2n+2}(\omega) = T(x_{2n+1}(\omega)) = f(x_{2n+2}(\omega)) \tag{3}$$

If $d(f(x_{2n}(\omega)), S(x_{2n}(\omega))) + d(g(x_{2n+1}(\omega)), T(x_{2n+1}(\omega))) \neq 0$. Then from (1), (2), and (3), we get

$$\begin{aligned}
&F(d(S(x_{2n}(\omega)), T(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), g(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), S(x_{2n}(\omega))),\\
&d(g(x_{2n+1}(\omega)), T(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), T(x_{2n+1}(\omega))), d(S(x_{2n}(\omega)), g(x_{2n+1}(\omega))))\\
&= F(d(y_{2n+1}(\omega), y_{2n+2}(\omega)), d(y_{2n}(\omega), y_{2n+1}(\omega)), d(y_{2n}(\omega), y_{2n+1}(\omega)),\\
&d(y_{2n+1}(\omega), y_{2n+2}(\omega)), d(y_{2n}(\omega), y_{2n+2}(\omega)), d(y_{2n+1}(\omega), y_{2n+1}(\omega)))\\
&\leq 0.
\end{aligned}$$

By (F_a), we get

$$d(y_{2n+1}(\omega), y_{2n+2}(\omega)) \leq h d(y_{2n}(\omega), y_{2n+1}(\omega))$$

Similarly, if

$$d(f(x_{2n+2}(\omega)), S(x_{2n+2}(\omega))) + d(g(x_{2n+1}(\omega)), T(x_{2n+1}(\omega))) \neq 0.$$

we obtain

$$d(y_{2n}(\omega), y_{2n+1}(\omega)) \leq h d(y_{2n-1}(\omega), y_{2n}(\omega)),$$

hence

$$d(y_{2n+1}(\omega), y_{2n+2}(\omega)) \leq h^2 d(y_{2n-1}(\omega), y_{2n}(\omega)).$$

On continuing this process, we have

$$d(y_{2n+1}(\omega), y_{2n+2}(\omega)) \leq h^{2n} d(y_0(\omega), y_1(\omega)).$$

Also, for $n > m$, we get

$$\begin{aligned}
d(y_n(\omega), y_m(\omega)) &\leq d(y_n(\omega), y_{n-1}(\omega)) + d(y_{n-1}(\omega), y_{n-2}(\omega)) + \cdots + d(y_{m+1}(\omega), y_m(\omega))\\
&\leq (h^{n-1} + h^{n-2} + \cdots + h^m) d(y_0(\omega), y_1(\omega))\\
&\leq (\frac{h^m}{1-h}) d(y_0(\omega), y_1(\omega)).
\end{aligned}$$

Let $0 \ll \varepsilon$ is given. Choose a natural number N such that $(\frac{h^m}{1-h}) d(y_0(\omega), y_1(\omega)) \ll \varepsilon$ for every $m \geq N$, hence

$$d(y_n(\omega), y_m(\omega)) \leq (\frac{h^m}{1-h}) d(y_0(\omega), y_1(\omega)) \ll \varepsilon,$$

this implies that $\{y_n(\omega)\}$ is Cauchy sequence in $\Omega \times X$. Since (X, d) is complete, then there exists $z(\omega) \in \Omega \times X$ such that $y_n(\omega) \to z(\omega)$ as $n \to \infty$. Then from (2) and (3), we get

$$\lim_{n\to\infty} S(x_{2n}(\omega)) = \lim_{n\to\infty} g(x_{2n+1}(\omega)) = z(\omega)$$

 ISBN: 978-84-617-8694-7

and

$$\lim_{n\to\infty} T(x_{2n+1}(\omega)) = \lim_{n\to\infty} f(x_{2n+2}(\omega)) = z(\omega).$$

Therefore

$$\lim_{n\to\infty} S(x_{2n}(\omega)) = \lim_{n\to\infty} g(x_{2n+1}(\omega)) = \lim_{n\to\infty} T(x_{2n+1}(\omega)) = \lim_{n\to\infty} f(x_{2n+2}(\omega)) = z(\omega) \quad (4)$$

Since $T(\omega, X) \subseteq f(\omega, X)$, then there exists $v(\omega) \in \Omega \times X$ such that

$$z(\omega) = f(v(\omega)). \quad (5)$$

From (1), we obtain

$$F(d(S(x_{2n}(\omega)), T(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), g(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), S(x_{2n}(\omega))),$$
$$d(g(x_{2n+1}(\omega)), T(x_{2n+1}(\omega))), d(f(x_{2n}(\omega)), T(x_{2n+1}(\omega))), d(S(x_{2n}(\omega)), g(x_{2n+1}(\omega)))) \leq 0,$$

this implies that $d(z(\omega), T(v(\omega))) \leq 0$, thus $-d(z(\omega), T(v(\omega))) \in p$. But $d(z(\omega), T(v(\omega))) \in p$, therefore by Definition 2.1 (c_3), we have $d(z(\omega), T(v(\omega))) = 0$ and so $d(z(\omega) = T(v(\omega)))$. Form (5) we get

$$z(\omega) = f(v(\omega)) = T(v(\omega)).$$

Hence $v(\omega)$ is a random coincidence point of T and f. Since the pair T and f are random weakly compatible, i.e. $T(f(v(\omega))) = f(T(v(\omega)))$ this implies that

$$T(z(\omega)) = f(z(\omega)).$$

Now we show that $z(\omega)$ is a random fixed point of S, we have from (1) that

$$\begin{aligned} &F(d(S(u(\omega)), T(v(\omega))), d(f(u(\omega)), g(v(\omega))), d(f(u(\omega)), S(u(\omega))), \\ &d(g(v(\omega)), T(v(\omega))), d(f(u(\omega)), T(v(\omega))), d(S(u(\omega)), g(v(\omega)))) \\ &= F(d(S(u(\omega)), (z(\omega))), 0, d(z(\omega), S(u(\omega))), 0, 0, d(S(u(\omega)), z(\omega))) \\ &\leq 0. \end{aligned}$$

By (F_b) we get $f(z(\omega)) = S(z(\omega))$ and $g(z(\omega)) = T(z(\omega))$. Since $d(f(z(\omega)), S(z(\omega))) + d(g(v(\omega)), T(v(\omega))) = 0$, it follows that $d(S(z(\omega)), T(v(\omega))) = 0$ i.e.

$$z(\omega) = S(z(\omega)) = f(z(\omega)). \quad (6)$$

By a similar way and using (6), we can prove that for all $\omega \in \Omega$,

$$z(\omega) = T(z(\omega)) = g(z(\omega)). \quad (7)$$

 ISBN: 978-84-617-8694-7

The equations (6) and (7) show that $z(\omega)$ is common random fixed point of T, S, f, g. For uniqueness. Let $z(\omega) \neq q(\omega)$ be another common random fixed point of four mappings, then from (1), one can write

$$\begin{aligned}
&F(d(S(u(\omega)), T(q(\omega))), d(f(u(\omega)), g(q(\omega))), d(f(u(\omega)), S(u(\omega))),\\
&d(g(q(\omega)), T(q(\omega))), d(f(u(\omega)), T(q(\omega))), d(S(u(\omega)), g(q(\omega))))\\
&= F(d(q(\omega), (z(\omega))), 0, d(z(\omega), q(\omega)), 0, 0, d(q(\omega), z(\omega)))\\
&\leq 0.
\end{aligned}$$

a contradiction. Hence $z(\omega) = q(\omega)$ and so $z(\omega)$ is a unique common random fixed point of T, S, f, g. □

If we take, $f = g$ in above theorem we obtain the following corollary.

Corollary 3.2. *Let (X, d) be a complete cone random metric space with respect to a cone $\mathcal{P}$ and let $\mathcal{M}$ be nonempty separable closed subset of X. Assume that S, T and f be three continuous random operators defined on $\mathcal{M}$ such that $\omega \in \Omega$, $S(\omega, \cdot), T(\omega, \cdot), f(\omega, \cdot) : \Omega \times \mathcal{M} \to \mathcal{M}$ satisfying the following conditions:*

(i) $S(\omega, X) \subseteq f(\omega, X)$ and $T(\omega, X) \subseteq f(\omega, X)$,

(ii) the pairs $\{S, f\}$ and $\{T, f\}$ are random weakly compatible mappings,

(iii)

$$\begin{aligned}
&F(d(S(x(\omega)), T(y(\omega))), d(f(x(\omega)), f(y(\omega))), d(f(x(\omega)), S(x(\omega))),\\
&d(f(y(\omega)), T(y(\omega))), d(f(x(\omega)), T(y(\omega))), d(S(x(\omega)), f(y(\omega)))) \leq 0
\end{aligned}$$

for all $x(\omega), y(\omega) \in \Omega \times X$ and $F \in F_6$ satifies (F_1) if $d(f(x(\omega)), S(x(\omega))) + d(f(y(\omega)), T(y(\omega))) \neq 0$, or $d(S(x(\omega)), T(x(\omega))) = 0$ if $d(f(x(\omega)), S(x(\omega))) + d(f(y(\omega)), T(y(\omega))) = 0$.
Then the three random mapping have unique common random fixed point in X.

If we take, $f = g$ and $S = T$ in above theorem we obtain the following corollary.

Corollary 3.3. *Let (X, d) be a complete cone random metric space with respect to a cone $\mathcal{P}$ and let $\mathcal{M}$ be nonempty separable closed subset of X. Assume that S and f be two continuous random operators defined on $\mathcal{M}$ such that $\omega \in \Omega$, $S(\omega, \cdot), f(\omega, \cdot) : \Omega \times \mathcal{M} \to \mathcal{M}$ satisfying the following conditions:*

(i) $S(\omega, X) \subseteq f(\omega, X)$,

(ii) the pairs $\{S, f\}$ is a random weakly compatible mappings,

 ISBN: 978-84-617-8694-7

(iii)

$$F(d(S(x(\omega)),S(y(\omega))),d(f(x(\omega)),f(y(\omega))),d(f(x(\omega)),S(x(\omega))),$$
$$d(f(y(\omega)),S(y(\omega))),d(f(x(\omega)),S(y(\omega))),d(S(x(\omega)),f(y(\omega)))) \leq 0$$

for all $x(\omega), y(\omega) \in \Omega \times X$ *and* $F \in F_6$ *satifies* (F_1) *if* $d(f(x(\omega)),S(x(\omega)))+d(f(y(\omega)),S(y(\omega))) \neq 0$, *or* $d(S(x(\omega)),S(x(\omega))) = 0$ *if* $d(f(x(\omega)),S(x(\omega))) + d(f(y(\omega)),S(y(\omega))) = 0$.
Then the two random mapping have unique common random fixed point in X.

Abstract

Recent results on the construction and applications of the transmutation (transformation) operators are discussed. Three new representations for solutions of the one-dimensional Schrödinger equation are considered. Due to the fact that they are obtained with the aid of the transmutation operator all the representations possess an important for practice feature. The accuracy of the approximate solution is independent of the real part of the spectral parameter. This makes the representations especially useful in problems requiring computation of large sets of eigendata with a nondeteriorating accuracy.

Applications of the exact representations for the transmutation operators to partial differential equations are discussed as well. In particular, it is shown how the methods based on complete families of solutions can be extended onto equations with variable coefficients.

Key words: Sturm-Liouville equation, Transmutation operator, Neumann series of Bessel functions, Spectral problem, Complete family of solutions, Method of fundamental solutions

MSC 2000: AMS codes (optional)

1 Transmutation operators

Transmutation operators also called transformation operators are a widely used tool in the theory of linear differential equations (see, e.g., [2], [4], [5] [18], [19], [20] and many other publications). In particular, let $q \in C[-b, b]$ be a complex valued function. Consider the Sturm-Liouville equation

$$Ay := y'' - q(x)y = -\omega^2 y. \tag{1}$$

It is well known (see, e.g., [19]) that there exists a Volterra integral operator T called the transmutation (or transformation) operator defined on $C[-b,b]$ by the formula

$$Tu(x) = u(x) + \int_{-x}^{x} K(x,t)u(t)dt$$

such that for any $u \in C^2[-b,b]$ the following equality is valid

$$ATu = Tu''$$

and hence any solution of (1) can be written as $y = T[u]$ where $u(x) = c_1 \cos \omega x + c_2 \sin \omega x$ with c_1 and c_2 being arbitrary constants.

The transmutation kernel K is a solution of a certain Goursat problem for the hyperbolic equation

$$\left(\frac{\partial^2}{\partial x^2} - q(x)\right) K(x,t) = \frac{\partial^2}{\partial t^2} K(x,t).$$

2 Construction of the transmutation kernel and new representations for solutions of the Sturm-Liouville equation

In spite of fundamental importance of the transmutation kernel K in the theory of linear differential equations, besides the method of successive approximations derived directly from the Goursat problem (see, e.g., [5]) very few attempts of its practical construction have been reported. In this relation we mention the paper [3] where analytic approximation formulas for the integral kernel were obtained and the recent publications [14], [15] where another procedure of analytical approximation was proposed.

To the difference of those previous results, in the recent paper [13] an exact representation for K in the form of a Fourier-Legendre series with explicit formulas for the coefficients was obtained. Suppose that $q \in W_2^{-1}[-b,b]$ (that is, q can be a piecewise continuous function, may have a singularity, e.g., $q(x) \sim c/x$, etc.). In this case $K(x,t)$ is an L_2-function. Under these conditions the following theorem was proved in [13].

Theorem 1 *The kernel K has the form*

$$K(x,t) = \sum_{n=0}^{\infty} \frac{\beta_n(x)}{x} P_n\left(\frac{t}{x}\right) \tag{2}$$

where for every $x \in [-b,b]$ the series converges with respect to t in the L_2-norm (if $q \in C[-b,b]$ the series converges uniformly),

$$\beta_n(x) = \frac{2n+1}{2}\left(\sum_{k=0}^{n} \frac{l_{k,n}\varphi_k(x)}{x^k} - 1\right),$$

 ISBN: 978-84-617-8694-7

with $l_{k,n}$ being the coefficient at x^k of the Legendre polynomial P_n, and φ_k being the so-called formal powers constructed as follows (see [8], [12]).

Definition 2 (Formal powers φ_k) *Let f be a solution of*

$$f'' - q(x)f = 0, \quad x \in [-b, b], \tag{3}$$

$$f(0) = 1, \quad f'(0) = 0.$$

Then $\{\varphi_k\}_{k=0}^{\infty}$ are defined by the equalities

$$\varphi_k = \begin{cases} fX^{(k)}, & k \text{ odd}, \\ f\widetilde{X}^{(k)}, & k \text{ even}, \end{cases}$$

where

$$X^{(0)} \equiv 1, \qquad X^{(n)}(x) = n \int_0^x X^{(n-1)}(s) \left(f^2(s)\right)^{(-1)^n} \mathrm{d}s,$$

and

$$\widetilde{X}^{(0)} \equiv 1, \qquad \widetilde{X}^{(n)}(x) = n \int_0^x \widetilde{X}^{(n-1)}(s) \left(f^2(s)\right)^{(-1)^{n-1}} \mathrm{d}s.$$

It is worth mentioning that φ_k are easily computable (at least numerically) in practice (see, e.g., [13] for additional details).

A representation for the kernel K leads to a representation for the solution of (1). Let $u(\omega, x)$ denote the solution of (1) satisfying the initial conditions

$$u(\omega, 0) = 1, \qquad u'(\omega, 0) = i\omega.$$

Then we have

$$u(\omega, x) = e^{i\omega x} + \int_{-x}^{x} K(x, t) e^{i\omega t} dt.$$

Substitution of (2) into the last integral gives us the equality [13]

$$u(\omega, x) = e^{i\omega x} + \sum_{n=0}^{\infty} \beta_n(x) \int_{-1}^{1} P_n(y)\, e^{i\omega x y} dy = e^{i\omega x} + \sum_{n=0}^{\infty} i^n \beta_n(x) j_n(\omega x)$$

where $j_n(z) = \sqrt{\frac{\pi}{2z}} J_{n+1/2}(z)$ are spherical Bessel functions. The series converges uniformly with respect to x.

Moreover, take $\omega \in \mathbb{R}$. Consider

$$K_N(x, t) = \sum_{n=0}^{N} \frac{\beta_n(x)}{x} P_n\left(\frac{t}{x}\right)$$

 ISBN: 978-84-617-8694-7

and

$$u_N(\omega,x)=e^{i\omega x}+\sum_{n=0}^{N}i^n\beta_n(x)j_n(\omega x),\quad x>0.$$

We have [13]

$$\begin{aligned}|u(\omega,x)-u_N(\omega,x)|&=\left|\int_{-x}^{x}\left(K(x,t)-K_N(x,t)\right)e^{i\omega t}dt\right|\\&\le\|K(x,\cdot)-K_N(x,\cdot)\|_{L_2(-x,x)}\left\|e^{i\omega t}\right\|_{L_2(-x,x)}\\&=\varepsilon_N(x)\sqrt{2x}\end{aligned}$$

—independent of ω. More generally, for any $\omega\in\mathbb{C}$, $\omega\neq 0$ belonging to the strip $|\mathrm{Im}\,\omega|\le C$, $C\ge 0$,

$$|u(\omega,x)-u_N(\omega,x)|\le\varepsilon_N(x)\frac{\sinh(Cx)}{C}.$$

This ω-independence of the approximation accuracy was shown in [13] to give a very fast and efficient method for computing large sets of eigendata with a nondeteriorating accuracy. In [17] it was generalized onto perturbed Bessel equations, and in [16] onto Sturm-Liouville equations.

Another representation for the kernel K and as a corollary for the solutions of (1) was obtained in [9]. Consider the following extension of the transmutation kernel K,

$$\widetilde{K}(x,t)=\begin{cases}K(x,t), & -x\le t\le x,\\ 0, & -\infty<t<-x.\end{cases}$$

Then

$$u(\omega,x)=e^{i\omega x}+\int_{-\infty}^{x}\widetilde{K}(x,y)e^{i\omega y}dy=e^{i\omega x}\left(1+\int_0^{\infty}\widetilde{K}(x,x-t)e^{-i\omega t}dt\right).$$

Consider

$$\widetilde{K}(x,x-t)=\mathbf{k}(x,t)e^{-t}.$$

The function $\mathbf{k}(x,\cdot)$ then belongs to the space $L_2\left(0,\infty;e^{-t}\right)$ equipped with the scalar product $\langle u,v\rangle:=\int_0^{\infty}u(t)\overline{v}(t)e^{-t}dt$. Thus, $\mathbf{k}(x,\cdot)$ admits a Fourier-Laguerre expansion convergent in the corresponding norm,

$$\mathbf{k}(x,t)=\sum_{n=0}^{\infty}a_n(x)L_n(t).$$

The kernel has the form [9]

$$\widetilde{K}(x,y)=\sum_{n=0}^{\infty}a_n(x)L_n(x-y)e^{-(x-y)},$$

 ISBN: 978-84-617-8694-7

with the coefficients a_n defined by

$$a_n(x) = \sum_{j=0}^{n} (-1)^j \left(\varphi_j(x) - x^j\right) \sum_{k=j}^{n} (-1)^k \frac{n!}{(n-k)!k!(k-j)!j!} x^{k-j}. \tag{4}$$

The solution $u(\omega, x)$ has the form [9]

$$u(\omega, x) = e^{i\omega x} \left(1 + \sum_{n=0}^{\infty} a_n(x) \frac{(i\omega)^n}{(1+i\omega)^{n+1}}\right). \tag{5}$$

The following estimate is valid for any $\omega \in \mathbb{R}$,

$$|u(\omega, x) - u_N(\omega, x)| \le \varepsilon_N(x), \tag{6}$$

where

$$u_N(\omega, x) := e^{i\omega x} \left(1 + \sum_{n=0}^{N} a_n(x) \frac{(i\omega)^n}{(1+i\omega)^{n+1}}\right),$$

and $\varepsilon_N(x)$ is a nonnegative function independent of ω and such that $\varepsilon_N(x) \to 0$ for all $x \in [-b, b]$ when $N \to \infty$. More generally,

$$|u(\omega, x) - u_N(\omega, x)| \le \frac{\varepsilon_N(x) e^{-\operatorname{Im}\omega x}}{\sqrt{1 - 2\operatorname{Im}\omega}}, \qquad \text{when } \operatorname{Im}\omega < 1/2.$$

Consideration of another extension of the transmutation kernel defined by

$$\widetilde{K}(x, y) := \begin{cases} K(x, y) & \text{when } x \in [-b, b] \text{ and } y \in [-x, x] \\ 0 & \text{otherwise.} \end{cases}$$

leads to the following series expansion

$$\widetilde{K}(x, y) = \sum_{n=0}^{\infty} c_n(x) H_n(y) e^{-y^2}$$

where H_n stands for an Hermite polynomial of order n and the coefficients c_n are to be found. Note that

$$\int_{-\infty}^{\infty} \widetilde{K}(x, y) H_n(y) dy = \sqrt{\pi} n! 2^n c_n(x).$$

Hence

$$c_n(x) = \frac{1}{\sqrt{\pi} n! 2^n} \int_{-x}^{x} K(x, y) H_n(y) dy = \frac{1}{\sqrt{\pi} n! 2^n} \sum_{k=0}^{n} h_{k,n} \left(\varphi_k(x) - x^k\right) \tag{7}$$

 ISBN: 978-84-617-8694-7

where $h_{k,n}$ denotes the coefficient of x^k from the Hermite polynomial $H_n(x)$.

This leads to another representation for the solution of (1),

$$\begin{aligned} u(\omega,x) &= e^{i\omega x} + \int_{-\infty}^{\infty} \widetilde{K}(x,y) e^{i\omega y} dy \\ &= e^{i\omega x} + \sum_{n=0}^{\infty} c_n(x) \int_{-\infty}^{\infty} H_n(y) e^{i\omega y} e^{-y^2} dy \\ &= e^{i\omega x} + \sqrt{\pi} e^{-\frac{\omega^2}{4}} \sum_{n=0}^{\infty} c_n(x) \, (i\omega)^n \, . \end{aligned}$$

Consider the partial sum

$$u_N(\omega,x) = e^{i\omega x} + \sqrt{\pi} e^{-\frac{\omega^2}{4}} \sum_{n=0}^{N} c_n(x) \, (i\omega)^n \, .$$

Then it is easy to see that

$$|u(\omega,x) - u_N(\omega,x)| \le \pi^{\frac{1}{4}} e^{\frac{(\operatorname{Im}\omega)^2}{2}} \varepsilon_N(x)$$

which means that the truncation error is uniformly bounded in any strip $|\operatorname{Im}\omega| \le C$.

3 Applications to PDEs

Exact representations of the transmutation kernel lead to numerous applications for partial differential equations admitting certain symmetry. In particular, let us consider the possibility to obtain complete systems of solutions. For example, application of the transmutation operator T to a complete system of harmonic functions leads to a complete system of solutions of the equation

$$(\Delta - q(x)) \, u(x,y) = 0. \tag{8}$$

Indeed,

$$(\Delta - q(x)) \, T = T \Delta$$

whenever the domain of interest is such that the integration in T is well defined.

Example Harmonic polynomials ($\operatorname{Re} z^n$ and $\operatorname{Im} z^n$) can be written in the form

$$\begin{aligned} p_0(x,y) &= 1, \\ p_{2m+1}(x,y) = \operatorname{Re} z^{m+1} &= \sum_{\text{even } k=0}^{m} (-1)^{\frac{k}{2}} \binom{m+1}{k} x^{m+1-k} y^k, \qquad m \ge 0, \\ p_{2m}(x,y) = \operatorname{Re}(iz^m) &= \sum_{\text{odd } k=1}^{m} (-1)^{\frac{k+1}{2}} \binom{m}{k} x^{m-k} y^k, \qquad m \ge 1. \end{aligned}$$

 ISBN: 978-84-617-8694-7

Since

$$T : x^k \mapsto \varphi_k(x),$$

the following functions are the images of p_m under the action of T and represent a complete system of solutions of (8)

$$\begin{aligned} u_0(x,y) &= f(x), \\ u_{2m+1}(x,y) &= \sum_{\text{even } k=0}^{m+1} (-1)^{\frac{k}{2}} \binom{m+1}{k} \varphi_{m+1-k}(x) y^k, \qquad m \geq 0, \\ u_{2m}(x,y) &= \sum_{\text{odd } k=1}^{m} (-1)^{\frac{k+1}{2}} \binom{m}{k} \varphi_{m-k}(x) y^k, \qquad m \geq 1. \end{aligned}$$

Other complete systems of solutions can be obtained.

Example The method of fundamental solutions (discrete sources) (see, e.g., [1], [6]) can be extended onto equations with variable coefficients. Consider the fundamental solution for the Laplace operator on the plane

$$\log|x + iy - (\eta + i\xi)| = \log|x - Z|\,.$$

Application of T leads to the following integrals

$$T\left[\log|x - Z|\right] = \log|x - Z| + \sum_{n=0}^{\infty} \frac{\beta_n(x)}{x} \int_{-x}^{x} P_n\left(\frac{t}{x}\right) \log|t - Z|\; dt.$$

Their calculation gives us the image of the fundamental solution in the form

$$\begin{aligned} T\left[\log|x - Z|\right] = \log|x - Z| + \beta_0(x)\,\mathrm{Re}\left(\log\left((Z + x)\,(Z - x)\right) + 2Q_1\left(\frac{Z}{x}\right)\right) \\ + 2\sum_{n=1}^{\infty} \frac{\beta_n(x)}{2n+1}\,\mathrm{Re}\left(Q_{n+1}\left(\frac{Z}{x}\right) - Q_{n-1}\left(\frac{Z}{x}\right)\right) \end{aligned}$$

where Q_n are Legendre functions of the second kind.

Similar considerations can be applied to systems arising in hypercomplex analysis (see, e.g., [7]) and may lead to extensions of well known methods based on monogenic polynomials or other complete systems of solutions onto systems with variable coefficients [10], [11] important, e.g., in electromagnetic theory and quantum physics.

1 Introduction

The question about solvability of particular forms of ordinary or partial differential equations is naturally the first to ask. But the answer is unfortunately not easily acquired. By transforming a particular differential equation into a fixed point equation, we can reduce the difficulty of the question and we can apply various fixed point theorems to the equation and obtain the desired affirmative answer.

In discrete time domain, major considerations turn to the difference equations and generating functions. While in the latter one, under which we shall be considering mainly for this chapter, the system is usually represented by differential equations. It might be more influential to talk about the inclusion problems if a set-valued system is to be analyzed.

The very first and fundamental dynamical system is known now a days under the term Cauchy problem. It is represented with the following C^1 initial-valued problem:

$$\begin{cases} u'(t) = f(t, u(t)), \\ u(0) = u_0. \end{cases}$$

In this case, we assume that $f : [0,T] \times R \to R$ is continuous and $u \in C^1([0,T])$. From simple calculus, we may see that this system is equivalent to the following integral equation:

$$u(t) = u_0 + \int_{[0,t]} f(s, u(s))ds. \tag{1}$$

This is where Banach got the idea to solve the problem. He proposed his famous fixed point theorem known today as the contraction principle in 1922 [4], mainly to solve this Cauchy problem effectively. Recall that the contraction principle states that if X is a complete metric space and $T : X \to X$ is Lipschitz continuous with constant $0 < L < 1$, then T has a unique fixed point.

Let us consider a map $\Lambda : C^1([0,T]) \to C^1([0,T])$ given by

$$\Lambda(u)(t) := u_0 + \int_{[0,t]} f(s, u(s))ds, \quad \forall u \in C^1([0,T]),\ \forall t \in [0,T].$$

One can notice that $u \in C^1([0,T])$ solves Cauchy problem (1) if and only if it is a fixed point of Λ. With this approach, by considering $C^1([0,T])$ with the supremum norm $\|\cdot\|_\infty$, we end up with the local solvability of the Cauchy problem.

2 Example of Fixed Point Theory

Let X be a nonempty set and $\lambda \in (0, \infty)$. Due to the disparity of the arguments, a function $\omega : (0, \infty) \times X \times X \to [0, \infty]$ will be written as $\omega_\lambda(x, y) = \omega(\lambda, x, y)$ for all $\lambda > 0$ and $x, y \in X$. [8] Let X be a nonempty set. A function $\omega : (0, \infty) \times X \times X \to [0, \infty]$ is called a *metric modular* on X is satisfies the following condition: for all $x, y, z \in X$,

(i) $\omega_\lambda(x, y) = 0$ for all $\lambda > 0$ if and only if $x = y$;

(ii) $\omega_\lambda(x, y) = \omega_\lambda(y, x)$ for all $\lambda > 0$;

(iii) $\omega_{\lambda+\mu}(x, y) \leq \omega_\lambda(x, z) + \omega_\mu(z, y)$ for all $\lambda, \mu > 0$.

If, instead of (i), we have only the following condition:

(i′) $\omega_\lambda(x, x) = 0$ for all $\lambda > 0$, then ω called a *(metric) pseudomodular* on X.

If $\omega_\lambda(x, y) = \omega(x, y)$ does not depend on $\lambda > 0$ and has only finite values, then the axioms (i)-(iii) mean that ω is a metric on X if (i) is replaced by (i′).

We next give another route of investigation of fixed point inclusion in modular metric spaces. This time, we shall apply more on analytical assumptions. Briefly said, we shall use the contractivity assumptions (see [16]).

2.1 Fixed point theorems in modular metric spaces

In this section, we prove new existence theorems of fixed points for contraction mappings in modular metric spaces. Let ω be a metric modular on X, X_ω be a modular metric space induced by ω and $T : X_\omega \to X_\omega$ be an arbitrary mapping. A mapping T is called a *contraction* if, for all $x, y \in X_\omega$ and $\lambda > 0$, there exists $0 \leq k < 1$ such that

$$\omega_\lambda(Tx, Ty) \leq k\omega_\lambda(x, y). \tag{2}$$

Let X_ω be a complete modular metric space and $T : X_\omega \to X_\omega$ be a contraction mapping. Assume that there exists $x_0 \in X$ such that $\omega_\lambda(x_0, Tx_0) < \infty$ for all $\lambda > 0$. Then T has a fixed point in $x_* \in X_\omega$ and the sequence $\{T^n x_0\}$ converges to x_*. Moreover, if, $z \in F(X_\omega)$, where $F(X_\omega)$ is a set of fixed point of T such that $\omega_\lambda(x_*, z) < \infty$ for all $\lambda > 0$, then $x_* = z$. Let x_0 be an element in X_ω such that $\omega_\lambda(x_0, Tx_0) < \infty$ for all $\lambda > 0$ and we write $x_1 = Tx_0$, $x_2 = Tx_1 = T^2 x_0$ and, in general, $x_n = Tx_{n-1} = T^n x_0$ for all $n \geq 1$. Observe that

$$\omega_\lambda(T^n x_0, T^{n+1} x_0) \leq k\omega_\lambda(T^{n-1} x_0, T^n x_0) \leq \cdots \leq k^n \omega_\lambda(x_0, Tx_0) < \infty$$

 ISBN: 978-84-617-8694-7

for all $n \geq 1$. Assume that n and m are two positive integers with $m > n$. Then we have

$$\begin{aligned}
\omega_\lambda(T^n x_0, T^m x_0) &\leq \omega_{\frac{\lambda}{m-n}}(T^n x_0, T^{n+1} x_0) + \omega_{\frac{\lambda}{m-n}}(T^{n+1} x_0, T^{n+2} x_0) \\
&\quad + \cdots + \omega_{\frac{\lambda}{m-n}}(T^{m-1} x_0, T^m x_0) \\
&\leq (k^n + k^{n+1} + \cdots + k^{m-1}) \omega_{\frac{\lambda}{m-n}}(x_0, Tx_0) \\
&\leq (k^n + k^{n+1} + \cdots) \omega_{\frac{\lambda}{m}}(x_0, Tx_0) \\
&= k^n 1 - k\omega_{\frac{\lambda}{m}}(x_0, Tx_0).
\end{aligned}$$

Since $\omega_\lambda(x_0, Tx_0) < \infty$ for all $\lambda > 0$, we deduce that, for any $\epsilon > 0$, $\omega_\lambda(T^n x_0, T^m x_0) < \epsilon$ for all $m > n > N$ with sufficiently large. Thus $\{T^n x_0\}$ is a Cauchy sequence and hence it converges to some $x_* \in X_\omega$ by the completeness of X_ω. Observe further that

$$\omega_\lambda(x_*, Tx_*) \leq \omega_{\frac{\lambda}{2}}(x_*, T^n x_0) + k\omega_{\frac{\lambda}{2}}(T^{n-1} x_0, x_*).$$

Letting $n \to \infty$, we have $\omega_\lambda(x_*, Tx_*) = 0$ for all $\lambda > 0$. Therefore, x_* is a fixed point of f.

Let z be another fixed points of T such that $\omega_\lambda(x_*, z) < \infty$ for all $\lambda > 0$, then we get

$$\omega_\lambda(x_*, z) \quad = \omega_\lambda(Tx_*, Tz) \leq \quad k\omega_\lambda(x_*, z)$$

for all $\lambda > 0$. Since $0 \leq k < 1$, we get $\omega_\lambda(x, z) = 0$ for all $\lambda > 0$, which implies that $x_* = z$. This completes the proof.

Theorem 2.1 *Let X_ω be a complete modular metric space and $T : X_\omega \to X_\omega$ be a contraction mapping. Suppose that $x^* \in X_\omega$ is a fixed point of T, $\{\varepsilon_n\}$ is a sequence of positive numbers for which $\lim_{n\to\infty} \varepsilon_n = 0$ and $\{y_n\} \subseteq X_\omega$ satisfies*

$$\omega_\lambda(y_{n+1}, Ty_n) \leq \varepsilon_n$$

for all $\lambda > 0$. Then $n \to \infty \lim y_n = x^*$.

Let $y_0 = x \in X_\omega$. Then we observe that, for all $m \geq 1$,

$$\begin{aligned}
\omega_\lambda(T^{m+1} x, y_{m+1}) &= \omega_{\frac{\lambda \cdot m}{m}}(T^{m+1} x, y_{m+1}) \\
&\leq \omega_{\frac{\lambda \cdot (m-1)}{m}}(T^{m+1} x, Ty_m) + \omega_{\frac{\lambda}{m}}(Ty_m, y_{m+1}) \\
&\leq k\omega_{\frac{\lambda \cdot (m-1)}{m}}(T^m x, y_m) + \varepsilon_m \\
&\leq k\omega_{\frac{\lambda \cdot (m-2)}{m}}(T^m x, Ty_{m-1}) + kw_{\frac{\lambda}{m}}(Ty_{m-1} x, y_m) + \varepsilon_m \\
&\leq k^2 \omega_{\frac{\lambda \cdot (m-2)}{m}}(T^{m-1} x, y_{m-1}) + k\varepsilon_{m-1} + \varepsilon_m \\
&\quad \vdots \\
&\leq \sum_{i=0}^{m} k^{m-i} \varepsilon_i
\end{aligned} \tag{3}$$

 ISBN: 978-84-617-8694-7

for all $\lambda > 0$. Thus we get

$$\begin{aligned} \omega_\lambda(y_{m+1}, x^*) &\leq \omega_{\frac{\lambda}{2}}(y_{m+1}, T^{m+1}x) + \omega_{\frac{\lambda}{2}}(T^{m+1}x, x^*) \\ &\leq \sum_{i=0}^{m} k^{m-i}\varepsilon_i + \omega_{\frac{\lambda}{2}}(T^{m+1}x, x^*). \end{aligned} \tag{4}$$

Next, we claim that $m \to \infty \lim \omega_\lambda(y_{m+1}, x^*) = 0$ for all $\lambda > 0$. Now, let $\varepsilon > 0$. Since $n \to \infty \lim \varepsilon_n = 0$, there exists a positive integer N such that, for all $m \geq N$, $\varepsilon_m \leq \varepsilon$. Thus we have

$$\begin{aligned} \sum_{i=0}^{m} k^{m-i}\varepsilon_i &= \sum_{i=0}^{N} k^{m-i}\varepsilon_i + \sum_{i=N+1}^{m} k^{m-i}\varepsilon_i \\ &\leq k^{m-N} \sum_{i=0}^{N} k^{N-i}\varepsilon_i + \varepsilon \sum_{i=N+1}^{m} k^{m-i}. \end{aligned} \tag{5}$$

Taking limit as $m \to \infty$ in (5), we have

$$\lim_{m\to\infty} \sum_{i=0}^{m} k^{m-i}\varepsilon_i = 0. \tag{6}$$

Since x^* is a fixed point of T, using Theorem 2.1, it follows that the sequence $\{T^n x\}$ converge to x^*. This implies that

$$\lim_{m\to\infty} \omega_{\frac{\lambda}{2}}(T^{m+1}x, x^*) = 0 \tag{7}$$

for all $\lambda > 0$. Therefore, from (4), (6) and (7), we have

$$\lim_{m\to\infty} \omega_\lambda(y_{m+1}, x^*) = 0 \tag{8}$$

for all $\lambda > 0$, which implies that $\lim_{n\to\infty} y_n = x^*$. This completes the proof.

Theorem 2.2 *Let X_ω be a complete modular metric space and, for any $x^* \in X_\omega$, define*

$$B_\omega(x^*, \gamma) := \{x \in X_\omega : \omega_\lambda(x, x^*) \leq \gamma, \ \forall \lambda > 0\}.$$

If $T : B_\omega(x^*, \gamma) \to X_\omega$ is a contraction mapping with

$$\omega_{\frac{\lambda}{2}}(Tx^*, x^*) \leq (1 - k)\gamma \tag{9}$$

for all $\lambda > 0$, where $0 \leq k < 1$, then T has a fixed point in $B_\omega(x^*, \gamma)$.

By Theorem 2.1, we only prove that $B_\omega(x^*, \gamma)$ is complete and $Tx \in B_\omega(x^*, \gamma)$ for all $x \in B_\omega(x^*, \gamma)$. Suppose that $\{x_n\}$ is a Cauchy sequence in $B_\omega(x^*, \gamma)$, and then also $\{x_n\}$ is a Cauchy sequence in X_ω. Since X_ω is complete, there exists $x \in X_\omega$ such that

$$\lim_{n\to\infty} \omega_{\frac{\lambda}{2}}(x_n, x) = 0 \tag{10}$$

 ISBN: 978-84-617-8694-7

for all $\lambda > 0$. Since, for each $n \geq 1$, $x_n \in B_\omega(x^*, \gamma)$, using the property of a metric modular, we get

$$\begin{aligned} \omega_\lambda(x^*, x) &\leq \omega_{\frac{\lambda}{2}}(x^*, x_n) + \omega_{\frac{\lambda}{2}}(x_n, x) \\ &\leq \gamma + \omega_{\frac{\lambda}{2}}(x_n, x^*) \end{aligned} \tag{11}$$

for all $\lambda > 0$. It follows the inequalities (10) and (11) that $w_\lambda(x^*, x) \leq \gamma$, which implies that $x \in B_\omega(x^*, \gamma)$. Therefore, $\{x_n\}$ is a convergent sequence in $B_\omega(x^*, \gamma)$ and also $B_\omega(x^*, \gamma)$ is complete.

Next, we prove that $Tx \in B_\omega(x^*, \gamma)$ for all $x \in B_\omega(x^*, \gamma)$. Let $x \in B_\omega(x^*, \gamma)$. From the inequalities (9), the contraction of T and the notion of a metric modular, we have

$$\begin{aligned} \omega_\lambda(x^*, Tx) &\leq \omega_{\frac{\lambda}{2}}(x^*, Tx^*) + \omega_{\frac{\lambda}{2}}(Tx^*, Tx) \\ &\leq (1-k)\gamma + k\omega_{\frac{\lambda}{2}}(x^*, x) \\ &\leq (1-k)\gamma + k\gamma \\ &= \gamma. \end{aligned}$$

Therefore, $Tx \in B_\omega(x^*, \gamma)$. This completes the proof.

Theorem 2.3 *Let X_ω be a complete modular metric space and T be a self-mapping on X_ω satisfying*

$$\omega_\lambda(Tx, Ty) \leq k(\omega_{2\lambda}(Tx, x) + \omega_{2\lambda}(Ty, y)) \tag{12}$$

for all $x, y \in X_\omega$, where $k \in \left[0, \frac{1}{2}\right)$. Assume that there exists $x_0 \in X$ such that $\omega_\lambda(x_0, Tx_0) < \infty$ for all $\lambda > 0$. Then T has a fixed point in $x \in X_\omega$ and the sequence $\{T^n x_0\}$ converges to x. Moreover, if, $z \in F(X_\omega)$, where $F(X_\omega)$ is a set of fixed point of T such that $\omega_\lambda(x_*, z) < \infty$ for all $\lambda > 0$, then $x_* = z$.

Let x_0 be an element in X_ω such that $\omega_\lambda(x_0, Tx_0) < \infty$ for all $\lambda > 0$. We write $x_1 = Tx_0, x_2 = Tx_1 = T^2x_0$ and, in general, $x_n = Tx_{n-1} = T^n x_0$ for all $n \geq 1$. If $Tx_{n_0-1} = Tx_{n_0}$ for some $n_0 \geq 1$, then $Tx_{n_0} = x_{n_0}$. Thus x_{n_0} is a fixed point of T.

Suppose that $Tx_{n-1} \neq Tx_n$ for all $n \geq 1$. For any $k \in [0, \frac{1}{2})$, we have

$$\begin{aligned} \omega_\lambda(x_{n+1}, x_n) &= \omega_\lambda(Tx_n, Tx_{n-1}) \\ &\leq k(\omega_{2\lambda}(Tx_n, x_n) + \omega_{2\lambda}(Tx_{n-1}, x_{n-1})) \\ &\leq k(\omega_\lambda(x_{n+1}, x_n) + \omega_\lambda(x_n, x_{n-1})) \end{aligned} \tag{13}$$

for all $\lambda > 0$ and $n \geq 1$. Hence we have

$$\omega_\lambda(x_{n+1}, x_n) \leq \tfrac{k}{1-k}\omega_\lambda(x_n, x_{n-1}) \tag{14}$$

for all $\lambda > 0$ and $n \geq 1$. Put $\beta := \frac{k}{1-k}$. Since $k \in (0, \frac{1}{2})$, we get $\beta \in (0, 1)$ and hence

$$\begin{aligned} \omega_\lambda(x_{n+1}, x_n) &\leq \beta\omega_\lambda(x_n, x_{n-1}) \\ &\leq \beta^2\omega_\lambda(x_{n-1}, x_{n-2}) \\ &\vdots \\ &\leq \beta^n\omega_\lambda(x_1, x_0) \end{aligned} \tag{15}$$

 ISBN: 978-84-617-8694-7

for all $\lambda > 0$ and $n \geq 1$. Similar to the proof of Theorem 2.1, we can conclude that $\{x_n\}$ is a Cauchy sequence and, by the completeness of X_ω there exists a point $x \in X_\omega$ such that $x_n \to x$ as $n \to \infty$. By the property of a metric modular and the inequality (12), we have

$$\begin{aligned} \omega_\lambda(Tx, x) &\leq \omega_{\frac{\lambda}{2}}(Tx, Tx_n) + \omega_{\frac{\lambda}{2}}(Tx_n, x) \\ &\leq k(\omega_\lambda(Tx, x) + \omega_\lambda(Tx_n, x_n)) + \omega_{\frac{\lambda}{2}}(Tx_n, x) \\ &\leq k(\omega_\lambda(Tx, x) + \omega_{\frac{\lambda}{2}}(Tx_n, x) + \omega_{\frac{\lambda}{2}}(x, x_n)) + \omega_{\frac{\lambda}{2}}(Tx_n, x) \\ &= k(\omega_\lambda(Tx, x) + \omega_{\frac{\lambda}{2}}(x_{n+1}, x) + \omega_{\frac{\lambda}{2}}(x, x_n)) + \omega_{\frac{\lambda}{2}}(x_{n+1}, x) \end{aligned} \tag{16}$$

for all $\lambda > 0$ and $n \geq 1$. Taking $n \to \infty$ in the inequality (16), we obtain

$$\omega_\lambda(Tx, x) \leq k\omega_\lambda(Tx, x). \tag{17}$$

Since $k \in [0, \frac{1}{2})$, we have $Tx = x$. Thus x is a fixed point of T.

Let z be another fixed points of T such that $\omega_\lambda(x_*, z) < \infty$ for all $\lambda > 0$, then we get

$$\begin{aligned} \omega_\lambda(x, z) &= \omega_\lambda(Tx, Tz) \\ &\leq k(\omega_{2\lambda}(Tx, x) + \omega_{2\lambda}(Tz, z)) \\ &= 0 \end{aligned}$$

for all $\lambda > 0$, which implies that $x = z$. This completes the proof.

2.2 Kannan's set valued contraction mappings

Before we could stomp into the main exploration, we need the following knowledge of metric modular of sets.

We write (X) to denote the set of all nonempty closed subsets of X. For any subset $A \subset X_w$ and point $x \in X$, we denote $w_t(x, A) := \inf_{y \in A} w_t(x, y)$.

Given two subsets $A, B \in (X)$, define $w_t(A, B) := \sup_{x \in A} w_t(x, B)$. Most importantly, the Hausdorff-Pompieu metric modular $W_t(A, B) := \max\{w_t(A, B), w_t(B, A)\}$.

Let (X, w) be a modular metric space, $A \in (X)$, and $x \in X$. Then,

$\mathrm{w}_t(x, A) = 0$ for all $t > 0 \iff x \in A$.

Given a modular metric space (X, w) and an arbitrary point $x \in X$. A subset $Y \subset X$ is said to be *reachable* from x if

$$\inf_{y \in Y} \sup_{t>0} w_t(x, y) = \sup_{t>0} w_t(x, Y) < \infty.$$

This lemma gives a simple criterion of when the reachability holds. Let (X, w) be a modular metric space with w being l.s.c., $Y \subset X$ a nonempty compact subset. For a point

 ISBN: 978-84-617-8694-7

$x \in X$, if either $\inf_{y\in Y} \sup_{t>0} w_t(x,y) < \infty$ or $\sup_{t>0} w_t(x,Y) < \infty$, then Y is reachable from x.

The following lemma is essential in showing the solvability of fixed point inclusion for contractivity condition. Suppose that $Y, Z \in (X)$ are nonempty and $z \in Z$. If Y is reachable from z, then for each $\varepsilon > 0$, there exists a point $y_\varepsilon \in Y$ such that $\sup_{t>0} w_t(z, y_\varepsilon) \leq \sup_{t>0} W_t(X,Y) + \varepsilon$.

Now, we state the notion of the contraction and the Kannan's contraction. Make note that these two concepts are not generalizations of one another.

Let (X, w) be a modular metric space. A set-valued operator $F : X \rightrightarrows X$ is said to be a *contraction* if there exists a constant $k \in [0, 1)$ such that

$$W_t(Fx, Fy) \leq k w_t(x, y), \tag{18}$$

for all $t > 0$ and $x, y \in X$. If k is restricted in $[0, \frac{1}{2})$ and the equation above is replaced with the following inequality:

$$W_t(F(x), F(y)) \leq k[w_t(x, F(x)) + w_t(y, F(y))].$$

Then, we call F a *Kannan's contraction.*

Now, we present the main existence theorems (see [7]).

Theorem 2.4 *Let (X, w) be a complete modular metric space with w being l.s.c., and F a contraction on X having compact values with contraction constant k. Suppose that there exists a pair of points $x_0 \in X$ and $x_1 \in F(x_0)$ with the following properties:*

1. *the set $\{x_0, x_1\}$ is bounded,*
2. *$F(x_1)$ is reachable from x_1.*

Then, F has at least one fixed point.

3 Fractional Integral Inclusion

In this section, we shall illustrate some use of the theorems presented in the previous section. We focus on applications to integral inclusion.

For another application, we investigate the solvability of the fractional inclusion problem in which we include also the delayed behaviors. Fractional integral is used in describing various natural phenomena, and also in electric transmission, travelling waves, fluid dynamics, and in control engineering

It is natural to raise the situation of set-valued integral, which proved itself for its importance in practical applications especially in engineering. In 1965, Aumann [2] introduced

 ISBN: 978-84-617-8694-7

the concept of definite set-valued integral on real line and Euclidean spaces. Suppose that Ψ is an interval $[0,T]$, where $T>0$. Let $F:\Psi\to 2^{\mathbb{R}}$ be a set-valued operator. A selection of F is the function $f:\Psi\to\mathbb{R}\cup\{\pm\infty\}$ such that $f(t)\in F(t)$ a.e. $t\in\Psi$. We write F to denote the set containing all integrable selections of F. According to Aumann [2], the set-valued integral is determined by the operator in the following:

$$ {}_{\Psi}F(t)dt := \left\{ \int_{\Psi} f(t)dt \ ; \ f\in F \right\}, $$

i.e., the set of the integrals of integrable selections of F.

On the other hand, in elementary calculus, one deals with derivatives and integrals, including the higher-integer-order iterations. Here, in fractional integral, one looks at a broader concept where the real-order iteration is taken into account. There are many approaches to study this kind of extensions. In our context, we shall use the classical notion introduced by Riemann and Liouville, the latter of which is the first one to point out the possibility of fractional calculus in 1832. Given a function $f\in L^1(\Psi,\mu)$, the fractional integral of order $\alpha>0$ is given by

$$ {}^{\alpha}_{\Psi}f(t)dt := \frac{1}{\Gamma(\alpha)}\int_{\Psi}(t-\tau)^{\alpha-1}f(\tau)d\tau. $$

Naturally, we may further consider the following fractional integral:

$$ {}^{\alpha}_{\Psi}F(t)dt := \left\{ {}^{\alpha}_{\Psi}f(t)dt \ ; \ f\in F \right\}. $$

In this particular subsection, we shall use notations a bit differently than those of earlier sections. This is due to conventional uses of variables and functions that is common to integral and differential equations.

Suppose that Ψ is the interval mentioned in the previous section. Let us assume throughout the section that the real line $\mathbb{R}$ is equipped with the metric modular

$$ \omega^{\mathbb{R}}_{\lambda}(x,y) := \frac{1}{1+\lambda}\left|x-y\right|, $$

for $\lambda>0$ and $x,y\in\mathbb{R}$. Thus, for the space $C(\Psi)$ of all continuous (in $\omega^{\mathbb{R}}$-topology) real-valued functions on Ψ, we shall use the metric modular

$$ \omega^{C(\Psi)}_{\lambda}(\varphi,\psi) := \sup_{t\in\Psi}\omega^{\mathbb{R}}_{\lambda}(\varphi(t),\psi(t)), $$

for $\lambda>0$ and $\varphi,\psi\in C(\Psi)$. Note that both $\omega^{\mathbb{R}}$ and $\omega^{C(\Psi)}$ satisfy the Fatou's property. Also note that the set $\mathbb{R}$ is second countable, i.e., it has a countable base, w.r.t. $\omega^{\mathbb{R}}$-topology. Moreover, it is clear that the set $\{\varphi,\psi\}$ is bounded w.r.t. $\omega^{C(\Psi)}$, for any $\varphi,\psi\in C(\Psi)$. Suppose that $F:\Psi\times\mathbb{R}\to 2^{\mathbb{R}}$ is a set-valued operator with nonempty compact values,

 ISBN: 978-84-617-8694-7

and $u \in C(\Psi)$. We shall use the following notation to explain the collection of integrable selections:

$$S_F(u) := \left\{ f \in L^1(\Psi, \mu) \; ; \; f(t) \in F(t, u(t)) a.e.t \in \Psi \right\}.$$

It is clear that $S_F(u)$ is closed. Next, for each $i \in \{0, 1, \cdots, N\}$, $N \in \mathbb{N}$, assume that $\beta_i : \Psi \to \mathbb{R}$ is continuous, and $\tau_i : \Psi \to \mathbb{R}_+$ is a function with $\tau_i(t) \leq t$. We write $B := \max_{0 \leq i \leq N} \sup_{t \in \Psi} \beta_i(t)$. The main aim of this section is to consider the fractional integral inclusion:

$$u(t) - \sum_{i=0}^{N} \beta_i(t) u(t - \tau_i(t)) \in {}^{\alpha}_{\Psi} F(t, u(t)) dt, \quad \alpha \in (0, 1]. \quad (FII)$$

In the above inclusion, the summation here is interpreted to be the delay term.

We shall define a set-valued operator $\Lambda : C(\Psi) \to 2^{C(\Psi)}$ by

$$\Lambda(u) := \left\{ w \in C(\Psi) \; ; \; w(t) = \sum_{i=0}^{N} \beta_i(t) u(t - \tau_i(t)) + {}^{\alpha}_{\Psi} f(t, u(t)) dt, \quad f \in S_F(u) \right\}.$$

Note here that for any $\varphi \in C(\Psi)$, we have $\Lambda(\varphi)$ is reachable from φ w.r.t. $\omega^{C(\Psi)}$.
To restrict the operator Λ with some nice property, we assume that $S_F(u)$ is nonempty.

Lemma 3.1 *The operator Λ given above is compact valued if $S_F(u)$ is nonempty.*

For the proof, we shall show the compactness by its sequential characterization. Suppose that $u \in C(\Psi)$, and (w_n) is an arbitrary sequence in $\Lambda(u)$. By definition, there corresponds a convergent sequence (f_n) in $S_F(u) \subset F(\cdot, u(\cdot))$ satisfying

$$w_n(t) = \sum_{i=0}^{N} \beta_i(t) u(t - \tau_i(t)) + {}^{\alpha}_{\Psi} f_n(t, u(t)) dt.$$

The conclusion is then followed.

Now, we shall state now the solvability result for the problem (FII). It is clear that $u \in C(\Psi)$ solves (FII) if and only if u is a fixed point of Λ.

Theorem 3.2 *Suppose that F defined above is compact-valued, and $S_F(u)$ is nonempty. Assume further that*

1. *for any given $u, v \in C(\Psi)$ and a selection $f \in S_F(u)$ of F, there corresponds a function $f' \in S_F(v)$ such that*

$$\begin{cases} \omega^{\mathbb{R}}_{\lambda}(f(t, u(t)), f'(t, v(t))) = \omega^{\mathbb{R}}_{\lambda}(f_1(t, u(t)), F(t, v(t))), \\ \omega^{\mathbb{R}}_{\lambda}(f(t, u(t)), f'(t, v(t))) \leq L \omega^{C(\Psi)}_{\lambda}(u, v), \end{cases}$$

for all $t \in \Psi$;

 ISBN: 978-84-617-8694-7

2. $\frac{(N+1)B\Gamma(\alpha)+LT^{\alpha}}{\Gamma(\alpha)} < 1.$

Then, Λ has a fixed point.

For each $u, v \in C(\Psi)$, we may choose, from the assumption, functions f_1, f_2 such that

$$\begin{cases} f_1 \in S_F(u), \\ f_2 \in S_F(v), \\ \omega_{\lambda}^{\mathbb{R}}(f_1(t,u(t)), f_2(t,v(t))) = \omega_{\lambda}^{\mathbb{R}}(f_1(t,u(t)), F(t,v(t))), \\ \omega_{\lambda}^{\mathbb{R}}(f_1(t,u(t)), f_2(t,v(t))) \leq L\omega_{\lambda}^{C(\Psi)}(u,v), \end{cases}$$

for each $t \in \Psi$. Consider the two functions $w_1 \in \Lambda(u)$ and $w_2 \in \Lambda(v)$, respectively as follows:

$$\begin{cases} w_1(t) := \sum_{i=0}^{N} \beta_i(t)u(t-\tau_i(t)) +_{\Psi}^{\alpha} f_1(t,u(t))dt, \\ w_2(t) := \sum_{i=0}^{N} \beta_i(t)v(t-\tau_i(t)) +_{\Psi}^{\alpha} f_2(t,v(t))dt. \end{cases}$$

Now, consider the following computation:

$$\begin{aligned} &\omega_{\lambda}^{\mathbb{R}}(w_1(t), w_2(t)) \\ &\leq \sum_{i=0}^{N} \beta_i(t)\omega_{\lambda}^{\mathbb{R}}(u(t-\tau_i(t)), v(t-\tau_i(t)) \\ &\quad +\omega_{\lambda}^{C(\Psi)}({}_{\Psi}^{\alpha}f_1(t,u(t))dt, {}_{\Psi}^{\alpha} f_2(t,u(t))dt) \\ &\leq (N+1)B\omega_{\lambda}^{C(\Psi)}(u,v) +_{\Psi}^{\alpha} \omega_{\lambda}^{\mathbb{R}}(f_1(t,u(t)), f_2(t,v(t))) \\ &\leq (N+1)B\omega_{\lambda}^{C(\Psi)}(u,v) + \frac{LT^{\alpha}}{\Gamma(\alpha)}\omega_{\lambda}^{C(\Psi)}(u,v) \\ &= \left[\frac{(N+1)B\Gamma(\alpha)+LT^{\alpha}}{\Gamma(\alpha)}\right]\omega_{\lambda}^{C(\Psi)}(u,v). \end{aligned}$$

It follows that

$$\Omega_{\lambda}^{C(\Psi)}(\Lambda(u), \Lambda(v)) \leq \left[\frac{(N+1)B\Gamma(\alpha)+LT^{\alpha}}{\Gamma(\alpha)}\right]\omega_{\lambda}^{C(\Psi)}(u,v).$$

The proof ends here by applying Theorem 2.4.

4 Conclusion

Taking into account several classes of nonlinear differential equations, either ordinary or partial, we may design the corresponding nonlinear operator to suit a particular class of the original problem with the most important property; the fixed point of the corresponded

 ISBN: 978-84-617-8694-7

operator solves the original problem. By imposing some conditions on the involved differential equations, we can show equivalence between the original differential equation and the transformed fixed point equation. Moreover, we can also derive the solution existence from appropriate fixed point theorems and finally obtain the desired results.

Using simple conditions on the underlying space and operators, we show existence of fixed point for such operators. We emphasize results in nonlinear spaces and on generalized contractive operators. Finally, we deliver an equivalence existence theorems for certain classes of nonlinear system of differential equations. Our results cover both initial valued and boundary value problems.

Abstract

In this paper, we introduce a new iterative method for finding the common zeros of two accretive operators in the framework of uniformly smooth Banach spaces. Also, we will prove the strong convergence theorems for the iterative algorithms and give the example of the main theorems. The results of this paper are improvements and extensions of the corresponding ones announced by many others.

Key words: common zeros, accretive operator

1 Introduction

Let E be a real Banach space, C a nonempty closed convex subset of E, and Let $f : C \to C$ be a mapping. Recall that f is said to be contractive if there exists a constant $\sigma \in (0, 1)$ such that $\|fx - fy\| \leq \sigma\|x - y\|$ for all $x, y \in C$, f is said to be nonexpansive if $\sigma = 1$.

A point $x \in C$ is a fixed point of T provided $Tx = x$. Denote by $F(T)$ the set of fixed points of T; that is, $F(T) = \{x \in C : Tx = x\}$. It is assumed throughout the paper that T is a nonexpansive mapping such that $F(T) \neq \emptyset$.

For an operator $A : E \to 2^E$, we denote its domain, range and graph as follows:

$$D(A) = \{x \in E : Ax \neq \emptyset\},$$
$$\mathcal{R}(A) = \cup\{Az : z \in D(A)\},$$

and

$$G(A) = \{(x, y) \in E \times E : x \in D(A), y \in Ax\},$$

respectively. The inverse A^{-1} ofA is defined by $x \in A^{-1}y$, if and only if $y \in Ax$.

Let E be a real Banach space with norm $\|\cdot\|$ and let E^* be its dual. The value of $f \in E^*$ at $x \in E$ will be denoted by $\langle x, f\rangle$. A Banach space E is said to be strictly convex if $\frac{\|x+y\|}{2} < 1$ for all $x, y \in E$ with $\|x\| = \|y\| = 1$. It is also said to be uniformly convex if $\lim_{n\to\infty} \|x_n - y_n\| = 0$. for any two sequences $\{x_n\}, \{y_n\}$ in E such that $\|x\| = \|y\| = 1$. and $\lim_{n\to\infty} \frac{\|x+y\|}{2} = 1$.

The (normalized) duality mapping J from E into the family of nonempty (by Hahn Banach theorem) weak-star compact subsets of its dual E is defined by

$$J(x) = \{f \in E^* : \langle x, f\rangle = \|x\|^2 = \|f\|^2\}$$

for each $x \in E$, where $\langle\cdot, \cdot\rangle$ denotes the generalized duality pairing.

The norm of E is said to be Gâteaux differentiable if

$$\lim_{t\to 0} \frac{\|x + ty\| - \|x\|}{t}$$

exists for each x, y in its unit sphere $U = \{x \in E : \|x\| = 1\}$.

A closed convex subset C of a Banach space E is said to have the fixed point property for nonexpansive mappings if every nonexpansive mapping of a nonempty closed convex subset D of C into itself has a fixed point in D.

A subset C of Banach space E is called a retract of E if there is a continuous mapping Q from E onto C such that $Qx = x$ for all $x \in C$. We call such Q a retraction of E onto C. It follows that if a mapping Q is a retraction, then $Qy = y$ for all y in the range of Q. A retraction Q is said to be sunny if $Q(Qx + t(xQx)) = Qx$ for all $x \in E$ and $t \geq 0$. If a sunny

 ISBN: 978-84-617-8694-7

retraction Q is also non expansive, then C is said to be a sunny non expansive retract of E [1]. In a smooth Banach space E, it is known (cf. [1], p. 48) that $Q : C \to D$ is a sunny nonexpansive retraction if and only if the following condition holds:

$$\langle x - Q(x), J(z - Q(x))\rangle \leq 0,\ x \in C,\ z \in D.$$

We know that the sunny non expansive retract mapping form Hilbert space H onto a closed convex subset $C \subset H$ is metric projection and we use P_C to denote the metric projection from H onto C.

An accretive operator A in a Banach space X is said to satisfy the range condition if $\overline{D(A)} \subset \mathcal{R}(I + \lambda A)$ for all $\lambda > 0$, where $\overline{D(A)}$ denotes the closure of the domain of A. We know that for an accretive operator A which satisfies the range condition, $A^{-1}0 = F(J_\lambda^A)$ for all $\lambda > 0$.

2 Preliminaries

Lemma 2.1. *[2] A Banach space E is uniformly smooth if and only if the duality map J is the single-valued and norm-to-norm uniformly continuous on bounded sets of E.*

Lemma 2.2. *[3] Let E be a Banach space. Then for every $x, y \in E$, we have*

$$\|x + y\|2 \leq \|x\|^2 + 2\langle y, j(x + y)\rangle,$$

for all $j(x + y) \in J(x + y)$.

Lemma 2.3. *[4] Let E be a Banach space and let Let $A : D(A) \to 2^E$ be an accretive operator. For $\lambda > 0, \mu > 0$ and $x \in E$, we have $J_\lambda x = J_\mu(\frac{\mu}{\lambda}x + (1 - \frac{\mu}{\lambda})J_\lambda x)$, where $J_\lambda = (I + \lambda A)^{-1}$ and $J_\mu = (I + \mu A)^{-1}$.*

Lemma 2.4. *[6] Let $\{a_n\}$ be a sequence of nonnegative real numbers such that $a_{n+1} \leq (1 - t_n)a_n + b_n + c_n$, where $\{c_n\}$ is a sequence of nonnegative real numbers, $\{t_n\} \subset (0, 1)$ and $\{b_n\}$ is a number sequence. Assume that $\sum_{n=0}^{\infty} t_n = \infty, \limsup_{n\to\infty} \frac{b_n}{t_n} \leq 0$, and $\sum_{n=0}^{\infty} c_n < \infty$. Then $\lim_{n\to\infty} a_n = 0$.*

Theorem 2.5. *[7] Let E be a reflexive Banach space with a uniformly Gâteaux differentiable norm such that every weakly compact convex subset of E has fixed point property for nonexpansive mappings. Let C be a closed convex subset of E and T non expansive mapping from C into itself with $F(T) \neq \emptyset$. Then $\{x_t\}$ defined by $x_t = tfx_t + (1 - t)Tx_t$ where $f : C \to C$ is a contraction mapping and $t \in (0, 1)$, converges strongly to a point in $x^* \in F(T)$ which satisfies $Q_{F(T)}f(x^*) = x^*$.*

 ISBN: 978-84-617-8694-7

3 Main results

Theorem 3.1. *Let C be a nonempty closed convex subset of a uniformly convex and uniformly smooth Banach space X. Let $A : D(A) \subseteq C \to 2^X$ and $B : D(B) \subseteq C \to 2^X$ be accretive operators such that $\Omega = A^{-1}0 \cap B^{-1}0 \neq \emptyset$, $\overline{D(A)} \subset C \subset \bigcap_{r>0} \mathcal{R}(I + rA)$ and $\overline{D(B)} \subset C \subset \bigcap_{r>0} \mathcal{R}(I + rB)$. Let $f : C \to C$ be a contrative mapping with contractive constant $\sigma \in (0, 1)$. Let $\{x_n\}$ be a sequence generated by $x_0 \in C$ and*

$$\begin{cases} y_n = \beta_n x_n + (1 - \beta_n) J^A_{\lambda_n} x_n \\ x_{n+1} = \alpha_n f(x_n) + (1 - \alpha_n) J^B_{\gamma_n} y_n, \end{cases} \tag{1}$$

where the sequence $\{\alpha_n\}, \{\beta_n\}$, and $\{\gamma_n\}$ satisfy the following restrictions:

(i) $\lim_{n\to\infty} \alpha_n = 0, \sum_{n=1}^{\infty} \alpha_n = \infty$;

(ii) $\lambda_n \geq \epsilon, \gamma_n \geq \epsilon$ *for some* $\epsilon > 0$ *and for all* n,
$\sum_{n=0}^{\infty} |\alpha_{n+1} - \alpha_n| < \infty$, $\sum_{n=0}^{\infty} |\beta_{n+1} - \beta_n| < \infty$, $\sum_{n=0}^{\infty} |\lambda_{n+1} - \lambda_n| < \infty$,
and $\sum_{n=0}^{\infty} |\gamma_{n+1} - \gamma_n| < \infty$.

Then $\{x_n\}$ converges strongly to $w = Qf(w)$, where Q is a sunny nonexpansive retraction of E onto Ω.

Theorem 3.2. *Let H be a Hilbert space. Let $A : H \to 2^H$ and $B : H \to 2^H$ be maximal monotone operators such that $S = A^{-1}0 \cap B^{-1}0 \neq \emptyset$. Let $f : C \to C$ be a contrative mapping with contractive constant $\sigma \in (0, 1)$. Let $\{x_n\}$ be a sequence generated by* (1)*, where the sequence $\{\alpha_n\}, \{\beta_n\}$, and $\{\gamma_n\}$ satisfy the following restrictions:*

(i) $\lim_{n\to\infty} \alpha_n = 0, \sum_{n=1}^{\infty} \alpha_n = \infty$;

(ii) $\lambda_n \geq \epsilon, \gamma_n \geq \epsilon$ *for some* $\epsilon > 0$ *and for all* n,
$\sum_{n=0}^{\infty} |\alpha_{n+1} - \alpha_n| < \infty$, $\sum_{n=0}^{\infty} |\beta_{n+1} - \beta_n| < \infty$, $\sum_{n=0}^{\infty} |\lambda_{n+1} - \lambda_n| < \infty$,
and $\sum_{n=0}^{\infty} |\gamma_{n+1} - \gamma_n| < \infty$.

Then $\{x_n\}$ converges strongly to $P_S f(w^*) = w^*$, where $P_S : H \to S$ is a metric projection from H onto S.

Abstract

The primary goal of this work is to introduce two Steffensen-like adaptive with memory methods with the highest efficiency indices. In the existing methods, to improve the convergence order applying the with memory concept, it has only been focused on the current and previous iterations. However, it is possible to improve the accelerators, considering date from the first to the current iterations. Therefore, we achieve superior convergence orders and obtain as high as possible efficiency indices. These are the main contributions of this work. *Key words: Nonlinear equations, iterative methods, Steffensen-like method, with memory methods, adaptive methods.*

1 Introduction

One of the most important subjects in developing numerical algorithms is to establish optimal algorithms with economic complexity. For example, developing iterative methods for approximating zero(s) of a given nonlinear equation falls within this matter, and many studies have been devoted to it [3, 2]. Inspired by this, we will set up two adaptive Steffensen-like with memory methods in which they are improvement of existing methods. To our knowledge, these kinds of adaptive methods have not been studied in the literature.

Truab developed the first method with memory from Steffensen's method [4] as following [2]:

$$\begin{cases} w_k = x_k + \gamma_k\, f(x_k), \\ x_{k+1} = x_k - \frac{f(x_k)}{f[x_k, w_k]}, \qquad k = 0, 1, 2, \cdots, \\ \gamma_{k+1} = -\frac{1}{N_1'(x_{k+1})}, \end{cases} \tag{1.1}$$

 ISBN: 978-84-617-8694-7

where x_0 and γ_0 are given initially suitable, and $N_1(t) = f(x_{k+1}) + (t - x_{k+1})f[x_{k+1}, x_k]$ is the linear Newton's interpolation. The convergence order of the with memory method (1.1) is $1 + \sqrt{2} \approx 2.414$. Also, Džunnić and Petković improved Traub's idea, introducing a better accelerator [3]:

$$\begin{cases} w_k = x_k + \gamma_k f(x_k), \\ x_{k+1} = x_k - \frac{f(x_k)}{f[x_k, w_k]}, \qquad k = 0, 1, 2, \cdots, \\ \gamma_{k+1} = -\frac{1}{N_2'(x_{k+1})}, \end{cases} \tag{1.2}$$

where x_0 and γ_0 are given initially suitable, and $N_2(t)$ is the Netwon's interpolation polynomial given by

$$N_2(t) = f(x_{k+1}) + (t - x_{k+1})f[x_{k+1}, w_k] + (t - x_{k+1})(t - w_k)f[x_{k+1}, w_k, x_k].$$

The convergence order of the with memory method (1.2) is $1 + \sqrt{4} = 3$. Moreover, Džunić added another parameter to the Steffensen's method and obtained a more efficient with memory method [3]:

$$\begin{cases} x_{k+1} = x_k - \frac{f(x_k)}{f[x_k, w_k] + \lambda_k f(w_k)}, \qquad k = 0, 1, 2, \cdots, \\ \gamma_{k+1} = -\frac{1}{N_2'(x_{k+1})}, \\ w_{k+1} = x_{k+1} + \gamma_{k+1} f(x_{k+1}), \\ \lambda_{k+1} = \frac{-N_3''(w_{k+1})}{2N_3'(w_{k+1})}, \end{cases} \tag{1.3}$$

where x_0, γ_0, and λ_0 are given initially suitable. This method has convergence order $\frac{3+\sqrt{17}}{2} \approx 3.56$.

Remark 1.1. *If γ and λ are constants, then the methods (1.2) and (1.3) are without memory methods with convergence order two with the following error equations, respectively:*

$$e_{k+1} = c_2\big(1 + \gamma f'(\alpha)\big)e_k^2 + O(e_k^3), \tag{1.4}$$

and

$$e_{k+1} = \big(c_2 + \lambda\big)\big(1 + \gamma f'(\alpha)\big)e_k^2 + O(e_k^3). \tag{1.5}$$

In this work, we will attempt to carry two adaptive with memory methods out from (1.2) and (1.3) which are superior to them. To this purpose, we first update the accelerator γ_k in each iteration using available data not only from the current and previous iterations, but also from the current and *all* previous iterations (adaptive concept). We prove that this method has convergence order 3.4 using the same function evaluations as (1.2), so its efficiency index is much better as well. Similarly, we derive another adaptive with memory for (1.3) which acquires convergence order 3.9 using the same functional evaluations. Therefore, this method is better not only than our adaptive method with one accelerator, but also than all the existing methods.

 ISBN: 978-84-617-8694-7

2 Developing adaptive with memory methods

This section deals with two new adaptive methods with memory. To this end, we modify and extend methods (1.2) and (1.3) in such a way that they consider all previous information to attain as high as possible convergence order without any new functional evaluation. In this manner we use the adaptive idea which has not been considered to our best knowledge.

2.1 Mono accelerator adaptive with memory method

In (1.2), to update accelerator γ_k in each iteration, we only use the information from the current and previous iterations and reach the convergence order 3. However, as the procedure goes ahead it is possible to use the old information not only from the current and previous step, but also from the current and all the previous steps. In other words, we wish to apply the adaptive idea to construct the new methods with memory. Accordingly, we introduce the following new adaptive method with memory

$$\begin{cases} w_k = x_k + \gamma_k f(x_k), \\ x_{k+1} = x_k - \frac{f(x_k)}{f[x_k, w_k]}, \\ \gamma_{k+1} = -\frac{1}{N'_{2k+2}(x_{k+1})}, \end{cases} \qquad k = 0, 1, 2, \cdots, \tag{2.1}$$

where x_0 and γ_0 are given initially suitable, and $N_{2k+2}(t)$ is Netwon's interpolation polynomial of degree $2k+2$ at the points $x_{k+1}, w_k, x_k, \ldots, w_0, x_0$.

Referring to the Error Equation (1.4), it is observed that if $1 + \gamma f'(\alpha) = 0$, then convergence order of the method without memory (2.1), for a moment suppose γ_k is fix, increases. Since α is unknown, we cannot suppose $\gamma = -1/f'(\alpha)$. Even if we assumed that α was known, we could not use it to evaluate $f'(\alpha)$, since it increases the functional evaluation, and optimality of the methods is destroyed. It is assumed that the sequence $\{x_k\}$ converges to α. Moreover, f' is at least continuous, so $\lim f'(x_k) = f'(\alpha)$ as $k \to \infty$. Thus, we can use $N'_{2k+2}(x_k)$ instead of $f'(x_k)$ to our mission, i.e., $\gamma_k = -1/N'_{2k+2}(x_k)$. To discuss the convergence order of (2.1), we need:

Lemma 2.1. *If* $\gamma_k = -1/N'_{2k+2}(x_k)$, *and* $\lambda_{k+1} = \frac{-N''_{2k+2}(w_{k+1})}{2N'_{2k+2}(w_{k+1})}$ *then*

$$1 + \gamma f'(\alpha) \sim \prod_{i=0}^{k-1} e_{w,i} e_i, \quad c_2 + \lambda \sim \prod_{i=0}^{k-1} e_{w,i} e_i, \tag{2.2}$$

where $e_i = x_i - \alpha$ *and* $e_{w,i} = w_i - \alpha$.

Theorem 2.2. *Let the initial approximation* x_0 *be sufficiently close to the zero* α *of* f, R *and* p *denote the convergence order of the sequences* $\{x_k\}$ *and* $\{w_k\}$, *respectively, generated*

 ISBN: 978-84-617-8694-7

by the adoptive method with memory (2.1). Then, we have

$$\begin{cases} R^k p - R^k - (p+1)\sum_{i=0}^{k-1} R^i = 0, \\ R^{k+1} - R^k - (p+1)\sum_{i=0}^{k-1} R^i = 0. \end{cases} \tag{2.3}$$

Proof. We can assume

$$e_{k+1} \sim e_k^R. \tag{2.4}$$

Hence,

$$e_{k+1} \sim (e_{k-1}^R)^R = e_{k-1}^{R^2}. \tag{2.5}$$

Inductively,

$$e_{k+1} \sim e_0^{R^{k+1}}. \tag{2.6}$$

Similarly, we have

$$e_{w,k} \sim e_k^p = (e_{k-1}^R)^p = e_{k-1}^{Rp}. \tag{2.7}$$

Thus,

$$e_{w,k} \sim e_0^{R^k p}. \tag{2.8}$$

By (2.4) and (2.7), Lemma 2.1 results

$$1 + \gamma f'(\alpha) \sim e_0^{(p+1)\sum_{i=0}^{k-1} R^i}. \tag{2.9}$$

On the other hand, since $e_{w,k} \sim (1 + \gamma f'(\alpha))e_k$ and $e_{k+1} \sim (1 + \gamma f'(\alpha))e_k^2$, taking into account (2.9), then

$$e_{w,k} \sim e_0^{R^k + (p+1)\sum_{i=0}^{k-1} R^i}, \tag{2.10}$$

and

$$e_{k+1} \sim e_0^{2R^k + (p+1)\sum_{i=0}^{k-1} R^i}. \tag{2.11}$$

From (2.8)-(2.10) and (2.6)-(2.11), we conclude that

$$e_0^{R^k p} \sim e_0^{R^k + (p+1)\sum_{i=0}^{k-1} R^i}, \tag{2.12}$$

$$e_0^{R^{k+1}} \sim e_0^{R^k + (p+1)\sum_{i=0}^{k-1} R^i}. \tag{2.13}$$

Consequently,

$$\begin{cases} R^k p - R^k - (p+1)\sum_{i=0}^{k-1} R^i = 0, \\ R^{k+1} - R^k - (p+1)\sum_{i=0}^{k-1} R^i = 0. \end{cases} \tag{2.14}$$

 ISBN: 978-84-617-8694-7

2.2 Bi accelerators adaptive with memory method

We now introduce bi accelerators adaptive with memory method. Since much of the details are similar to the descriptions of (2.1) we confine ourselves to repeat them.

$$\begin{cases} x_{k+1} = x_k - \frac{f(x_k)}{f[x_k,w_k]+\lambda_k f(w_k)}, & k = 0,1,2,\cdots, \\ \gamma_{k+1} = -\frac{1}{N'_{2k+2}(x_{k+1})}, \\ w_{k+1} = x_{k+1} + \gamma_{k+1} f(x_{k+1}), \\ \lambda_{k+1} = \frac{-N''_{2k+3}(w_{k+1})}{2N'_{2k+3}(w_{k+1})}, \end{cases} \tag{2.15}$$

Also, we have

Theorem 2.3. *Let the initial approximation x_0 be sufficiently close to the zero α of f, R and p denote the convergence order of the sequences $\{x_k\}$ and $\{w_k\}$, respectively, generated by the adoptive method with memory (2.15). Then, we have*

$$\begin{cases} R^k p - R^k - (p+1)\sum_{i=0}^{k-1} R^i = 0, \\ R^{k+1} - 2R^k - 2(p+1)\sum_{i=0}^{k-1} R^i = 0. \end{cases} \tag{2.16}$$

The proof is similar in spirit to the Theorem 2.2.

Abstract

This research was motivated by a real technological problem of vibrations of bodies hanging on chains or ropes in tubes or spaces limited by walls or other bodies. The system has two degrees of freedom. Its movement is governed by a set of nonlinear ordinary differential equations. As the main result it is shown that the system exhibits regular, irregular and chaotic patterns for suitable choice of parameters.

Key words: mechanical model, chaos tests, bifurcation, vibration
MSC 2000: 34H20, 34H10, 37N30

1 Introduction

The research area of multi-pendulum systems are widely studied by many authors form different point of view under several motivations. In [3] a control system combining input shaping and feedback is developed for double-pendulum systems subjected to external disturbances. The authors in [2] proposed a parametrically excited pendulum with irrational

nonlinearity which comprises a simple pendulum linked by a linear spring under base excitation. The dynamics of hybrid systems and analytical dynamics of discrete material particle system containing creep elements described by fractional order derivatives, is presented in [4] (see references therein for more literature about dynamics of multi-pendulum systems and solutions of the system equations).

The main aim of the present paper is to derive equations of motions of the double-pendulum with both sided walls where collisions of the pendulums occur. The pendulums movement analysis is performed in dependence of the sliding motion excitation frequency; movements are showing periodic and also chaotic patterns that are supported by bifurcation diagrams and 0-1 test for chaos.

2 Mathematical model of the system

The investigated system consists of a driving body and of the upper and lower pendulums see Fig. 1). The driving body performs sliding motion in the horizontal direction which excites the movement of both pendulums. The motion of the pendulums is limited by two vertical walls. All bodies included the walls are considered as absolutely rigid, some elasticity is taken into account in the contact area between the pendulums and the walls.

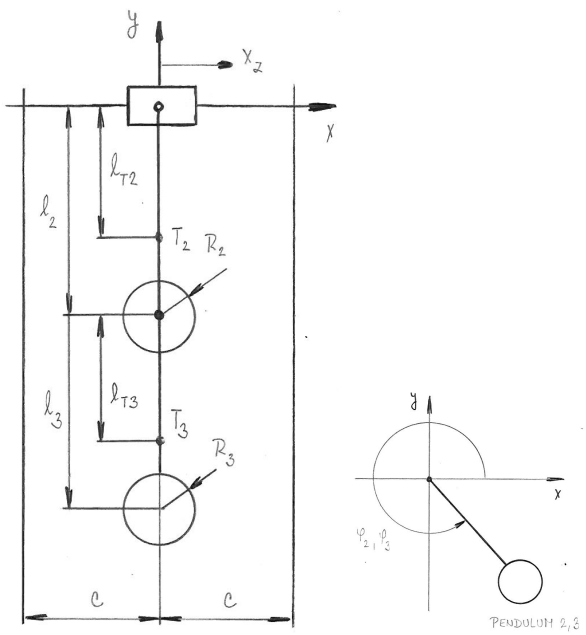

Figure 1: Model of investigated system

 ISBN: 978-84-617-8694-7

The task of the present research is to investigate the influence of the systems parameters, especially the frequency of kinematic excitation on a character of the double-pendulum movement. The investigated system has two degrees of freedom. Its instantaneous position is defined by two generalized coordinates:

φ_2 - angel of rotation of the upper pendulum,

φ_3 - angel of rotation of the lower pendulum.

The equations of motion have been derived using the Lagrange equations of the second kind:

$$\begin{aligned}(J_{T2}+m_2l_{T2}^2+m_3l_2^2)\ddot{\varphi}_2+A\ddot{\varphi}_3 &= Q_2+B\dot{\varphi}_3^2-m_2gl_{T2}\cos\varphi_2-m_3gl_2\cos\varphi_3+\\ &\quad +m_2\ddot{x}_zl_{T2}\sin\varphi_2+m_3\ddot{x}_zl_2\sin\varphi_2\\ (J_{T3}+m_3l_{T3}^2)\ddot{\varphi}_3+A\ddot{\varphi}_2 &= Q_3-B\dot{\varphi}_2^2+\\ &\quad +m_3\ddot{x}_zl_{T3}\sin\varphi_3-m_3gl_{T3}\cos\varphi_3\end{aligned} \tag{1}$$

where

$$A = m_3l_2l_{T3}(\sin\varphi_2\sin\varphi_3+\cos\varphi_2\cos\varphi_3) \tag{2}$$

$$B = m_3l_2l_{T3}(\cos\varphi_2\sin\varphi_3-\sin\varphi_2\cos\varphi_3) \tag{3}$$

$$Q_2 = -(F_{R2}+F_{R3})l_2\sin\varphi_2+Q_{D2} \tag{4}$$

$$Q_3 = -F_{R3}l_3\sin\varphi_3+Q_{D3} \tag{5}$$

$$Q_{D2} = (b_2+b_3)\dot{x}_zl_2\sin(\varphi_2)-(b_2+b_3)l_2^2\dot{\varphi}_2-b_3l_2l_3(\sin\varphi_2\sin\varphi_3+\cos\varphi_2\cos\varphi_3)\dot{\varphi}_2 \tag{6}$$

$$Q_{D3} = b_3\dot{x}_zl_3\sin(\varphi_3)-b_3l_3^2\dot{\varphi}_3-b_3l_2l_3(\sin\varphi_2\sin\varphi_3+\cos\varphi_2\cos\varphi_3)\dot{\varphi}_2 \tag{7}$$

here $(\dot{})$ and $(\ddot{})$ denote the first and second derivative with respect to time, respectively.

The impact forces F_{R2} and F_{R3} are defined as follows:

$$F_{R2}=\begin{cases}\text{if } x_{R2M}<-c & \text{then } F_{R2}=-k_c(x_{R2M}+c),\\ \text{if } x_{R2P}>c & \text{then } F_{R2}=-k_c(x_{R2P}-c),\\ \text{else } F_{R2}=0,\end{cases} \tag{8}$$

$$F_{R3}=\begin{cases}\text{if } x_{R3M}<-c & \text{then } F_{R3}=-k_c(x_{R3M}+c),\\ \text{if } x_{R3P}>c & \text{then } F_{R3}=-k_c(x_{R3P}-c),\\ \text{else } F_{R3}=0,\end{cases} \tag{9}$$

where

$$x_{R2M} = x_z-r_2+l_2\cos\varphi_2, \tag{10}$$

$$x_{R2P} = x_z+r_2+l_2\cos\varphi_2, \tag{11}$$

$$x_{R3M} = x_z-r_3+l_2\cos\varphi_2+l_3\cos\varphi_3, \tag{12}$$

$$x_{R3P} = x_z+r_3+l_2\cos\varphi_2+l_3\cos\varphi_3. \tag{13}$$

 ISBN: 978-84-617-8694-7

The horizontal position position of the driving body is given by

$$x_z(t) = A\,(1 - \mathrm{e}^{-\alpha t})\sin(\omega t) \tag{14}$$

where A is the amplitude of the kinematic excitation of the upper pendulum, α the run up coefficient and ω stands for the excitation frequency. All system parameters are summarized in Table 1.

At the beginning the system takes the equilibrium position, which corresponds to the initial conditions:

$$\begin{aligned}
\varphi_2(0) &= 3/2\,\pi, && (15)\\
\varphi_3(0) &= 3/2\,\pi, && (16)\\
\dot{\varphi}_2(0) &= 0, && (17)\\
\dot{\varphi}_3(0) &= 0. && (18)\\
& && (19)
\end{aligned}$$

3 Main results

Main results were reached by numerical simulations of (1) for system parameters summarized in Table 1 where the excitation frequency ω was changed form 1 rad s^{-1} to 100 rad s^{-1}.

The character of movement of the double-pendulum system is analyzed in detail. The first observations are shown in bifurcation diagrams Figs. 2, where periodic as well as chaotic movements are visible for suitable choices of ω. Here, x_2 and x_3 stand for the horizontal displacements of the upper and lower pendulum ball centers, respectively. In this figures it is also marked that for the excitation frequencies $\omega \in [1, 10] \cup \{25,\ 28,\ 29\}$ there are no contacts of the upper pendulum with the wall (marked green) and for $\omega \in [11, 24] \cup \{26,\ 27\} \cup [30, 100]$ collision of the upper pendulum with the wall occurs; and for the excitation frequencies $\omega \in [1, 10]$ there are no contacts of the lower pendulum with the wall (marked green) and for $\omega \in [11, 100]$ collision of the upper pendulum with the wall occurs.

It is visible form phase portraits (see Figs. 3, 4 and 5) that the movement is periodic and also chaotic and its character is changing with increasing excitation frequency.

The output parameter of the 0-1 test for chaos can acquire only one of the values 0 or 1 which correspond to the regular and chaotic motions, respectively. More details can be found in [1]. The results of the 0-1 test for the range of investigated frequencies are shown in Fig. 6 where chaotic and non-chaotic movements were detected. Note, that the result of 0-1 test coincides with bifurcation diagrams in Fig. 2 and with phase diagrams, for special choices of the excitation frequencies shown in Figs. 3, 4 and 5.

4 Conclusions

In this paper, a mechanical system with two degrees of freedom has been investigated and the movement of the double-pendulum with both sides walls was analyzed. This model was inspired by a real problem of bodies hanging on chains or ropes in tubes or spaces limited by walls or stops.

The equation of movement was solved numerically using Runge-Kutta method implemented as *ode45* solver in Matlab.

It was observed that the movement is showing regular and also chaotic patterns for suitable choice of parameters, mainly excitation frequency of the driving body played a key role here. For this purpose 0-1 test for chaos and bifurcation diagrams were used.

Abstract

In this paper we will investigate one certain application of polynomial 2-surfaces possessing the polynomial area element in the Minkowski space $\mathbb{R}^{3,1}$, where they coincide with the so called MOS surfaces (i.e., medial surface transforms with rational domain boundaries). We formulate an efficient algorithm for Hermite interpolation by MOS surfaces and apply the developed method to the construction of branching pieces which occur during the operation of rational skinning. We recall that when branched skins of systems of spheres are constructed then the envelopes of suitable two-parametric systems of spheres must be considered. MOS surfaces are presented as especially suitable candidates for modelling these shapes because they provide not only rational envelopes but also all offsets of these envelopes are rational.

Key words: Medial surface transforms; MOS surfaces; rational envelopes; skinning

1 Introduction

We continue with the investigation of modelling parts of branched skins using special medial surface transforms yielding rational envelope surfaces. We recall that the operation of skinning can be considered as a certain analogy to the well-known interpolation of point data sets, which is a problem often solved in geometric modelling, see [7]. For us it is a construction of a G^k/C^k continuous interpolation surface of an ordered sequence of spatial shapes, in particular of spheres/balls. Due to its technical importance, skinning has

 ISBN: 978-84-617-8694-7

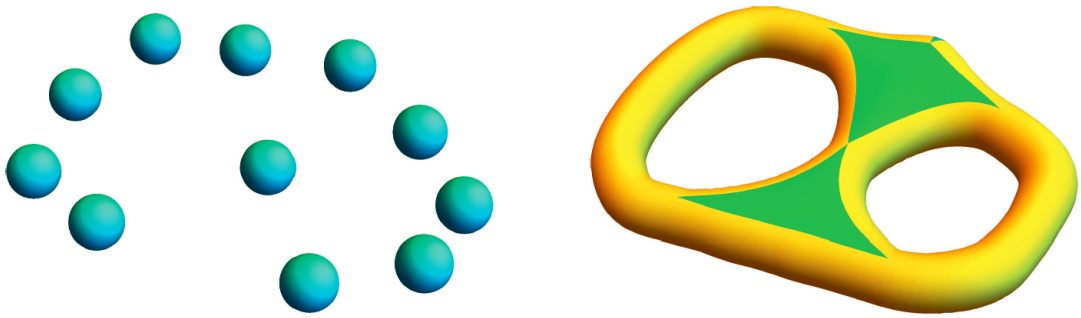

Figure 1: Branched skin of a system of spheres Σ in 3D containing a triangular and quadrangular branching element (green).

attracted the researchers in recent years and one can find a growing number of articles on this subject, see e.g. [14, 9, 1].

The problem of skinning can be identified in various situations, maybe the best known is the application in computer animation. Computing skins of a system of spheres/balls in 3D appears further for instance in the area of computational chemistry or molecular biology when surface meshes for molecular models are supposed to be generated. In a discrete sense, skinning can be considered as a part of the problem of computing envelopes of families of spheres using the cyclographic mapping [12, 13]. Skinning is closely related to representing shapes with the help of the associated medial axis/surface transforms [4, 11] and the theory of canal surfaces [10, 6].

When constructing the skin of spheres in the linear configuration then finding the solution is relatively mastered. However the problem is more complicated when branching of skins is allowed. Branching in this sense means that there exists a sphere which is connected via the skin with more than two neighbouring spheres. In these scenarios, the rational envelopes of suitable two-parameter systems of spheres must be thoroughly investigated and functional algorithms for interpolations with them must be designed. By utilizing polynomial MOS surfaces, we present a simple method for computing pieces of rational branched skins of a system of spheres/balls in 3D. We present MOS surfaces as very suitable candidates for modelling these parts as they give not only rational envelopes but also rational offsets of these envelopes.

2 Branched skins of systems of spheres

Using the method from [9], we consider a given sequence of spheres $\Sigma = \{S_1, S_2, \ldots, S_n\}$, admissible as defined in [1]. The goal is to construct a smooth spline surface $\mathcal{S}(\Sigma)$ skinning

 ISBN: 978-84-617-8694-7

this system. We will admit not only linear sequences of input spheres but also more complicated cases. In particular, we plan to focus on configurations when branched skins are designed and when special branching elements shall be constructed, cf. Fig. 1.

If we construct the skin of spheres in some linear configuration, $\mathcal{S}(\Sigma)$ consists of the following elements: (i) parts of S_i obtained as the differences of S_i and the spherical caps determined by the contact circles; (ii) surfaces smoothly joining two consecutive spheres S_{i-1} and S_i along prescribed contact circles, e.g. parts of canal surfaces, see Fig. 1 and we refer also to [2] for more details. These scenarios are quite sufficiently solved in the literature. However, the problem is significantly more complicated when branching of skins is allowed and new challenges dealing with new types of elements must be discussed.

When branching of skins occurs then two types of situations must be discussed. Either, branching takes place on a particular sphere and then the skin consists again of the elements of type (i) and (ii) only. Or, a joining part between more than two spheres is needed then an element of a new type must be constructed. In this case, the rational envelopes of suitable two-parameter systems of spheres must be investigated in more detail. We recall that this problem was suitably solved in [2] devoted to study of rational envelope (RE) surfaces, where formulated efficient algorithms for G^1 data interpolation using RE surfaces were applied also to rational skinning. Using the recent results from [3] we present polynomial MOS surfaces as shapes especially suitable for modelling rational branching elements. The extra-feature of these newly constructed elements is that they guarantee also the rationality of their offsets. This is a main contribution of the designed method.

3 Medial surface transforms yielding rational envelopes

Let be given a spatial domain $\Omega \subset \mathbb{R}^3$ and the family of all inscribed spheres partially ordered with respect to inclusion of the associated balls. The *medial surface* (MS) of Ω is the set of all centers $(x,y,z)^\top \in \mathbb{R}^3$ of maximal inscribed spheres and the *medial surface transform* (MST) of Ω is obtained by appending the corresponding sphere radius r to the MS, i.e., it consists of the points $(x,y,z,r)^\top$ in the four-dimensional Minkowski space $\mathbb{R}^{3,1}$.

Let a medial surface transform $\mathbf{x}(u,v) = (x,y,z,r)^\top \subset \mathbb{R}^{3,1}$ be given. If we denote by $\hat{\mathbf{x}}(u,v) = (x,y,z)^\top$ the corresponding medial surface in $\mathbb{R}^3$ then the *envelope formula* is

$$\mathbf{b}^{\pm}(u,v) = \hat{\mathbf{x}}(u,v) - r\mathbf{n}^{\pm}(u,v), \tag{1}$$

with

$$\mathbf{n}^{\pm} = \frac{1}{\hat{E}\hat{G}-\hat{F}^2}\left[\left(\frac{\partial r}{\partial u}\hat{G}-\frac{\partial r}{\partial v}\hat{F}\right)\hat{\mathbf{x}}_u + \left(\frac{\partial r}{\partial v}\hat{E}-\frac{\partial r}{\partial u}\hat{F}\right)\hat{\mathbf{x}}_v \mp \sqrt{EG-F^2}(\hat{\mathbf{x}}_u\times\hat{\mathbf{x}}_v)\right], \tag{2}$$

where $\mathbf{n}^{\pm}$ is a unit vector perpendicular to $\mathbf{b}^{\pm}$. The components E,F,G of the first fundamental form of $\mathbf{x}(u,v)$ are computed using the indefinite Minkowski inner product $\langle \cdot,\cdot \rangle$

 ISBN: 978-84-617-8694-7

with the signature (3,1), whereas the components $\hat{E}, \hat{F}, \hat{G}$ of the first fundamental form of $\hat{\mathbf{x}}(u,v)$ are determined using the standard Euclidean inner product in $\mathbb{R}^3$.

MOS surfaces, i.e., Medial surfaces Obeying the Sum of squares condition, were introduced in [8] as the shapes satisfying the distinguishing property that if considered as an MST of a spatial domain, then the associated envelope and its offsets admit exact rational parameterization. So, they are given by the condition

$$EG - F^2 = \sigma^2(u,v), \qquad \text{where } \sigma(u,v) \in \mathbb{R}(u,v), \tag{3}$$

which guarantees the rationality of (2) and thus of the envelope $\mathbf{b}^{\pm}(u,v)$.

From this it is evident that MOS surfaces are simultaneously surfaces with rational *area element* in $\mathbb{R}^{3,1}$ as the squared area element of the parametric surface $\mathbf{x}(u,v)$ has the form

$$\mathrm{d}A^2 = \begin{vmatrix} \langle \mathbf{x}_u, \mathbf{x}_u \rangle & \langle \mathbf{x}_u, \mathbf{x}_v \rangle \\ \langle \mathbf{x}_u, \mathbf{x}_v \rangle & \langle \mathbf{x}_v, \mathbf{x}_v \rangle \end{vmatrix} \mathrm{d}u^2 \mathrm{d}v^2 = (EG - F^2)\, \mathrm{d}u^2 \mathrm{d}v^2. \tag{4}$$

Moreover, all polynomial MOS surfaces possess polynomial surface area $A(u,v) = \iint \sqrt{EG - F^2}\, \mathrm{d}u\mathrm{d}v$. This offers many useful computational advantages compared to other surfaces.

In what follows, we will study suitable normal vector fields that help us to construct parameterizations of polynomial MOS surfaces. We recall a result from [3] expressing that for a polynomial surface $\mathbf{x}(u,v)$ in $\mathbb{R}^{3,1}$ it holds

$$\Gamma(\mathbf{x}_u, \mathbf{x}_v) = f^2\, \Gamma(\mathbf{n}_1, \mathbf{n}_2), \tag{5}$$

where $\mathbf{n}_1, \mathbf{n}_2$ are the normal vectors generating the normal space $\mathrm{span}\{\mathbf{n}_1(u,v), \mathbf{n}_2(u,v)\}$, Γ is the the Grammian of the considered vectors and $f(u,v) \in \mathbb{R}(u,v)$ is a non-zero factor. This means that it is possible to start with suitable normal vectors when constructing parameterizations of polynomial MOS surfaces as the distinguishing condition (3) depends on $\Gamma(\mathbf{n}_1, \mathbf{n}_2)$ equally as on $\Gamma(\mathbf{x}_u, \mathbf{x}_v) = EG - F^2$. Moreover, when at least one of the normal vectors $\mathbf{n}_1$, or $\mathbf{n}_2$ is isotropic, i.e., its squared norm is zero, then $\Gamma(\mathbf{n}_1, \mathbf{n}_2)$ is automatically a perfect square.

Hence we can recall the main ideas from the approach discussed in [3]. We start with the normal space $\mathrm{span}\{\mathbf{n}^+(u,v), \mathbf{n}^-(u,v)\}$ given by the polynomial isotropic vectors of degree k, i.e., $\langle \mathbf{n}^{\pm}, \mathbf{n}^{\pm} \rangle \equiv 0$. Their parameterizations can be obtained e.g. from polynomial Pythagorean quadruples, see [5]. To find an associated polynomial MOS surface of degree $\ell + 1$, it is necessary to find suitable polynomial vector fields

$$\begin{aligned} \mathbf{q}(u,v) &= \left(\sum_{i+j \le \ell} q_{1ij} u^i v^j, \sum_{i+j \le \ell} q_{2ij} u^i v^j, \sum_{i+j \le \ell} q_{3ij} u^i v^j, \sum_{i+j \le \ell} q_{4ij} u^i v^j \right)^{\top}, \\ \mathbf{r}(u,v) &= \left(\sum_{i+j \le \ell} r_{1ij} u^i v^j, \sum_{i+j \le \ell} r_{2ij} u^i v^j, \sum_{i+j \le \ell} r_{3ij} u^i v^j \sum_{i+j \le \ell} r_{4ij} u^i v^j \right)^{\top}, \end{aligned} \tag{6}$$

 ISBN: 978-84-617-8694-7

which will play the role of $\mathbf{x}_u$, $\mathbf{x}_v$, respectively. Thus, $\mathbf{q}$, $\mathbf{r}$ must satisfy the following conditions

$$\begin{aligned} \langle \mathbf{q}, \mathbf{n}^{\pm} \rangle &\equiv 0, \\ \langle \mathbf{r}, \mathbf{n}^{\pm} \rangle &\equiv 0, \\ \frac{\partial \mathbf{q}}{\partial v} - \frac{\partial \mathbf{r}}{\partial u} &\equiv 0, \end{aligned} \tag{7}$$

where the last equation expresses the condition of integrability. For ℓ large enough, system of linear equations (7) with unknowns $q_{1ij}, q_{2ij}, q_{3ij}, q_{4ij}, r_{1ij}, r_{2ij}, r_{3ij}, r_{4ij}$ possesses a solution and thus we arrive at a MOS parameterization $\mathbf{x}(u,v)$, for which it holds $EG - F^2 = f(u,v)^2 \Gamma(\mathbf{n}^+, \mathbf{n}^-)$, where $f(u,v)$ is a factor relates suitably the degrees of $\mathbf{n}^{\pm}$ and $\mathbf{x}$.

4 MOS branching elements for skinning of spheres

The G^1 Hermite interpolations by polynomial MOS surfaces can be efficiently used when branching elements of rational skinning surfaces shall be constructed as the rational envelopes of two-parameter families of spheres. We present the approach at least for triangular and quadrilateral patches.

Consider three or four points $\mathbf{p}_{ij} \in \mathbb{R}^{3,1}$, $i,j = 0,1$ (and $i+j < 2$ for the case of three points), and three or four associated tangent planes τ_{ij} determined by the vectors $\mathbf{t}_{ij,1}$ and $\mathbf{t}_{ij,2}$. A choice of these points and associated tangent planes reflects a particular situation obtained when the branching skins shall be constructed. Following the previously presented ideas, we can formulate the whole algorithm consisting of three subparts:

(i) We find the isotropic vectors $\mathbf{n}_{ij}^{\pm}$ lying in the normal planes orthogonal to the given tangent planes τ_{ij}

(ii) We construct a normal vector field $\mathbf{n}^+(u,v)$ interpolating data $\lambda_{ij}\, \mathbf{n}_{ij}^+$ and having the polynomial norm.

(iii) We compute a polynomial patch interpolating the points $\mathbf{p}_{ij}$, possessing the isotropic normal vector field $\mathbf{n}^+(u,v)$ and in addition having $\mathbf{n}_{ij}^-$ as normal vectors at $\mathbf{p}_{ij}$.

As concerns step (i), we consider the projective closure of $\mathbb{R}^{3,1}$ consisting of the points with the homogeneous coordinates $(x_0 : x_1 : x_2 : x_3 : x_4)$, and the equation $x_0 = 0$ describes the points at infinity (the *ideal hyperplane*). We find the ideal lines of τ_{ij}, compute the conjugated lines with respect to Σ (i.e., the ideal lines of the normal planes at $\mathbf{p}_{ij}$), and by intersecting them with the absolute quadric $\Omega: \; x_1^2 + x_2^2 + x_3^2 - x_4^2 = x_0 = 0$, we arrive at the isotropic vectors $\mathbf{n}_{ij}^{\pm}$ associated to $\mathbf{p}_{ij}$. The isotropic normals $\mathbf{n}^{\pm}$ can be identified with points of the oval quadric Ω considered as the unit sphere in $\mathbb{R}^3$. Hence we consider the associated normals $\mathbf{N}_{ij} = (n_1, n_2, n_3)/n_4$ on the unit sphere $\mathcal{S}^2$.

 ISBN: 978-84-617-8694-7

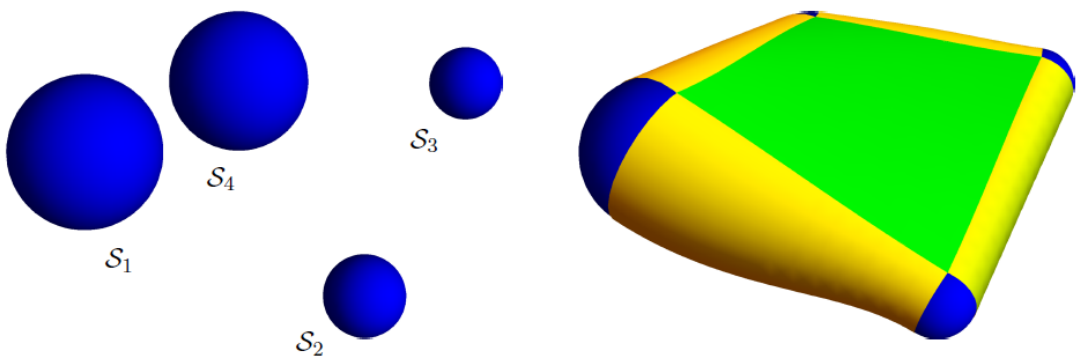

Figure 2.

Next we continue with step (ii) and interpolate the so called *isotropic Gauss image* $\mathcal{G}^+$ by a suitable rational patch $\mathbf{N}(u,v) = (N_1/N_4, N_2/N_4, N_3/N_4)$ on $\mathcal{S}^2$. For this purpose we apply a standard method based on using the stereographic projection $\pi_{\mathbf{w}}$ with the center $\mathbf{w}$, the consequent construction of a suitable polynomial patch in $\mathbb{R}^2$ interpolating $\pi_{\mathbf{w}}(\mathbf{N}_{ij})$ and applying the inverse stereographic projection on the obtained planar patch. Thus we arrive at $\mathbf{n}^+(u,v) = (N_1, N_2, N_3, N_4)$ interpolating data $\lambda_{ij}\,\mathbf{n}^+_{ij}$.

Finally in step (iii), we take $\mathbf{n}^+(u,v)$ as the input for (7) and add to this system the equations

$$\mathbf{x}(i,j) = \mathbf{p}_{ij}, \quad \langle \mathbf{x}_u(i,j), \mathbf{n}^-_{ij} \rangle = 0, \quad \langle \mathbf{x}_v(i,j), \mathbf{n}^-_{ij} \rangle = 0, \tag{8}$$

which guarantee satisfying the interpolation conditions. Solving the system of linear equations we arrive at an MOS patch interpolating given Hermite data $\{\mathbf{p}_{ij}, \tau_{ij}\}$.

The envelopes determined by these polynomial MOS patches. considered as MSTs in $\mathbb{R}^{3,1}$, can be taken as suitable branching elements of the constructed skins. Let us emphasize that not only they are rational, but the properties of MOS surfaces guarantee that also their offsets are rational, as they belong among the so called surfaces with Pythagorean normals (i.e., rational surfaces with rational offsets)

5 Computed examples

In this section we present the designed method on several particular examples. It is assumed that the connectivity (topology) of the skin is given.

Example 5.1 Consider 4 spheres given by ...

 ISBN: 978-84-617-8694-7

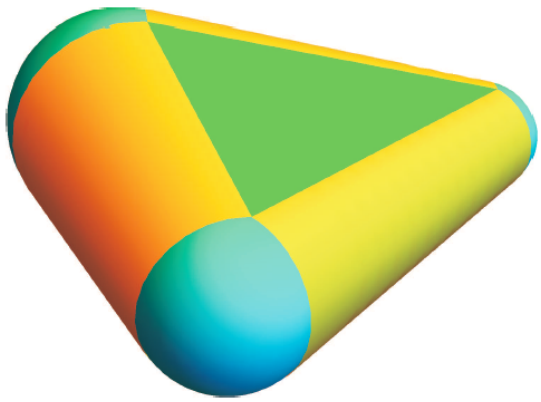

Figure 3.

Example 5.2 Consider 3 spheres given by ...

6 Conclusion

This paper was devoted to the construction of branching elements of rational skins of systems of spheres with the prescribed connectivity. We have shown how the so-called MOS surfaces can be used for this operation. The functionality of the presented method was illustrated on some examples. We would like to emphasize that the designed approach is not limited to constructing branching elements joining only 3 or 4 spheres. In the case when we have more than 4 spheres, the principles of the construction remain the same, but the goal is to construct an n-sided MOS patch which interpolates, at its corners, n points and their associated tangent planes. In our future work we would like to focus on further constructions, important in technical practice, in which MOS patches can be efficiently used – as e.g. when branching blends (i.e., smooth joins of several given shapes) shall be constructed, see Fig. 4.

Abstract

The understanding of complex physical or biological systems nearly always requires a characterisation of the variability that underpins these processes. In addition, the data used to calibrate such models may also often exhibit considerable variability. A recent approach to deal with these issues has been to calibrate populations of models (POMs), that is multiple copies of a single mathematical model but with different parameter values. To date this calibration has been limited to selecting models that produce outputs that fall within the ranges of the dataset, ignoring any trends that might be present in the data.

ISBN: 978-84-617-8694-7

We present here a novel and general methodology for calibrating POMs to the distributions of a set of measured values in a dataset. We demonstrate the benefits of our technique using a dataset from a cardiac atrial electrophysiology study based on the differences in atrial action potential readings between patients exhibiting sinus rhythm (SR) or chronic atrial fibrillation (cAF) and the Courtemanche-Ramirez-Nattel model for human atrial action potentials.

Our approach accurately captures the variability inherent in the experimental population, allows for uncertainty quantification and also allows us to identify the differences underlying stratified data as well as the effects of drug block.

Abstract

In this paper, we present the data-driven COS method, ddCOS. It is a Fourier-based financial option valuation method which assumes the availability of asset data samples: a characteristic function of the underlying asset probability density function is not required. As such, the method represents a generalization of the well-known COS method [1]. Convergence with respect to the number of asset samples is according the convergence of Monte Carlo methods for pricing financial derivatives. The ddCOS method is particularly interesting for density recovery and also for the efficient computation of the option's sensitivities Delta and Gamma. This paper is a short version of an already available preprint [6].

Key words: The COS method, density estimation, data-driven approach, Greeks, the SABR model

1 Introduction

In quantitative finance, statistical distributions are commonly used for the valuation of financial derivatives and within risk management. The underlying assets are often modeled by means of stochastic differential equations (SDEs). Except for the classical and most simple asset models, the corresponding *probability density function* (PDF) and *cumulative distribution function* (CDF) are typically not known and need to be approximated.

In order to compute option prices, and to approximate statistical distributions, Fourier-based methods are commonly used numerical techniques. They are based on the connection between the PDF and the *characteristic function* (ChF), which is the Fourier transform of the probability density. The ChF is often available, and sometimes even in closed form, for the broad class of regular diffusions and also for Lévy processes. Here, we focus on the COS method from [1], which is based on an approximation of the PDF by means of a cosine series expansion.

Still, however, the asset dynamics for which the ChF are known is not exhaustive, and for many relevant asset price processes we do not have such information to recover the density. In this work, we extend the applicability of the COS method to the situation where only data (like samples from an unknown underlying risk neutral asset distribution) are available. We will focus on the framework of *statistical learning*, see [7].

The use of the COS method gives us expressions for option prices and, in particular, for the *option sensitivities or Greeks*. These option Greeks are the derivatives of option price with respect to a variable or parameter. The efficient computation of the Greeks is a challenging problem when only asset samples are available. Existing approaches are based on Monte Carlo (MC)-based techniques, like on finite-differences (bump and revalue), pathwise or likelihood ratio techniques, for which details can be found in [2], chapter 7. The ddCOS method is not directly superior to Monte Carlo methods for option valuation, but it is competitive for the computation of the corresponding sensitivities. We derive simple expressions for the Greeks Delta and Gamma.

This paper is organized as follows. The ddCOS method, and the origins in statistical learning and Fourier-based option pricing, are presented in Section 2. Numerical experiments, with a focus on the option Greeks, are presented in Section 3. We conclude in Section 4.

2 The data-driven COS method

In this section we will discuss the ddCOS method, in which aspects of the MC method, density estimators and the COS method are combined to approximate, in particular, the option Greeks Delta and Gamma for European options. The connection with the COS method is found in the fact that the data-driven PDF appears as a cosine series expansion.

2.1 The COS method

The starting point for the well-known COS method is the risk-neutral option valuation formula, where the value of a European option at time t, $v(x,t)$, is an expectation under the risk neutral pricing measure, i.e.,

$$v(x,t) = \mathrm{e}^{-r(T-t)}\mathbb{E}\left[v(y,T)|x\right] = \mathrm{e}^{-r(T-t)}\int_{\mathbb{R}} v(y,T)f(y|x)\mathrm{d}y, \tag{1}$$

 ISBN: 978-84-617-8694-7

with r the risk-free rate, T the maturity time, and $f(y|x)$ the PDF of the underlying process, and $v(y,T)$ represents the option value at maturity time, being the payoff function. Typically, x and y are chosen to be scaled variables,

$$x := \log\left(\frac{S(0)}{K}\right) \quad \text{and} \quad y := \log\left(\frac{S(T)}{K}\right),$$

where $S(t)$ is the underlying asset process at time t, and K is the strike price.

Density $f(y|x)$ is unknown in most cases and in the COS method it is approximated, on a finite interval $[a,b]$, by a cosine series expansions, i.e.,

$$f(y|x) = \frac{1}{b-a}\left(A_0 + 2\sum_{k=1}^{\infty} A_k(x)\cdot\cos\left(k\pi\frac{y-a}{b-a}\right)\right),$$
$$A_0 = 1, \quad A_k(x) = \int_a^b f(y|x)\cos\left(k\pi\frac{y-a}{b-a}\right)\mathrm{d}y, \quad k = 1,2,\ldots.$$

By substituting this expression in Equation (1), interchanging the summation and integration operators using Fubini's Theorem, and introducing the following definition,

$$V_k := \frac{2}{b-a}\int_a^b v(y,T)\cos\left(k\pi\frac{y-a}{b-a}\right)\mathrm{d}y,$$

we find that the option value is given by

$$v(x,t) \approx \mathrm{e}^{-r(T-t)}\sum_{k=0}^{\infty}{}' A_k(x)V_k, \tag{2}$$

where $'$ indicates that the first term is divided by two. So, the product of two real-valued functions in Equation (1) is transformed into the product of their cosine expansion coefficients, A_k and V_k. Density coefficients A_k can be computed by the ChF and V_k is known analytically (for many types of options).

Closed-form expressions for the option Greeks can also be derived. From the COS option value formula, Δ and Γ are obtained by

$$\begin{aligned}\Delta &= \frac{\partial v(x,t)}{\partial S} = \frac{1}{S(0)}\frac{\partial v(x,t)}{\partial x} \approx \exp(-r(T-t))\sum_{k=0}^{\infty}{}' \frac{\partial A_k(x)}{\partial x}\frac{V_k}{S(0)},\\ \Gamma &= \frac{\partial^2 v(x,t)}{\partial S^2} = \frac{1}{S^2(0)}\left(-\frac{\partial v(x,t)}{\partial x} + \frac{\partial^2 v(x,t)}{\partial x^2}\right)\\ &\approx \exp(-r(T-t))\sum_{k=0}^{\infty}{}'\left(-\frac{\partial A_k(x)}{\partial x)} + \frac{\partial^2 A_k(x)}{\partial x^2)}\right)\frac{V_k}{S^2(0)}\end{aligned} \tag{3}$$

Due to the rapid decay of the coefficients, $v(x,t)$, Δ and Γ can be approximated with high accuracy by truncating the infinite summation in Equations (2) and (3) to N terms. Under suitable assumptions, exponential convergence is proved and numerically observed.

 ISBN: 978-84-617-8694-7

2.2 Statistical learning theory for density estimation

In the setting of this paper, we assume a vector of n independent and identically distributed (i.i.d.) samples, $X_1, X_2, \ldots, X_n$. Based on these samples, we wish to find an accurate approximation of the PDF estimator, $f_n(x)$, which should approximate density $f(x)$.

By definition, the PDF is related to its CDF $F(x)$,

$$\int_{-\infty}^{x} f(y)\mathrm{d}y = F(x). \tag{4}$$

Function $F(x)$ is approximated by the empirical approximation,

$$F_n(x) = \frac{1}{n}\sum_{j=1}^{n} \eta(x - X_j), \tag{5}$$

where $\eta(\cdot)$ is a step function. This approximation converges to the "true CDF" with rate $\mathcal{O}(1/\sqrt{n})$. Rewriting Equation (4) as a linear operator equation, gives us,

$$Cf = F \approx F_n,$$

where the operator $Ch := \int_{-\infty}^{x} h(z)\mathrm{d}z$.

As explained in [7], this matrix equation represents an ill-posed problem, and therefore a *risk functional* should be constructed, with a regularization term, as follows

$$R_{\gamma_n}(f, F_n) = L^2_{\mathcal{H}}(Cf, F_n) + \gamma_n W(f), \tag{6}$$

where $L_{\mathcal{H}}$ is a metric of the space $\mathcal{H}$, $\gamma_n > 0$ is a parameter which gives a weight to the regularization term $W(f)$, with $\gamma_n \to 0$ as $n \to \infty$. The solution of $Cf = F_n$ belongs to $\mathcal{D}$, the domain of definition of $W(f)$. Functional $W(f)$ takes real non-negative values in $\mathcal{D}$. Furthermore, $\mathcal{M}_c = \{f : W(f) \leq c\}$ is a compact set in $\mathcal{H}$ (the space where the solution exists and is unique).

The solution f_n, minimizing the functional in Equation (6), converges almost surely to the desired density. By considering particular choices of $L_{\mathcal{H}} = L_2(0, \pi)$ and W (see [7] for details), the the risk functional in Equation (6) becomes

$$R_{\gamma_n}(f, F_n) = \int_0^{\pi} \left(\int_0^{x} f(y)\mathrm{d}y - F_n(x) \right)^2 \mathrm{d}x + \gamma_n \int_0^{\pi} \left(f^{(p)}(x) \right)^2 \mathrm{d}x. \tag{7}$$

Given a cosine series expansion, $\psi_1(\theta) = \cos(\theta), \ldots, \psi_k(\theta) = \cos(k\theta), \ldots$, the approximation to the unknown PDF will be of the form

$$f_n(\theta) = \frac{1}{\pi} + \frac{2}{\pi}\sum_{k=1}^{\infty} \tilde{A}_k \cos(k\theta), \tag{8}$$

 ISBN: 978-84-617-8694-7

with $\tilde{A}_0, \tilde{A}_1, \ldots, \tilde{A}_k, \ldots$ expansion coefficients, defined as $\tilde{A}_k =< f_n, \psi_k >$. We need to compute the expansion coefficients so that the functional in Equation (7) is minimized. The coefficients $\tilde{A}_k$ cannot be directly computed from the definition since the unknown PDF, f_n, is implicitly involved in the expression, but from the equivalent expression $\tilde{A}_k =< \hat{f}_n, \hat{\psi}_k >$. Thus, it can be proved that the minimum of the functional using cosine series expansions (see [7]) is obtained when

$$\tilde{A}_k = \frac{1}{1+\gamma_n k^{2(p+1)}} \frac{1}{n} \sum_{j=1}^{n} \cos(k\theta_j), \tag{9}$$

where $\theta_j \in (0, \pi)$ are given samples of the unknown distribution.

Assuming that the samples are given, the solution contains two free parameters: *regularization parameter* γ_n, and *smoothing parameter* p. The parameter p is selected as $p = 0$, implying that the actual function enters in the regularization term. The choice of parameter γ_n impacts the efficiency of the data-driven COS method, since it is related to the required number of data samples, and by reducing the number of samples, the overall computational cost can be reduced. The parameter γ can be obtained by the following rule,

$$\gamma_n = \frac{\log \log n}{n}. \tag{10}$$

As proved in [7], this rule provides a robust asymptotic rate of convergence under the assumption of a compactly supported density. It implies, with probability one, uniformly converging approximations f_n to the unknown density.

2.3 The ddCOS method

We are now ready to present the ddCOS method, where we employ the series expansion coefficients from the regularization approach. We replace the A_k-coefficients from Equation (2) by those coefficients based on data, $\tilde{A}_k$ in Equation (9).

So, suppose we have risk neutral samples (or values) from an underlying asset at a future time t, i.e., $S_1(t), S_2(t), \ldots, S_n(t)$. We compute the value of a European option with maturity time T and strike price K, and require therefore the samples $S_j(T)$. With a logarithmic transformation, we have

$$Y_j := \log\left(\frac{S_j(T)}{K}\right).$$

Before employing these samples in the regularization approach and because the solution is defined in $(0, \pi)$, we need to transform the samples by the following change of variables,

$$\theta_j = \pi \frac{Y_j - a}{b - a},$$

 ISBN: 978-84-617-8694-7

where the boundaries a and b are defined as

$$a := \min_{1\leq j\leq n}(Y_j), \quad b := \max_{1\leq j\leq n}(Y_j).$$

The A_k coefficients in Equation (2) are replaced by the data-driven $\tilde{A}_k$ in Equation (9),

$$A_k \approx \tilde{A}_k = \frac{\frac{1}{n}\sum_{j=1}^{n}\cos\left(k\pi\frac{Y_j-a}{b-a}\right)}{1+\gamma_n k^{2(p+1)}}.$$

The ddCOS pricing formula for European options based on risk neutral data is now obtained as

$$\begin{aligned}\tilde{v}(x,t) &= \mathrm{e}^{-r(T-t)}\sum_{k=0}^{\infty}{}'\frac{\frac{1}{n}\sum_{j=1}^{n}\cos\left(k\pi\frac{Y_j-a}{b-a}\right)}{1+\gamma_n k^{2(p+1)}}\cdot V_k \\ &= \mathrm{e}^{-r(T-t)}\sum_{k=0}^{\infty}{}'\tilde{A}_k V_k.\end{aligned} \tag{11}$$

The samples Y_j should originate from one initial state, i.e. the dependency on the state x is implicitly assumed. In the case of European options this is typically fulfilled. In the Monte Carlo method, for example, all simulated asset paths depart from the same point $S(0)$, so that $x := \log\left(\frac{S(0)}{K}\right)$.

Regarding the Greeks, we can also derive data-driven expressions for the Δ and Γ sensitivities. We first define the corresponding sine coefficients as

$$\tilde{B}_k := \frac{\frac{1}{n}\sum_{j=1}^{n}\sin\left(k\pi\frac{Y_j-a}{b-a}\right)}{1+\gamma_n k^{2(p+1)}}.$$

Taking derivatives in Equation (11) w.r.t the samples, Y_j, and following the COS expression for the sensitivities in Equation (3), the data-driven Greeks, $\tilde{\Delta}$ and $\tilde{\Gamma}$, can be obtained by

$$\begin{aligned}\tilde{\Delta} &= \mathrm{e}^{-r(T-t)}\sum_{k=0}^{\infty}{}'\tilde{B}_k\cdot\left(-\frac{k\pi}{b-a}\right)\cdot\frac{V_k}{S(0)}, \\ \tilde{\Gamma} &= \mathrm{e}^{-r(T-t)}\sum_{k=0}^{\infty}{}'\left(\tilde{B}_k\cdot\frac{k\pi}{b-a}-\tilde{A}_k\cdot\left(\frac{k\pi}{b-a}\right)^2\right)\cdot\frac{V_k}{S^2(0)}.\end{aligned}$$

As in the original COS method, we must truncate the infinite sum to a finite number of terms N.

 ISBN: 978-84-617-8694-7

2.3.1 Application of variance reduction

Because of the focus on asset path data, the ddCOS method is related to the Monte Carlo method. Variance reduction in Monte Carlo methods is typically achieved by the use of variance reduction techniques. The ddCOS method also admits an additional variance reduction, in this case, for the computation of the expansion coefficients, $\tilde{A}_k$. We show how to introduce *antithetic variates (AV)* to our method. Since one of the assumptions for the regularization approach is that the samples are i.i.d., an immediate application of AV is not possible. Therefore, if we assume that antithetic samples, Y_i', to the original samples Y_i, can be computed without any serious computational effort, a new estimator for the coefficients can be defined as

$$\bar{A}_k := \frac{1}{2}\left(\tilde{A}_k + \tilde{A}_k'\right),$$

where we denote by $\tilde{A}_k'$ the corresponding "antithetic coefficients", obtained by Y_i'. By a similar derivation as for the standard AV technique, it can be proved that the use of coefficients $\bar{A}_k$ will give us a variance reduction compared to using the $\tilde{A}_k$ coefficients. Other variance reduction techniques may also be considered for the ddCOS method under the assumption of i.i.d. samples.

3 Applications of the ddCOS method

In this section, we present some applications of the ddCOS method. The first application is an option pricing experiment, where we show the method's convergence. Subsequently, we present the performance regarding the computation of the Greeks, where ddCOS exhibits a stable convergence and can be employed with involved models, as we only need asset samples. We also compute the Greeks under Merton and SABR models. The experiments have been carried out on a computer system with the following characteristics: CPU Intel Core i7-4720HQ 2.6GHz and RAM memory of 16GB RAM. The employed software package is Matlab R2016b.

3.1 Option valuation

First of all, we numerically test the convergence of the ddCOS method in an option valuation experiment. The *Geometric Brownian Motion* (GBM) asset dynamics are employed, since a reference value for the option value is available by the Black-Scholes formula. The regularization parameter γ_n is set as in Equation (10). As is common in MC experiments, the *Mean Squared Error* (MSE) is considered as the error measure. In the convergence tests, the reported values are computed as the average of 50 experiments.

The expected order of convergence for the option values is $\mathcal{O}(1/\sqrt{n})$, according to the convergence of the empirical CDF towards the true CDF in Equation (5). In Section

Figure 1: Convergence in prices and Greeks of the ddCOS method: Antithetic Variates (AV); GBM, $S(0) = 100$, $r = 0.1$, $\sigma = 0.3$, $K = S(0)$ and $T = 2$.

2.3.1, the application of antithetic variates in the ddCOS framework has been presented. In Figure 1a, we confirm that this variance reduction technique provides a similar improvement in terms of precision as when it is applied to the plain MC method.

3.2 Greeks

We have empirically shown in Figure 1a that the ddCOS method converges to the true price with the expected convergence rate $\mathcal{O}(1/\sqrt{n})$, which resembles the plain MC convergence. However, by the ddCOS method, not only the option value but also the sensitivities can readily be obtained. This is an advantage w.r.t MC-based methods for estimating sensitivities, where often, additional simulations, intermediate time-steps or prior knowledge are required. Thus, a similar convergence test is performed for the Δ and Γ sensitivities, see Figures 1b and 1c. As MC-based method for the Greeks calculation we consider the *Finite Difference* method (bump and revalue, denoted as MCFD). We have chosen MCFD for the comparison because it is flexible and it does not require prior knowledge. MCFD may require one or two extra simulations, and the choice of optimal *shift* parameter may not be trivial. The reference Delta and Gamma are given by the Black-Scholes formula. In both experiments, while the Δ is very well approximated by the ddCOS and MCFD methods, the second derivative, Γ, appears more complicated for the MCFD method. This fact was already pointed out by Glasserman in [2]. The ddCOS estimator, however, is accurate and stable as it is based on the data-driven PDF and the ddCOS machinery.

Using $n = 10^5$, in Table 1 we now compare the Δ and Γ estimations obtained under the GBM dynamics for several strikes. The performance of the ddCOS method is very satisfactory as it is accurate, with small *Relative Error* (RE, averaged over K) and reproduces the reference values very well. The difficulties of the MCFD estimating Γ are more clearly visible.

Table 1: GBM option Greeks: Call, $S(0) = 100$, $r = 0.1$, $\sigma = 0.3$ and $T = 2$.

We wish to test the ddCOS method in a more complex situation, by adding jumps in the form of a Merton jump-diffusion asset price process. To accurately compute the option sensitivities in this case gives rise to difficulties for MC-based methods. We perform a similar experiment as before, where now the underlying asset follows the Merton jump-diffusion model, and the obtained Δ and Γ are presented in Table 2. In this case, the reference value is provided by the COS method at a high accuracy.

The SABR model [3] is interesting within the ddCOS framework since the ChF is not known and, furthermore, the asset path MC simulation is not trivial. The authors provided a closed-form approximation formula for the *implied volatility* under the SABR dynamics, which is often used within the calibration. However, the closed-form expression is derived by perturbation theory, and therefore the formula is not accurate for small strike values, for long time to maturity options or for high volatilities (see, for example, [4, 5]). Therefore, the calculation of the Greeks under the SABR model becomes challenging but can be addressed by the ddCOS method. To employ the method, we need samples of the underlying asset at time T. Here, we make use of the one time-step SABR MC simulation introduced by Leitao et al. in [4]. Thus, the ddCOS method will be combined with the one time-step SABR simulation to efficiently compute Δ and Γ under the SABR dynamics.

For the numerical experiments, we consider two parameter settings. First of all, a basic parameter set is taken, where the SABR formula is valid and can be used as a reference. The results are presented in Table 3. For the second test we use a more difficult set of parameters (i.e., Set III in [4]), where the SABR formula does not provide accurate results anymore. In Table 4, we observe that the ddCOS provides accurate Δ-values in this case, without any problems. The reference value has been computed by the MCFD in combination with the

4 Conclusions

In this work, the ddCOS method has been introduced. The method extends the COS method applicability to cases when only data samples of the underlying asset are available. The method exploits a closed-form solution, in terms of Fourier cosine expansions, of a density. The use of the COS machinery in combination with density estimation allowed us to develop a data-driven method which can be employed for option pricing and risk management. The ddCOS method particularly results in an efficient method for the Δ and

Abstract

We analyze the implementation, performance and energy efficiency of an algoritm to compute the QR factorization of a dense matrix on a Field Programmable Gate Array (FPGA). Our implementation is based on a simple level-2 BLAS formulation of the factorization algorithm that relies on Householder reflectors. The results on a Xilinx Virtex-7 show a dissipation rate that is slightly above 3 Watts.

Key words: QR factorization, high performance, energy consumption, field programmable gate array (FPGA), linear algebra.

1 Introduction

The QR factorization is a key numerical algorithm for the solution of linear least squares problems arising, among others, in statistics, geodetics, signal processing, control and, in general, in any scenario where it is necessary to fit a model to observations containing errors [3]. As a consequence, over the past decades there has been a continuous effort to accelerate the computation and improve the stability of this factorization, via efficient algorithms and computational kernels for a wide variety of computer architectures. In particular, from the mathematical and algorithmic perspectives one of the most remarkable advances is the formulation of the QR factorization via Householder reflectors [5]. On the other hand, from the point of view of high performance on modern computer architectures, the introduction of the WY transform and its compact variant [6], which unleashed the utilization of compute-intensive kernels in the factorization, are two significant advances.

ISBN: 978-84-617-8694-7

As computer architectures progress on the road to Exascale systems, energy has arisen as a primary challenge on par with performance [4, 8]. A distinguisable milestone in high performance computing (HPC) system have been the shift towards heterogeneous systems, equipped with some sort of accelerator, in order to improve the performance-per-energy unit ratio [1]. As we move along this line, we can expect an eventual adoption of customizable technologies such as field programmable gate arrays (FPGAs) due to their flexibility, performance and energy efficiency, as recent movements from companies such as IBM, Intel and Microsoft hint.

In this paper we assess the performance and energy efficiency of an algorithm to compute the QR factorization on FPGA based on Householder reflectors and implemented on a Xilinx Virtex-7 board.

2 The QR Factorization

Given a nonzero vector $x \in \mathbb{R}^n$, the corresponding Householder reflector $H := \text{HOUSE}(x) = I_n - \tau v v^T$, where $v = x + \alpha e_1$, $\tau = 2/(v^T v)$, $\alpha = \pm ||x||_2$, I_n denotes the square identity matrix of order n and e_1 is the first column of I_n, satisfies $y := Hx = \mp ||x||_2 e_1$ [6]; that is, all entries of x are annihilated by the application (from the left) of the Housedoher reflector H, except the first entry of x which, after the application, becomes $\mp ||x||_2$.

For a matrix $A \in \mathbb{R}^{m \times n}$, this type of orthogonal reflectors can be applied to compute the QR factorization $A = QR$, where $Q \in \mathbb{R}^{m \times m}$ is orthogonal and $R \in \mathbb{R}^{m \times n}$ is upper triangular. For this purpose, the procedure commences with $A^{(0)} = A$ and consecutively applies a sequence of Householder reflectors $H_1, H_2, \ldots, H_n$ such that H_j annihilates the (subdiagonal) entries in the j-th column of $A^{(j-1)} = (H_{j-1} \ldots H_1)A$. Thus, upon completion, $A^{(n)} = R$, and $Q = H_1 H_2 \cdots H_n$ [6]. Figure 1 illustrates the calculation of this factorization, using the FLAME notation [7], via an unblocked algorithm that is implemented as routine GEQR2 in the *Linear Algebra Package* (LAPACK) [2]. Internally, the algorithm relies on routine LARFG to generate a Householder reflector for the vector consisting of α_{11} and a_{21}. Routine LARF then applies this reflector (from the left) to the trailing submatrix composed of a_{12}^T and A_{22}. The Householder reflector H is not explicitly built, but applied implicitly using the parameters v, τ. In particular, note that the application of the Householder reflector to a matrix $\hat{A}$ can be performed as $H\hat{A} = (I - \tau v v^T)\hat{A} = \hat{A} - \tau v (v^T \hat{A})$, which boils down to a matrix-vector product, $w^T := w^T \hat{A}$, followed by a (scaled) rank-1 update, $\hat{A} := \hat{A} - \tau v w^T$.

In practice, the upper triangular factor R overwrites the corresponding entries of A. Furthermore, the parameters v_j and τ_j that define the Householder reflector H_j (which annihilates the subdiagonal entries in the j-th column of $A^{(j-1)}$) are respectively stored using the annhilated entries of the column plus the j-th entry of an additional vector of size n. (Here, the first entry of v equals 1 and does not need to be explicitly stored.)

 ISBN: 978-84-617-8694-7

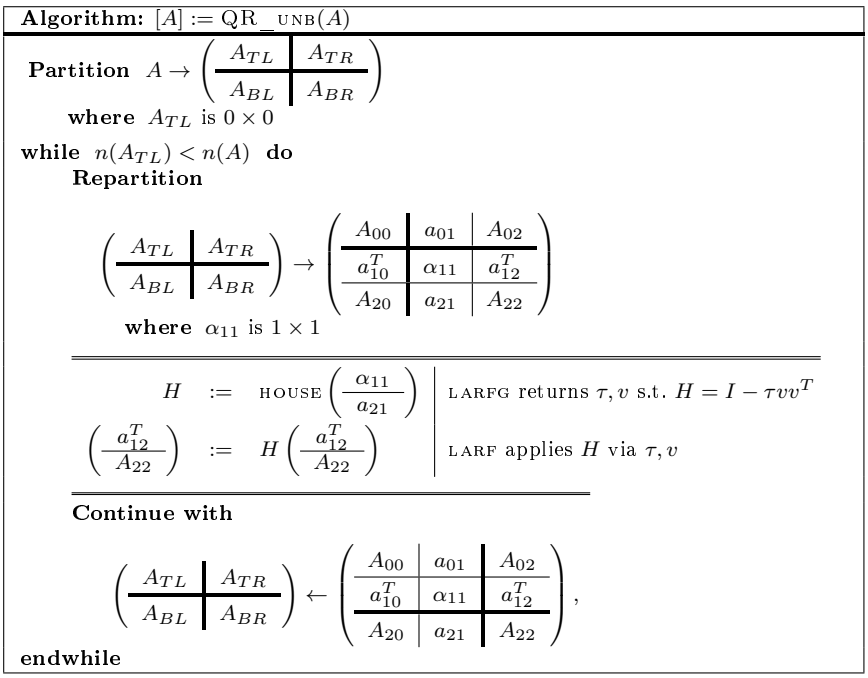

Figure 1: Unblocked algorithm for the QR factorization using Householder reflectors. $n(\cdot)$ is a function that returns the number of columns of its input argument.

3 Implementation on FPGAs

Figure 2 illustrates the hardware architecture that implements the algorithm for the QR factorization. The *memory* module provides the input data; the *House* module calculates the Householder reflector; and the *Row house* module applies the Householder reflector to the appropriate blocks of the data matrix.

Matrix $A \in \mathbb{R}^{m \times n}$ is partitioned, passsed to and processed by the FPGA by blocks of dimension $n \times n$, starting from the bottom and proceedings upwards. While processing two of these blocks, the block immediately above them is transferred to the FPGA in order to overlap communication with computation and avoid idle periods. Module *Memory* is composed of three banks: input, upper and lower. The input bank stores the block in transference while the remaining two banks provide the information to the rest of the processing system. When the calculation of a submatrix is completed, the roles of the banks are rotated so that the upper bank becomes the input bank, the receiver becomes the lower bank, and the lower becomes becomes the upper one.

The calculation modules (*House* and *Row house*) work in parallel. As soon as the first

 ISBN: 978-84-617-8694-7

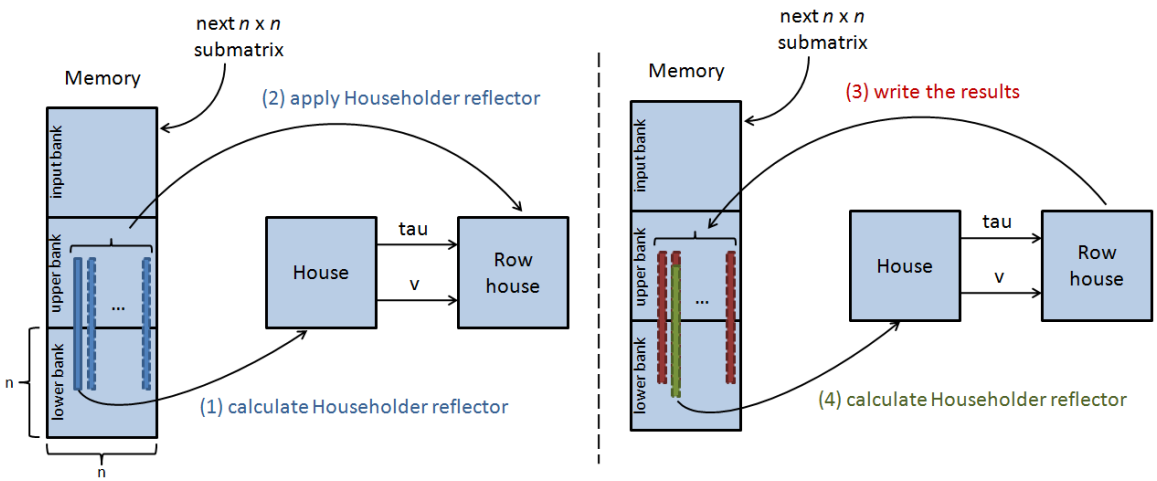

Figure 2: Hardware architecture used to implement QR factorization and steps involved in an intermediate iteration

column is updated, the Householder reflector for the next iteration can be calculated. Thus, steps (3) and (4) in Figure 2 are executed simultaneously. The generation of the Householder reflector exhibits a reduced degree of parallelism and does not have a contiguous source of data. Therefore, the design of module *House* aims to offer low latency and consume a low number of DSP resources. The majority of DSPs are dedicated to the implementation of the *Row house* module to take full advantage of the parallelism of this operation.

There are two versions for the *Row house* module. The first one utilizes the maximum number of floating–point units (following a non-blocking pipeline architecture). The second version adapts the design depending on the number of resources, implementing operators of smaller size and multiplexing the data entry (following a blocking pipeline architecture) in time.

4 Experimental Results

Table 1: Summary of resource utilization

Resource	LUT	LUTRAM	BRAM	DSP
Available	433,200	174,200	1,470	3,600
Utilization (%)	251,042 (57.95%)	4,604 (2.64%)	617 (41.97%)	2,649 (73.58%)

We study three metrics of our FPGA implementation: Board usage, computational performance and power consumption. The hardware architecture was implemented on a Xilinx

Virtex-7 XC7VX690T. Table 1 shows the resources necessary for our hardware implementation for a problem of size $n = 256$. In reference to performance, in order to factorize a block of dimension 256×256, the implementation requires a total of 175,205 clock cycles and proceeds at 60 MHz. Looking at power consumption, the static power consumption is 0.58 Watts while the dynamic power consumption is 2.42 Watts, for a total of 3 Watts.

Abstract

In this paper we look at a non-age-structured model for the spread of the Zika Virus and Microcephaly in Brazil. We first outline the non-seasonal differential equation model, and discuss parameter values and their estimation. Then we talk about the basic reproduction number and details of the calculation of the number of Microcephaly cases. Next we estimate how the model can be made more realistic by introducing seasonality into the mosquito population. Finally we consider sensitivity of the results to the mosquito biting rate.

Key words: Zika, Brazil, Microcephaly, Aedes Aegypti mosquito, basic reproduction number, differential equation model, seasonality.
MSC 2000: AMS codes 92B15, 92C60, 92D30.

1 Extended Abstract

1.1 Non-seasonal Model

The Zika virus is spread by the same species of mosquito, namely the *Aedes Aegypti* (*A. Aegypti*), as Dengue. Zika is a member of the virus family *Flaviviridae*. The first discovery of the Zika virus was in 1947, however despite being around for a while, Zika has not received much attention until recently when it has been discovered that it is associated with Microcephaly which is a serious birth defect in newborns, caused if women are infected with Zika during pregnancy. Most importantly there is still no vaccine to prevent the Zika virus. Apart from causing severe birth defects to newborn babies, infected individuals can also experience fever, rash and joint pain. As a result, in this paper we will use an existing

 ISBN: 978-84-617-8694-7

Parameter values	Biological meanings	Values
a	*A. Aegypti* biting rate	0.5×7/week [1, 5]
b	Probability of transmission of Zika when an infectious mosquito bites a susceptible human	$0.10 - 0.75$ [1]
c	Probability of transmission of Zika when a susceptible mosquito bites an infectious human	$0.30 - 0.75$ [3]
N_H	Human population in Brazil in 2015	$207,848,000$ [12]
μ_H	Per capita human mortality rate in Brazil	$1/(75 \times 52)$/week [12]
γ	Per capita human recovery rate	7/6/week [5]
μ_v	Per capita mortality rate for *A. Aegypti*	0.025×7/week [9]
N_v	*A. Aegypti* population	$1.5 \times N_H$ [4, 6]
τ	Zika extrinsic incubation period	8.2/7 weeks [5]

Table 1: Parameter values given in Equation (1).

time-delayed mathematical model for Dengue mentioned in [9] to analyse the dynamical behaviour for the Zika virus, in Brazil, as well as estimating the future expected number of cases of Microcephaly due to Zika.

The definitions of the parameter values used in the differential equation model and their corresponding values are given in Table 1. The model that we are working with is given as follows:

$$\begin{aligned}
\frac{dS_H(t)}{dt} &= -abI_v(t)\frac{S_H(t)}{N_H} - \mu_H S_H(t) + \mu_H N_H, \\
\frac{dI_H(t)}{dt} &= abI_v(t)\frac{S_H(t)}{N_H} - (\mu_H + \gamma)I_H(t), \quad \frac{dR_H(t)}{dt} = \gamma I_H(t) - \mu_H R_H(t), \qquad (1) \\
\frac{dS_v(t)}{dt} &= -acS_v(t)\frac{I_H(t)}{N_H} - \mu_v S_v(t) + \mu_v N_v, \\
\frac{dL_v(t)}{dt} &= acS_v(t)\frac{I_H(t)}{N_H} - \mu_v L_v(t) - acS_v(t-\tau)\frac{I_H(t-\tau)}{N_H}e^{-\mu_v \tau}, \\
\frac{dI_v(t)}{dt} &= acS_v(t-\tau)\frac{I_H(t-\tau)}{N_H}e^{-\mu_v \tau} - \mu_v I_v(t),
\end{aligned}$$

with initial conditions $S_H(0), I_H(0), R_H(0), S_v(0), L_v(0)$ and $I_v(0)$, where $S_H(t), I_H(t)$ and $R_H(t)$ respectively represent the susceptible, infected and recovered individuals for humans, while $S_v(t), L_v(t)$ and $I_v(t)$ respectively represent the susceptible, latent and infected mosquitoes. Note that $N_H = S_H + I_H + R_H$ denotes the total human population size and $N_v = S_v + L_v + I_v$ represents the total *A. Aegypti* population size where both populations

 ISBN: 978-84-617-8694-7

are constant. Although the Zika virus and Dengue are spread by the same transmission route and thus some parameter values would remain the same, parameters such as the transmission probabilities between humans and *A. Aegypti* mosquitoes which are defined as b and c in Equation (1) may vary. Therefore one of the aims in this project is to use the least squares estimation technique and the real Zika virus data from Brazil given in [5] to estimate these two values.

We assume that a single Zika infected human enters the disease free population at some time t_0, where $t_0 < t_1$ and t_1 is the first time when we have available Zika data values in Brazil obtained from [5] as the first week in 2015. We have estimated t_0 and hence $S_H(t_1), I_H(t_1), R_H(t_1), S_v(t_1), L_v(t_1)$ and $I_v(t_1)$, used as simulation starting values, by least squares. The basic reproduction number for our delayed Zika model given in [10] is defined as

$$R_0 = \frac{ma^2bce^{-\mu_v\tau}}{\mu_v(\mu_H+\gamma)}, \tag{2}$$

where all the parameter values are defined as in Table 1. For a in the range 0.7 – 3.5/week we get R_0 in the range 1.27 – 11.01/week.

1.2 Numerical Solutions

Once all the parameter values are obtained and estimated, we use R to solve the differential equations given in Equation (1) and produced simulations which illustrate the number of susceptible, infected and recovered individuals over both a short time period, to represent the immediate future, and over a long time period, to represent what happens when the endemic equilibrium has been reached.

We focus on analysing the effect of pregnant women infected with Zika virus during their first trimester as various reports (e.g. [2, 8]) suggest that pregnant women who are infected with the Zika virus during the first trimester have a much higher risk of their babies developing Microcephaly as opposed to those who are infected with Zika in their second or third trimesters. We have obtained an estimated expected future number of cases of Microcephaly due to pregnant women infected with Zika during their first trimester both in the short and in the long term.

1.3 Model With Seasonality

It is well-known that the life cycle of *A. Aegypti* is influenced by many environmental factors such as rainfall and temperature (e.g. [7, 11, 13]). As a result, in order to fully capture the behaviour of the *A. Aegypti* mosquitoes under the influence of environmental factors and its effect on the number of Microcephaly cases, later on we decided to improve on our model by adding seasonality into the birth function of *A. Aegypti* mosquitoes. Similarly, with this seasonality model, we use the least squares estimation technique to parameter

 ISBN: 978-84-617-8694-7

estimate new values of b and c, and thus calculate the future expected number of cases of Microcephaly both in the short and long term due to pregnant women being infected in their first trimester.

1.4 Results

For both models, numerical simulations are produced to illustrate the spread of the Zika virus over a period of time and the future expected number of cases of Microcephaly as a result of the Zika virus are calculated. The suggested value of $a = 3.5$/week for the parameter a, the *A. Aegypti* biting rate, is high compared to the other values in the literature. So we discuss the sensitivity of our results to different values of this parameter. We will later extend the results to an age-structured model.

Abstract

With the advent of new high-throughput next generation sequencing technologies, the volume of genetic data processed has increased significantly. It is becoming essential for these applications to achieve large-scale alignments with thousands of sequences or even whole genomes. However, all current MSA tools have exhibited scalability issues when the number of sequences increases. The main drawback of these methods is that errors made in early pairwise alignments are propagated to the final result, affecting the accuracy of the global alignment. The use of consistency information allows the final result to be improved and makes it more stable from the accuracy point of view. However, such methods are severely limited by the memory required to store the consistency information. In the present paper, we use evolutionary algorithms to analyze and determine the optimal consistency data that must be stored with the dual aim of maximizing the quality of the resulting alignment, while also reducing the memory requirements.

Key words: Multiple Sequence Alignment, Memory Efficiency, T-Coffee, Consistency, Accuracy

1 Introduction

The Multiple Sequence Alignment (MSA) is gaining importance in the analysis of biological sequence data. Phylogenetic tree reconstruction ([3]), structure prediction ([8]) or hidden Markov modeling ([2]) require MSA to infer residue-level homology or structural or functional identity.

The alignment of two sequences can be done optimally using Dynamic Programming. However, for a greater number of sequences, the alignment was shown to be a non-deterministic

 ISBN: 978-84-617-8694-7

polynomial (NP)-complete problem [15], requiring the utilization of heuristics algorithms. In this case, the goal of MSA is to find an alignment that maximizes its accuracy, approximated by the sum of similarities for all pairs of sequences (SP score, [5]).

Among the different MSA approaches, progressive alignment is the most prevalent for large data sets. Progressive alignment builds up a final MSA by combining pairwise alignments beginning with the most similar pair and progressing, following a guide tree, to the most distantly related. The main drawback of these methods is that errors made in early pairwise alignments are propagated to the final result, thus affecting the accuracy of the global alignment. To lessen the early-error propagation, consistency-based methods were proposed.

Consistency-based methods use consistency information from different pairwise alignments to improve the final result. However, such methods are severely limited by the memory requirements needed to store the consistency information. In T-Coffee (TC) [9], the most representative method in this category, the consistency-library size is in the order of $O(N^2L^2)$, N being the number of sequences and L, the length of the sequence, which limits its performance and scalability considerably.

Our final goal is to develop an algorithm able to select the best consistency information for aligning the sequences, with the aim of reducing memory requirements but maintaining the accuracy of the original method. To this end, in this paper we analyzed the individual impact of consistency on the alignment accuracy.

Achieving these objectives requires a deeper analysis of the consistency, identifying the scores that compose the optimal consistency library, which is very useful in the alignment process. Finally, based on these, a new method is proposed for selecting/filtering where consistency information must be used, with the dual aim of maximizing the quality of the resulting alignment and reducing the memory requirements.

The paper is organized as follows: Section 2 presents a brief state of the art of consistency-based MSA tools. In Section 3, we define the problem statement. In Section 4, we explore the consistency distribution and significance. From these analyses, two new methods are derived, and these are presented in Section 5. The performance and accuracy evaluation are shown in Section 6 and finally, the main conclusions are presented in Section 7.

2 State of art

The consistency based MSA has been shown to be able to increase final alignment accuracy. In [4], O. Gotoh first introduced consistency to identify anchor points for reducing the search space of an MSA. Since then, some MSA tools based on consistency have appeared in the literature.

Do et al. presented ProbCons in [1]. This was a modification of the traditional sum-of-pairs scoring system that incorporates Hidden Markov Models to specify the probability

 ISBN: 978-84-617-8694-7

distribution over all alignments between a pair of sequences. Furthermore, Subramanian et al. developed a new tool, DIALIGN-T, in [13], which formulated consistency based on finding ungapped local alignments via segment-to-segment comparisons that determine new weights using consistency. Notredame et al. presented T-Coffee. This improves the alignment accuracy by seeking consistency from a set of global and local pairwise alignments. The scoring function for aligning two sequences or two pre-aligned groups is determined by the whole set of sequences via two processes called library generation and library extension. Although T-Coffee can produce high alignment accuracy, the consistency library is time and memory consuming when the number of sequences is large. Another method based on consistency, MAFFT, was presented by Katoh et al. in [6]. This uses a new objective function combining the WSP score from Gotoh and the COFFEE-like score ([10]), which evaluates the consistency between a multiple and pairwise alignments.

However, it is known that when the number of sequences to be aligned increases, there is a degradation of accuracy [12]. Other studies focusing on phylogeny estimation from nucleotide datasets, have confirmed this hypothesis [7]. This situation can be mitigated by the use of consistency. However, consistency-based methods do not scale well because of the computational resources required to calculate and store the consistency information, which grows quadratically.

3 Consistency stage

Consistency-based methods use the point of view that prevention is the best way to avoid errors in early stages of the alignment. However, next-generation sequencing applications are unable to take advantage of this improvement due to the bottleneck their huge memory requirements represent. This problem is evident in the analysis of homologous sequences. This is especially troublesome for marker genes, like the ribosomal RNA (rRNA) where millions of sequences are already publicly available and individual studies can easily produce hundreds of thousands of new sequences [11].

Newer methodologies to use consistency have been developed since COFFEE. Although some are faster, the consistency data is not as tractable as in TC. It allows input/output of libraries and also generate the library without aligning the sequences. In this paper, we use TC to generate the information needed to complete our analysis.

3.1 Consistency calculation

The consistency library information is a collection of pairwise alignments obtained from computing all-against-all pairwise alignments. It can be represented by an NxN matrix (see Figure 1), where each cell $S_i - S_j$ when $i \neq j$ contains a list of residue matches between those sequences. Each residue match is represented by a constraint/entry $\{x, y, W_{(x,y)}\}$, x being a residue of S_i matched with y a residue of S_j and a weight $W_{(x,y)}$ representing its

 ISBN: 978-84-617-8694-7

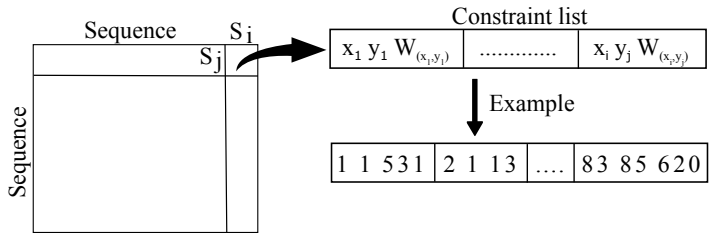

Figure 1: Library structure.

correctness. Each constraint list is used in the progressive alignment stage in order to fill the dynamic programming matrix.

The size of the consistency library is in the order of $O(N^2L^2)$, where N^2 is given by all the possible combinations of sequences without repetition and L^2 by the worst scenario in one pairwise (there is no matches between both sequences). In TC, this process is implemented in parallel as there are no dependencies between each position in the matrix.

3.2 Consistency analysis

It is impossible to calculate the optimal library. Thus, there are two alternatives for dealing with consistency: 1) Retain all the constraint information as in T-Coffee, which requires high computational resources; 2) Select only a subset of the library in order to reduce these requirements and improve efficiency. We explore this second approach, searching for a method capable of selecting a representative subset of data for a given library.

To make this possible, we need to analyze the consistency and discover patterns that allow us to discard information that does not generate added value for the alignment, preserving the consistency and ensuring the final quality. With this in mind, we designed a set of experiments to explore several consistency features. Firstly, we show the importance of the constraint selection policy. Secondly, we use evolutionary algorithms as an approximation to the optimal consistency library and then carry out a deeper study of the consistency from different points of view.

In order to carry out this analysis, a reliable database is needed. The choice is BAliBASE [14], a database of high-quality documented and manually-refined reference alignments based on 3D structural superpositions. The accuracy of the alignments is measured using two accuracy metrics: the Sum-of-Pairs (SP) and the Total Column Score (TCS), which are obtained by comparing the user alignment with a reference alignment.

We show all the results with the smallest data set included in BAliBASE, BB11001, so we are able to show more readable graphics, as the other datasets contains up to hundred sequences and longer residues per sequence. BB11001 is composed of 4 sequences and the original consistency method from TC generates 1540 constraints.

 ISBN: 978-84-617-8694-7

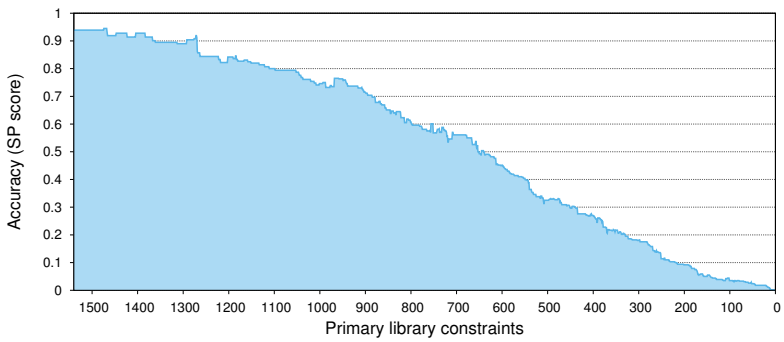

Figure 2: Random discarding policy when solving the BB11001 data set.

3.2.1 Influence of the constraints selection

First of all, we wished to demonstrate the effect of discarding the constraints of an alignment. In order to generate this test case, we developed a script which (1) executes TC and generates the output library for the input dataset and scores it, (2) removes a constraints from the library, (3) executes TC with the input library and generates a new output library scoring it and finally (4) repeats step (2) until the library is empty. In Figure 2, the alignment quality is plotted as the library size is decreased. It can be seen how a randomly discarding method behaves. Thus, it seems to be following a linear fall. When more constraints are discarded, less accuracy is achieved. For this reason, it is mandatory to have a policy capable of deciding which residue matches have to be discarded, because if not, the accuracy of the alignment is highly compromised.

The next important point is whether the residues (library information) are evenly distributed between sequences and along the alignment. From the point of view of the residue distribution in the sequences, we can observe that the number of constraints generated for each one is similar, all four of them having almost the same number of constraints, these being 853, 743, 701 and 783 respectively.

However, if we analyze the distribution of all the library residues over the alignment, we can observe more variability. Figure 3 shows that all the residue matches are grouped by their position regardless of the pairwise. A maximum (40 residues around positions 73-82) and a relative maximum (22 residues around positions 30-37) can be distinguished. These regions tend to be the most problematic areas of the alignment, because the more information you have, the more choices there are where the alignment may split. It must be decided if the histogram shape needs to be maintained when the library is reduced (maintaining more consistency in the maximums), or it could be better to trim the peaks and balance the histogram to the same level.

Finally, the distribution of the BB11001 library regarding the weighting score of the

 ISBN: 978-84-617-8694-7

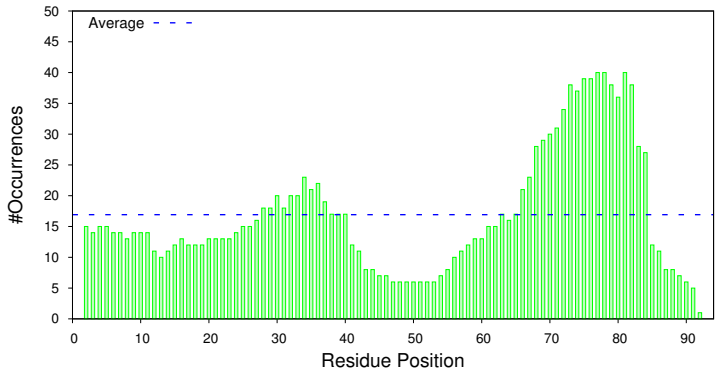

Figure 3: Constraints distribution in the Library when solving the BB11001 data set.

Table 1: Constraint weight distribution when solving the BB11001 data set.

Weight	*Occurrences*	*Percentage*	*Weight*	*Occurrences*	*Percentage*
999-900	247	16.04	499-400	42	2.73%
899-800	34	2.21	399-300	66	4.29%
799-700	47	3.05	299-200	72	4.68%
699-600	22	1.43	199-100	156	10.13%
599-500	33	2.14	99-1	821	53.31%

constrains is analyzed in Table 1. We can observe that the most outstanding weights seem to be the higher and the lower ones, while the intermediate values have a similar number of occurrences. Although the lower weighted constraints are the least valuable, regarding their correctness, half the library is filled with these. It has to be decided whether a range of weights must maintain a higher proportion of values, or if they need to be distributed equally.

3.2.2 Analyzing optimal libraries

For the following test, we need to obtain a representative approximation of the optimal library. It was decided to design a genetic algorithm (GA) to look for the best library constraints[1]. Our evolutionary gene defines which constrains are selected in the library. The genetic algorithm developed is capable of obtaining the best possible subset of constraints for a given size of the library.

The first execution showed that the GA was able to obtain an accuracy of 1 (perfect) with a subset size of 1540, meaning that some constraints add noise to the alignment (some

[1]The GA sources and its installation instructions can be found at: github.com/jllados/CL-GA.

 ISBN: 978-84-617-8694-7

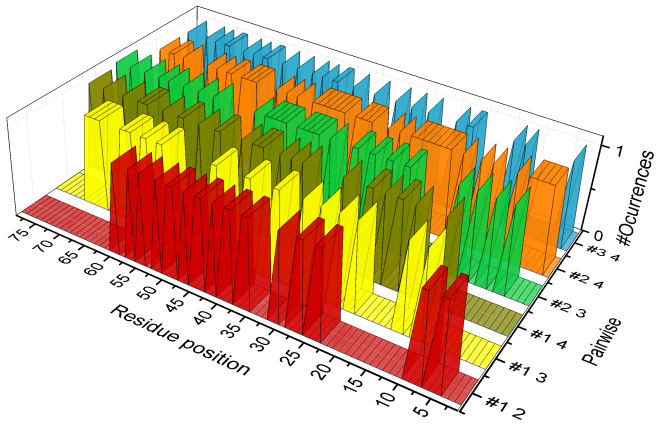

Figure 4: Residues selected with GA in the library for each pairwise in the data set BB11001 with 100 constraints (Accuracy 0.436).

constraints where repeated). This accuracy was consistent until the gene size was set below 250, so just 250 constraints were actually needed to obtain a perfect alignment.

Next, we decided to go further. We wanted to observe the behavior of the library under different situations. The following test consisted of generating 96 possible libraries with a given size of 100 constraints. On the other hand, we decided to use one hundred constraints, a few more than the length of each sequence in the data set. The reason was that we wanted to observe how well the selected residues from each constraint were distributed over the alignment length.

Figure 4 was generated using the BB11001 library as input and a given maximum library size of 100 constraints. It shows us that all the pairwise seem to have a rather similar number of constraints, #2 4 being the one with the most. This fact was interesting as in almost every data set analyzed, some pairwise always had a little more information than the others. Furthermore, there are no repeated occurrences in the data. Another fact is that we cannot see blocks of data. The constraints seem to be distributed over the length of the alignment. This is an indicator that the selected constraints may have a variety of weights (frequently the most heavily weighted constraints seem to be concentrated in the same region). This solves the previous doubt about Figure 3, we should balance the histogram among the residues.

Then we need to look at the constraints weight distribution. They were separated into different groups. Each group represents the weight range and a the average number of occurrences over the 96 test: 999-900: 64, 899-800: 4, 799-700: 8, 699-600: 1, 599-500: 3, 499-400: 2, 399-300: 3, 299-200: 2, 199-100: 3 and 99-1: 7. In this particular case, 64%

of the library is composed of the most weighted ones, while the rest is well distributed. In comparison with Table 1, were the library contained the 1540 constraints, the lower ranges are drastically reduced and a bigger proportion is maintained for the highest ones.

Regarding the fact of having more data in one pairwise, Figure 5a shows that #2 4 almost doubles the occurrences of the rest. The reason can be observed in Figure 5b, as it is known that MSA aligners follow the order of a guide tree to generate the alignment. It is reasonable that the first couple of sequences to be aligned (the most closely related ones) contain more information. We must ensure its accuracy to avoid propagating an error to the rest of profile alignments.

3.3 Memory efficient consistency library

The following premises were extracted from the previous analysis, in order to implement the new method for build de consistency library:

- The higher the weight, the better.
- The most closely related leaves of the guide trees must have more constraints.
- The constraints have to cover all the domain of the alignment.

These premises were used to define the pattern that we followed in the design of the method, named Memory Efficient consistency Library (MEL), to generate an algorithm capable of deciding whether or not a constraint should be maintained.

The implementation of MEL, Algorithm 1, is based on a temporary queue structure, in which all the library constraints are stored sorted by their weight. After this, each constraint is evaluated in order to determine if it must be pushed into the final list. The evaluation

for *each sequence* $S_i \in S_1..S_N$ *and* $S_i \neq S_j$ **do**
  for *each sequence* $S_j \in S_i..S_N$ *where* $S_i \neq S_N$ **do**
    PA_{ij}=Pairwaise_Alignment_Fork(S_i, S_j);
    for *each residue* $x \in S_i, y \in S_j|$ *are aligned in* $PA_{i,j}$ **do**
      $W_{(x,y)} = \frac{\sum OCCURRENCE(PA_{i,j})}{RESIDUES(PA_{i,j})}$;

    end
    MAX_Constraints_$PA_{ij} = \frac{MAX_Library}{C_{N,2}}$;
    Bound=Ceil(MAX_Constraints_PA_{ij},MAX_Length(S_i, S_j));
    if *isleaf*(S_i, S_j) **then**
      MAX_Constraints_PA_{ij}+=remainder;
    end
    for *each constraint* $x_i, y_j, W_{(xi,yi)} \in Q$ **do**
      if *balanced*($x_i, y_j, Bound$)$|$ *not full MAX_Constraints_*PA_{ij} **then**
        $L(S_i^x, S_j^y) = W_{(S_i^x, S_j^y)}$;
      end
    end
  end
end

Algorithm 1: Memory Efficient consistency Library (MEL) construction

function has to check a pair of parameters, the first being the maximum bound previously generated. With this value, the method prunes the number of residues matching the same region of the alignment. The second parameter indicates whether or not a new entry has enough memory to be allocated. Also, if the evaluated pairwise PA_{ij} is a leaf node, the remainder lost allocating each pairwise its added to the maximum number of constraints. As the queue is sorted by weight, the higher ones will be the first to be evaluated, thus ensuring that they have more chances of surviving than the lower ones.

Our functions and data structures were adapted to make use of the current parallelism implemented in TC.

4 Experimentation

In this section, we evaluate MEL. This experimental study evaluates (1) the effectiveness of the discarding method, (2) the accuracy obtained from our proposal decreasing the amount

Table 2: BAliBASE accuracy results with MEL.

of library/pairwise and finally (3) the global performance of T-Coffee[2].

The tests consisted of solving BAliBASE. The figures are total Sum-of-Pairs (SP) produced using bali score. The first column indicates the number of entries used in the run and the second the percentage reduction. The average score over all families is given in the third column. The results for BAliBASE subgroupings are in columns 4–9. Finally, the last column refers to the total execution time.

First, we present the results produced by reducing the total numbers of entries on BAliBASE with MEL. These are shown in Table 2. We must highlight the results between 84.89% and 48.73%. In comparison with the full library accuracy, all these cases behave quite similarly, losing on average 0.002 at most. Despite this, the library is reduced by 50%, which is a far greater improvement.

In general, we must say that the reduced scenarios attain a better accuracy with RV11 (equidistant sequences of similar length with very divergent conservation <20% identity) and a better gain is achieved with RV30 (equidistant divergent families with <25% residue identity between groups) and RV40 (sequences with N/C-terminal extensions). Furthermore, concerning time, we can see an inverted bell curve, fewer entries implies less execution time, until the minimum is achieved (47M entries), where time increases.

Next, we evaluated the above-mentioned random discard policy and the best possible scenario against the proposal presented. Figure 6 shows the accuracy of aligning as the number of entries decreases. The behavior is clear, the greater the reduction applied, the more pronounced the impact becomes. As can be seen, MEL is notably superior to the random one, so it is clear enough that a discarding policy is worth it. Even though there is a gap between our method and the GA, because GA uses the reference alignment and none algorithm will be able to reach that result. Despite this, both shapes are quite similar.

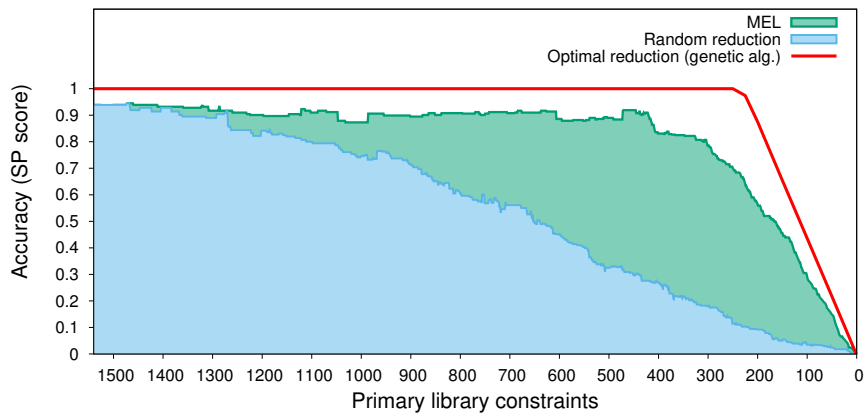

Figure 6: Comparison of MEL with the Optimal and a random policy for BB11001 dataset.

5 Conclusions

In this paper, the authors present a method to build the consistency library of a Multiple Sequence Aligner. The approach is applied during the process of building the library. Its goal is to maintain the best consistency information while reducing the size of the memory that the library may use without affecting the accuracy.

We proved that MEL is able to filter the consistency library more efficiently than the current methods. This has a positive effect on an MSA aligner, because the fewer the constraints used, the smaller the amount of memory needed. One of the best scenarios occurs when the library maintains around 50% of the entries. This means that we are able to reduce the memory requirements by half while obtaining almost the same results.

In the future, we must integrate consistency with a more basic MSA tool in order to avoid errors in the early stages of the alignment and maintain the accuracy.

[2] *CORISA, University of Salerno, Italy*

emails: loia@unisa.it, stomasiello@unisa.it

Abstract

In this paper we investigate the consensus of a new class of uncertain multi-agent systems, according to the Liu's uncertainty theory, as a counterpart of stochastic multi-agent systems. We revise the concept of finite-time stability in the context of uncertainty theory.

Key words: uncertain differential equation, stability, Liu process

1 Introduction

In the last decades, analysis and control design of multi-agent systems (MAS) have become very popular, because of their applications including traffic control, sensor networks, mobile robots and social networks.

In particular, stochastic MAS attracted attention due to the fact that in real-world applications, the behaviour of dynamical systems is concretely affected by disturbances and uncertainties because of the unpredictable environmental conditions (e.g. see [1]).

Stability problems, also known as consensus issues, for such class of MAS have been widely discussed. Consensus means the states of all the agents converge to a common value according to some control schemes. It is usually referred to the asymptotic behaviour of the trajectories of the system as time goes to infinity. The concept of finite-time stability for stochastic systems was introduced in [2] and adapted to the consensus problem in MAS (e.g. see [3]), in order to get a faster convergence rate.

Recently, an uncertainty theory has been proposed by Liu [4]. In particular, Liu [5] introduced the concept of uncertain process, in order to describe the evolution of an uncertain phenomenon, and designed a canonical Liu process [6], which is an uncertain process

 ISBN: 978-84-617-8694-7

with stationary and independent normal uncertain increments. Liu [6] founded the uncertain calculus as a counterpart of Ito calculus, by introducing a type of uncertain differential equation (UDE) driven by canonical Liu process.

In this work, we aim to introduce a new class of uncertain MAS, according to the Liu's theory, as a counterpart of stochastic MAS.

2 Preliminaries

Definition 1 *Let $\mathcal{L}$ be a σ-algebra on a nonempty set Γ. The uncertain measure $\mathcal{M}$ is a set function $\mathcal{M}: \mathcal{L} \to [0,1]$, satisfying three axioms:*

- $\mathcal{M}\{\Gamma\} = 1$ *for the universal set Γ (normality axiom);*
- $\mathcal{M}\{\Lambda\} + M\{\Lambda^c\} = 1$ *for any event Λ (duality axiom);*
- *for every countable sequence of events $\Lambda_1, \Lambda_2, \ldots$, we have* $\mathcal{M}\bigcup_{i=1}^{\infty}\Lambda_i \leq \sum_{i=1}^{\infty}\mathcal{M}\{\Lambda_i\}$ *(subadditivity axiom).*

The triplet $(\Gamma, \mathcal{L}, \mathcal{M})$ is called an uncertainty space.

Definition 2 *[6] An uncertain process C_t is said to be a canonical Liu process if*

- $C_0 = 0$ *and almost all sample paths are Lipschitz continuous;*
- C_t *has stationary and independent increments;*
- *every increment $C_{s+t} - C_s$ is a normal uncertain variable with expected value 0 and variance t^2, whose uncertainty distribution is*

$$\Phi_t(x) = \left(1 + \exp(-\frac{\pi x}{\sqrt{3}t})\right)^{-1} \tag{1}$$

Definition 3 *[6] Let C_t be a canonical Liu process, f and g two given functions. Then*

$$dX = f(t,X)dt + g(t,X)dC_t \tag{2}$$

is called an uncertain differential equation.

The UDE (2) has a unique solution if the functions $f(t,X)$ and $g(t,X)$ satisfy [7]

 ISBN: 978-84-617-8694-7

- the linear growth condition

$$|f(t,X)| + |g(t,X)| \leq K(1+|X|), \forall X \in \mathbb{R}, t \geq 0 \tag{3}$$

- the Lipschitz condition

$$|f(t,X) - f(t,Y)| + |g(t,X) - g(t,Y)| \leq K|X-Y|, \quad \forall X \in \mathbb{R}, t \geq 0 \tag{4}$$

  for any constant K.

Obviously, the UDE (2) admits a trivial solution.

Definition 4 *[6] An uncertain differential equation is said to be stable if for any solution X and Y, with initial values X_0 and Y_0 respectively, any given (though arbitrarily small) $\xi, \epsilon > 0$, there exists $\delta > 0$ s.t.*

$$\mathcal{M}\{|X-Y| > \xi\} < \epsilon, \qquad \forall t > 0 \tag{5}$$

whenever $|X_0 - Y_0| < \delta$.

In the following, we will revise some definitions in the context of the uncertainty theory.

We first introduce a new definition of finite-time stability for the UDE (2). This definition represents the counterpart of the one for stochastic nonlinear systems [2].

Definition 5 *The trivial solution of UDE (2) is said to be finite–time stable, if the equation admits a unique solution, say $X(t;X_0)$, for any initial value $X_0 \in \mathbb{R}^n$ s.t.*

- *the corresponding settling time τ_{X_0} is finite, that is $\mathcal{M}\{\tau < \infty\} = 0$;*
- *the UDE is stable.*

All the definitions above can be easily extended to the multi-dimensional case [8].

3 Problem formulation

Assumption 6 *Let C be a canonical Liu process. There exists a continuous function $\eta(t)$ s.t. $dC{=}\eta(t)dt$.*

Remark 7 *Let us consider, for instance, the continuously differentiable function $h(t,C) = tC$. By fixing $dh = Cdt + tdC = 0$, then the assumption is trivially true.*

 ISBN: 978-84-617-8694-7

Let the dynamics of a first-order multi-agent system along an undirected graph V be described as follows

$$\dot{x}_i = f(x_i) + u_i + g(x_i)\eta(t), \qquad x_i(0) = x_{0i}, \qquad i \in V \tag{6}$$

where $x_i \in \mathbb{R}$ is the state of the ith agent, $X^T = (x_1, x_2, \ldots, x_n)$ is the state of the whole network, u_i is the local control input and x_{0i} are the initial conditions. Henceforth it is assumed that the functions $f(x_i)$ and $g(x_i)$ satisfy the conditions (3) and (4).

Due to the Assumption 1, Eq. (6) can be written as follows

$$dx_i = (f(x_i) + u_i)dt + g(x_i)dC, \qquad x_i(0) = x_{0i}, \qquad i \in V \tag{7}$$

Now we introduce the finite-time quasi–consensus.

Definition 8 *The first-order finite-time consensus is achieved if there exists a settling time T, satisfying $\mathcal{M}\{T < \infty\} = 0$, such that*

$$\mathcal{M}\{x_i = x_j, \forall t \geq T\} = 0, \qquad \forall i \neq j = 1, \ldots, n. \tag{8}$$

In order to discuss the finite-time consensus, one has to prove that the trivial solution of the UDE (7) in terms of errors $e_i = x_i - \frac{1}{n}\sum_{j=1}^{n} x_j$ is finite–time stable.

Electron-nucleus cusp dressing in single-determinant wave functions

Pierre-François Loos[1], Anthony Scemama[1], Yann Garniron[1] and Michel Caffarel[1]

[1] *Laboratoire de Chimie et Physique Quantiques,, Université de Toulouse, CNRS, UPS, France*

emails: loos@irsamc.tps-tlse.fr, scemama@irsamc.tps-tlse.fr, garniron@irsamc.tps-tlse.fr, caffarel@irsamc.tps-tlse.fr

Abstract

Universal features of the many-electron wave function Φ are of continued interest to physicists and chemists, as they guide the construction of highly accurate wave functions [1, 2], explicitly correlated ansätze within F12 theory [3, 4] and accurate Jastrow factors for quantum Monte Carlo (QMC) calculations [5]. The Coulombic singularity at short interparticule distances dominates all other terms and, near the two-particle coalescence point, the behavior of Φ becomes independent of other details of the system.

Early work by Kato [6], and elaborations by Pack and Byers-Brown [7], showed that, as one electron at $\boldsymbol{r}_i$ approaches a nucleus of charge Z_A at $\boldsymbol{r}_A$, we have

$$\left.\frac{\partial \langle \Phi \rangle}{\partial r_i}\right|_{r_i=r_A} = -Z_A \, \langle \Phi \rangle|_{r_i=r_A} \, , \tag{1}$$

where $\langle \Phi \rangle$ is the spherical average of the n-electron wave function $\Phi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_n)$ about $\boldsymbol{r}_i = \boldsymbol{r}_A$.

To remove divergences in the local energy $\Phi^{-1}\hat{H}\Phi$ at the electron-nucleus coalesence points, cusp conditions such as (1) must be satisfied. These divergences are especially harmful in diffusion QMC calculations, where they can lead to a large increase of the statistical variance, population-control problems and significant biases [5].

In this talk, we propose to show how to introduce the correct electron-nucleus cusp within single-determinant wave functions (such as Hartree-Fock wavefunction) via a dressing of the Fock matrix. This method, involving effective Hamiltonian theory, has been shown to be also successful in other scenario [8, 9]. Illustrative examples will be given for atomic and molecular systems [10].

A consistent second order theory about the equilibrium figures of rotating celestial bodies

José Antonio López Ortí[1], Manuel Forner Gumbau[1] and Miguel Barreda Rochera[1]

[1] *Departmento de Matemáticas, Universidad Jaume I de Castellón*

emails: lopez@mat.uji.es, fornerm@mat.uji.es, barreda@mat.uji.es

Abstract

This paper is addressed to the study of equilibrium figures of uniform rotating celestial bodies. The study of this topic in the classical theory is based on the Laplace desideratum which, unfortunately cannot be proved.

After proving in a previous paper a first order amplitudes theory, the authors extend now their work up to second order. So, the main achievement of this work is its capacity to obtain the results up to second order in amplitudes without using the unproved Laplace desideratum needed by the classical theory.

The paper is based on the Clairaut method and the results about the deformation amplitudes obtained in the first order theory are used in our developments. From these results, by using the asymptotic properties of numerical quadrature, a consistent second order theory is obtained.

Key words: Celestial Mechanics. Figures of Celestial Bodies. Spherical Harmonics. Potential Theory.
MSC 2000: 70F15, 74Gxx.

1 Introduction

The main objective of this work is to develop a consistent second order amplitudes theory to evaluate the potential of a rotating deformable celestial body when the hydrostatic equilibrium of the system has been achieved. This case can be modeled as:

$$\overrightarrow{\nabla} P = \rho \overrightarrow{\nabla} \Psi$$
$$\triangle \Psi = -4\pi G\rho + 2\omega^2$$

 ISBN: 978-84-617-8694-7

where P is the pressure, ρ is the density, Ψ is the total potential, $\triangle$ is *Laplace* operator, G is the gravitational constant, and $\overrightarrow{\omega}$ is the system's angular velocity.

To integrate these equations in a general case of mass distribution a state equation relating pressure and density is needed.

To assess the full potential Ψ to calculate the self-gravitational potential Ω and the centrifugal potential V_c it is needed. The equilibrium configuration involves the hydrostatic equilibrium that is to say, the rigid rotation of the system corresponding to the minimum potential and, according with Kopal [4], this state involves the identification of equipotential, isobaric, isothermal and isopycnic surfaces.

To study the structure of the body, a coordinate system $OXYZ$ will be defined where O is the center of mass of the component, OX is an axis fixed in an arbitrary point of the body equator, OZ the axis parallel to angular velocity $\vec{\omega}$ and finally OY defines a direct trihedrom $OXYZ$.

For an arbitrary point P in the primary component the Clairaut coordinates are given by (a, θ, λ) where a is the radius of the sphere containing the same mass that the equipotential surface containing P and (θ, λ) the angular spherical coordinates of P.

Classical theory of this problem can see in Finlay [1], Kopal [3], [4].

To achieve our main objective two different methods are proposed in this paper: the first one, which we will call analytical method, is similar to that used by Laplace to develop the inverse of the distance between two planets, and the second one, which we have called numerical quadrature method, will be based on the asymptotic properties of numerical quadrature formulas.

The main problem to develop the total potential is the development of the self-gravitational potential. For this purpose we will proceed by using the classical development of the potential as

$$\Omega = U + V, \qquad U = G\int_{r_0}^{r_1}\int_0^{2\pi}\int_0^{\pi}\frac{dm'}{\Delta}, \quad V = G\int_0^{r_0}\int_0^{2\pi}\int_0^{\pi}\frac{dm'}{\Delta}$$

where Δ is the distance between the positions of element of mass dm' placed in P' and the point P, r_0 is the radius the sphere centered in O containing P and r_1 is the radius of the minor sphere centered in O containing the primary component. The mas element is given by $dm' = \rho r \cos\theta' d\theta' d\lambda' dr'$

2 Classical theory about the self-gravitational potential

The classical theory is based on the development of the inverse of the distance:

$$\frac{1}{\Delta} = \begin{cases} \frac{1}{r}\sum\limits_{n=0}^{\infty}\left(\frac{r'}{r}\right)P_n(\cos\gamma) & r > r' \\ \frac{1}{r'}\sum\limits_{n=0}^{\infty}\left(\frac{r}{r'}\right)P_n(\cos\gamma) & r < r' \end{cases}, \tag{1}$$

 ISBN: 978-84-617-8694-7

where γ is the angle between $\overrightarrow{OP}$ and $\overrightarrow{OP'}$. From this development we can write in the form $\Omega = \sum_{n=0}^{\infty} U_n r^n + \sum_{n=1}^{\infty} V_n r^{-n-1}$, where

$$U_n = \int_{r_0}^{r_1}\int_0^{\pi}\int_0^{2\pi} r'^{1-n} P_n(\cos\theta')dr'd\theta'd\lambda',\ V_n = \int_0^{r_0}\int_0^{\pi}\int_0^{2\pi} r'^{2+n} P_n(\cos\theta')dr'd\theta'd\lambda'. \tag{2}$$

By symmetry reasons the coordinate r is connected with the Clairaut coordinates (a,θ,λ) by $r = a(1+\sum_{n=0}^{\infty} f_{2n}(a)P_{2n}(\cos\theta))$, where $f_{2n}(a)$ are the amplitudes and $P_{2n}(\cos\theta)$ the Legendre polinomials. The classical theory assumes that

$$U_n = \frac{G}{2-n}\int_{a_0}^{a_1}\rho'\frac{\partial}{\partial a}\left[\int_0^{\pi}\int_0^{2\pi} r'^{1-n}P_n(\cos\theta')d\theta'd\lambda'\right]da',\quad if n\neq 2 \tag{3}$$

$$U_2 = G\int_{a_0}^{a_1}\rho'\frac{\partial}{\partial a}\left[\int_0^{\pi}\int_0^{2\pi}\ln(r')P_n(\cos\theta')d\theta'd\lambda'\right]da' \tag{4}$$

$$V_n = \frac{G}{n+3}\int_0^{a}\rho'\frac{\partial}{\partial a}\left[\int_0^{\pi}\int_0^{2\pi} r'^{n+3}P_n(\cos\theta')d\theta'd\lambda'\right]da' \tag{5}$$

Notice that these functions are defined in the internal and external region as the equipotential surface that contains P and it is necessary to assume these series converge in this region [2], [6]. This assumption is known as Laplace desideratum.

From these hypothesis and approaching r'^k and $\ln r'$ up to the required order in amplitudes we obtain $\Omega = \sum_{n=0}^{\infty}\sum_{m=-n}^{n}\left[F_{2n}(a)r^n + E_{2m}r^{-n-1}\right]P_{2n}(\cos\theta)$.

3 A second order consistent theory of autogravitatory potential

To solve the inconvenience to make use of the Laplace desideratum assumption, the authors have developed [5] two different methods to obtain the self-gravitational potential up to first order in amplitudes without using the referred non demonstrated hypotesis.

In this same paper the potential obtained in the classical theory has been shown to be right up to first order in ω^2.Therefore, from this it is derived that the amplitudes [4] it is only $f_2(a)$ are of first order in ω^2. From this result it easy to probe that up to second order in ω^2.

Being D the equipotential surface containing P and let $r = r_0$ the sphere containing P then equation of this sphere in Clairaut coordinates will be given up to second order in amplitudes by

$$a' = a(1 + D - D' + D'^2 - DD'),$$

 ISBN: 978-84-617-8694-7

where $D = \sum_{n=0}^{\infty} f_{2n}(a)P_{2n}(\cos\theta)$ and $D' = \sum_{n=0}^{\infty} f_{2n}(a')P_{2n}(\cos\theta')$. Evaluating the integrals (2) with a numerical quadrature method [5] it is easy to show that the obtained results up to second order (3), (4) and (5) are false.

As it has been discussed up to now, the classical theory developments of the inner and outer potentials of the auto gravitational potential up to second order do not coincide with those obtained in this work. However, the results up to the second order obtained in this work, without using Laplace's desiderata, prove that the auto gravitational potential up to the second order obtained in classical theory is correct.

Abstract

An active attack is presented which targets the well-known multiparty key exchange protocol CLIQUES and assumes malicious control of the communications of an arbitrary user for the duration of the key exchange only.

Key words: Group Key Management, Active Attack
MSC 2000: 95A60

1 Introduction

Group Key Management is a major concern in many applications nowadays, mainly due to the so called Internet of Things getting more and more widespread. One of the most important approaches to solve this matter is using a distributed solution, where users collaborate to build a common key. Examples of this type of protocols can be found in [2] and [6] and their references.

One of the best known protocols for distributed Group Key Management is known as CLIQUES and was proposed by Steiner et al. in [5]. In [4] the authors provided an active attack on this protocol based on the well-known man-in-the middle attack for the case of an attacker that is able to control communications of a user with a special role in the group, namely the last user during the set up phase, i.e., when the group is collaborating to agree on the first common key. They also show that it is possible that the attacker leaves the group without letting the group members know about the attack.

Our aim in this work is to show the possibility of extending the attack to any member of the group. The work is structured as follows. In the second section we describe the original protocol. In the third section we show the attack and in the last section we conclude the paper.

ISBN: 978-84-617-8694-7

2 The Group Key Agreement

The following protocol describes the Initial Key Agreement of CLIQUES named as IKA.2 in [5]. In [3], the authors generalize these schemes considering a general action on a semigroup, and this is how IKA.2 is presented below.

Suppose we have n users $\mathcal{U}_1, \ldots, \mathcal{U}_n$ who wish to agree upon a common key.

Let G be an abelian group, written multiplicatively. Let S be a set, and suppose we have a group action

$$\begin{aligned} G \times S &\to S \\ (g, s) &\mapsto g \cdot s. \end{aligned}$$

The users publicly agree on a common element $C_0 = s \in S$, and for each $i = 1, \ldots, n$, the user $\mathcal{U}_i$ selects a secret group element $g_i \in G$.

The protocol proceeds as follows:

(1) For $i = 1, \ldots, n-2$, $\mathcal{U}_i$ sends to $\mathcal{U}_{i+1}$ the message $C_i = g_i \cdot C_{i-1}$.

(2) $\mathcal{U}_{n-1}$ broadcasts $C_{n-1} = g_{n-1} \cdot C_{n-2}$ to the other users $\mathcal{U}_1, \ldots, \mathcal{U}_{n-2}, \mathcal{U}_n$.

(3) $\mathcal{U}_n$ computes the shared key $K = g_n \cdot C_{n-1}$.

(4) For $i = 1, \ldots, n-1$, $\mathcal{U}_i$ sends $D_i = g_i^{-1} \cdot C_{n-1}$ to $\mathcal{U}_n$.

(5) $\mathcal{U}_n$ broadcasts $\{g_n \cdot D_1, g_n \cdot D_2, \ldots, g_n \cdot D_{n-1}, C_{n-1}\}$ to $\mathcal{U}_i$, $i = 1, \ldots, n-1$.

(6) For $i = 1, \ldots, n-1$, $\mathcal{U}_i$ computes the shared key $K = g_i \cdot (g_n \cdot D_i)$.

3 The active attack

In this section we give an active attack on the protocol described in the preceding section. The aim of the attacker, $\mathcal{M}$, is that the users $\mathcal{U}_1, \ldots, \mathcal{U}_n$ agree on a shared key as it is obtained after running the protocol, but she will know the key as well, so she can listen and send messages using that common key as if she was a legal member of the group.

As in a usual man-in-the-middle attack, $\mathcal{M}$ needs to have full control over the communication of a user $\mathcal{U}_i$, $i \in \{1, \ldots, n\}$, but only during the key exchange. Then, unlike in a regular man-in-the-middle attack, she does not need to maintain this control after the key exchange is completed. In this paper we will assume that $i < n-1$. The case $i = \{n-1, n\}$ is given in [4].

In the beginning, $\mathcal{M}$ chooses her own secret group element $g \in G$. She then proceeds as follows:

 ISBN: 978-84-617-8694-7

(a) Step (1) is carried out as usual until $\mathcal{U}_i$ sends $C_i = g_i \cdot C_{i-1}$ to $\mathcal{U}_{i+1}$. At this point he is sitting in step (1) waiting for the broadcast of $\mathcal{U}_{n-1}$.

(b) $\mathcal{M}$ stops this message and sends $C_i' = g \cdot C_{i-1}$ to $\mathcal{U}_{i+1}$ as if she was $\mathcal{U}_i$.

(c) $\mathcal{U}_{n-1}$ broadcasts $C_{n-1} = g_{n-1} \cdot C_{n-2}$ to the other users $\mathcal{U}_1, \ldots, \mathcal{U}_{n-2}, \mathcal{U}_n$. At this point $\mathcal{U}_n$ computes the key $K = g_n \cdot C_{n-1}$.

(d) $\mathcal{M}$ stops this message for $\mathcal{U}_i$ and sends $D_i = g^{-1} C_{n-1} = \left(\prod_{j=1, j\neq i}^{n-1} g_j \right)$ to $\mathcal{U}_n$.

(e) $\mathcal{U}_n$ broadcasts $\{g_n \cdot D_1, g_n \cdot D_2, \ldots, g_n \cdot D_{n-1}, C_{n-1}\}$ to $\mathcal{U}_i$, $i = 1, \ldots, n-1$. $\mathcal{M}$ stops this message for $\mathcal{U}_i$.

(f) $\mathcal{M}$ computes $K = g \cdot (g_n \cdot D_i)$, which is the common key computed by all the remaining users.

(g) $\mathcal{M}$ chooses $b \in G$ and sends $b \cdot K$ to $\mathcal{U}_i$ as if it was the message that $\mathcal{U}_{n-1}$ broadcasts in (2).

(h) $\mathcal{U}_i$ sends $g_i^{-1} \cdot (b \cdot K)$ to $\mathcal{U}_n$.

(i) $\mathcal{M}$ stops this message, computes $g_i^{-1} \cdot K$ using b^{-1}, and sends back $\{g_n \cdot D_1, g_n \cdot D_2, \ldots, g_i^{-1} \cdot K, \ldots, g_n \cdot D_{n-1}, C_{n-1}\}$ to $\mathcal{U}_i$.

(j) $\mathcal{U}_i$ recovers $g_i \cdot (g_i^{-1} \cdot K) = K$.

By the end of the attack all users $\mathcal{U}_1, \ldots, \mathcal{U}_n$ and $\mathcal{M}$ share a common key and $\mathcal{M}$ stays in the group as another "invisible" legal member.

She can also leave the group without leaving any evidence of her stay in the group. To do so, before any rekeying takes place, $\mathcal{M}$ carries out the following simple strategy.

(i) $\mathcal{M}$ chooses g' and computes a new key $g' \cdot K = \left(g' g \prod_{j=1, j\neq i}^{n} g_j \right) \cdot s$.

(ii) $\mathcal{M}$ broadcasts $\{g' \cdot (g_n \cdot D_1), g' \cdot (g_n \cdot D_2), \ldots, g' \cdot (g_i^{-1} \cdot K), \ldots, g' \cdot (g_n \cdot D_{n-1}), g' \cdot C_{n-1}\}$ to $\mathcal{U}_1, \ldots, \mathcal{U}_n$.

Thus $\mathcal{U}_1, \ldots, \mathcal{U}_n$ and $\mathcal{M}$ will share the new key $g' \cdot K$ and she will keep being an "invisible" legal member of the group until a new rekeying is done by any user. Then they all will be rekeyed but they will never know about the attack.

We point out that $\mathcal{M}$ may take control of the group by carrying out the leaving strategy for as long as she wishes before any other member rekeys.

 ISBN: 978-84-617-8694-7

4 Conclusions

We have shown that IKA.2 implementation of CLIQUES is insecure unless the Initial Key Agreement takes place under an authenticated environment. In particular, we have presented an active attack that allows the attacker to share a common key with all the legal members in a communication group and a strategy to take control of the communications or leave the group without letting the legal members know about the attack.

In [1] the authors propose an authenticated version of IKA.2 for CLIQUES. An analogous attack can be also carried out for this, but a desynchronizing of users may take place and the attack will be discovered. However the attacker may also be part of the group without letting the legal members know about her presence during the attack.

Existence of unbounded solutions of IVPs with ϕ-Laplacian

Lucía López-Somoza[1]

[1] *Institute of Mathematics, University of Santiago de Compostela*

(Joint work with J. Burkotová, I. Rachunková, M. Rohleder, J. Stryja)

emails: lucia.lopez.somoza@usc.es

Abstract

We will study the existence of unbounded solutions of the problem

$$(p(t)\phi(u'(t)))' + p(t)f(\phi(u(t))) = 0, \quad u(0) = u_0 \in [L_0, L], \quad u'(0) = 0.$$

Key words: second order ODE, ϕ-Laplacian, unbounded solution, time singularity.

1 Introduction

Our aim is to analyze the singular nonlinear equation

$$(p(t)\phi(u'(t)))' + p(t)f(\phi(u(t))) = 0, \tag{1}$$

coupled with the initial conditions

$$u(0) = u_0, \quad u'(0) = 0, \quad u_0 \in [L_0, L]. \tag{2}$$

Problem (1)-(2) is investigated under the basic assumptions

$$\phi \in C^1(\mathbb{R}), \quad \phi'(x) > 0 \text{ for } x \in (\mathbb{R} \setminus \{0\}), \quad \phi(\mathbb{R}) = \mathbb{R}, \quad \phi(0) = 0, \tag{3}$$

$$L_0 < 0 < L, \quad f(\phi(L_0)) = f(0) = f(\phi(L)) = 0, \tag{4}$$

$$f \in C[\phi(L_0), \infty), \quad xf(x) > 0 \text{ for } x \in ((\phi(L_0), \phi(L)) \setminus \{0\}), \quad f(x) \leq 0 \text{ for } x > \phi(L), \tag{5}$$

$$p \in C[0, \infty) \cap C^1(0, \infty), \quad p'(t) > 0 \text{ for } t \in (0, \infty), \quad p(0) = 0. \tag{6}$$

Our problem can be singular in the sense that $p(0) = 0$ and $1/p(t)$ may not be integrable.

Definition 1.1. Let $[0, b) \subset [0, \infty)$ be a maximal interval such that a function $u \in C^1[0, b)$ with $\phi(u') \in C^1(0, b)$ satisfies equation (1) for every $t \in (0, b)$ and let u satisfy the initial conditions (2). Then u is called a *solution* of problem (1)-(2) on $[0, b)$.

 ISBN: 978-84-617-8694-7

Definition 1.2. Consider a solution of problem (1)-(2) on $[0,\infty)$ with $u_0 \in [L_0, L]$ and denote $u_{sup} = \sup\{u(t)\colon t \in [0,\infty)\}$.
If $u_{sup} = L$, then u is called a *homoclinic solution* of problem (1)-(2).
If $u_{sup} < L$, then u is called a *damped solution* of problem (1)-(2).

Definition 1.3. Let u be a solution of (1)-(2) on $[0,b)$. If there exists $c \in (0,b)$ such that $u(c) = L$, $u'(c) > 0$, then u is called an *escape solution* of problem (1)-(2) on $[0,b)$.

Analytical properties of solutions of problem (1)-(2) with a ϕ-Laplacian have already been studied in [1] with a focus on the existence of bounded solutions. The goal of this work (which can be found in [2]) is to find conditions which guarantee the existence of unbounded solutions of (1)-(2). Since in general an escape solution does not need to be unbounded, criteria for an escape solution to tend to infinity are necessary. We distinguish two cases:

- Case I: If functions ϕ^{-1} and f are Lipschitz continuous, the uniqueness of solution of problem (1)-(2) is guaranteed.
- Case II: If ϕ^{-1} and f are not Lipschitz continuous, the lack of uniqueness causes difficulties. Problems are overcome by means of the lower and upper function method.

2 Auxiliary Problem

To simplify our considerations we introduce the auxiliary equation

$$(p(t)\,\phi(u'(t)))' + p(t)\,\tilde{f}(\phi(u(t))) = 0, \quad t \in (0,\infty), \tag{7}$$

where

$$\tilde{f}(x) = \begin{cases} f(x) & \text{for } x \in [\phi(L_0), \phi(L)], \\ 0 & \text{for } x < \phi(L_0), \quad x > \phi(L). \end{cases}$$

Two important hypothesis that we will assume are

$$\lim_{t\to\infty} \frac{p'(t)}{p(t)} = 0, \tag{8}$$

$$\exists \bar{B} \in (L_0, 0)\colon \tilde{F}\left(\bar{B}\right) = \tilde{F}(L), \quad \text{where } \tilde{F}(x) = \int_0^x \tilde{f}(\phi(s))\,\mathrm{d}s, \quad x \in \mathbb{R}. \tag{9}$$

Under the previous hypothesis, the two following results are proved in [1].

Theorem 2.1. *If* (3)–(6) *hold, then for each* $u_0 \in [L_0, L]$, *there exists a solution of* (7)-(2). *Moreover, if*

$$f \in \mathrm{Lip}[\phi(L_0), \phi(L)], \quad \text{and} \quad \phi^{-1} \in \mathrm{Lip}_{\mathrm{loc}}(\mathbb{R}), \tag{10}$$

then any solution of (7)-(2) *with* $u_0 \in [L_0, L]$ *is unique on* $[0,\infty)$.

Theorem 2.2. *Assume* (3)–(6), (8) *and* (9). *Then, for each* $u_0 \in \left[\bar{B}, L\right)$, *problem* (1)-(2) *has a solution. If* $u_0 \in \left[\bar{B}, L\right)$, *every solution is damped.*

 ISBN: 978-84-617-8694-7

Now we will formulate the results of existence of escape solutions for the auxiliary problem. We note that, despite the results are quite similar, their proofs are quite different.

Theorem 2.3 (Existence of escape solutions of (7)-(2), Case I)**.** *If* (3)–(6), (8)–(10) *hold, then there exist infinitely many escape solutions of* (7)-(2) *with starting values in* $(L_0, \bar{B})$.

Theorem 2.4 (Existence of escape solutions of (7)-(2), Case II)**.** *If* (3)–(6), (8)–(9) *hold, then there exist infinitely many escape solutions of* (7)-(2) *with starting values in* $\left[L_0, \bar{B}\right)$.

3 Unbounded solutions

Now we will provide conditions for p and f to ensure the existence of unbounded solutions of (1)-(2). Assume that (3)–(6), (8) and (9) hold and let u be a solution of (7)-(2). Then

$$\exists\, c \in (0,\infty)\colon u(t) \in [L_0, L),\ t \in [0, c), \quad u(c) = L, \quad u'(c) > 0. \tag{11}$$

Clearly, u fulfils (1) on $[0, c]$ and can be extended as a solution of the original problem (1)-(2) on some maximal interval $[0, b)$, where $c < b \leq \infty$. So, unbounded solutions of the original problem (1)-(2) can be searched just as prolongations of escape solutions of (7)-(2).

Lemma 3.1. *Assume that* (3)–(6) *hold. Let u be an escape solution of* (1)-(2) *on* $[0, b)$. *Then* $u(t) > L$, $u'(t) > 0$, $t \in (c, b)$, *where c is from* (11). *If* $b < \infty$, *then* $\lim_{t\to b^-} u(t) = \infty$.

So, it is enough to investigate the boundedness of escape solutions having $[0, b) = [0, \infty)$.

Theorem 3.2. *Assume* (3)–(6) *hold and let*

$$\lim_{t\to\infty} p(t) < \infty. \tag{12}$$

Let u be an escape solution of problem (1)-(2). *Then* $\lim_{t\to\infty} u(t) = \infty$.

Theorem 3.3. *Assume* (3)–(6), (8) *and*

$$f(x) < 0 \quad \text{for } x > \phi(L). \tag{13}$$

Let u be an escape solution of problem (1)-(2). *Then* $\lim_{t\to\infty} u(t) = \infty$.

Theorem 3.4. *Assume* (3)–(6),

$$f(x) \equiv 0 \quad \text{for } x > \phi(L), \tag{14}$$

$$\phi(ab) = \phi(a)\,\phi(b), \quad a,\, b \in (0,\infty). \tag{15}$$

Let u be an escape solution of problem (1)-(2). *Then*

$$\lim_{t\to\infty} u(t) = \infty \quad \Longleftrightarrow \quad \int_1^\infty \phi^{-1}\left(\frac{1}{p(s)}\right) \mathrm{d}s = \infty.$$

If we replace condition (15) *by*

$$\phi(ab) \leq \phi(a)\,\phi(b), \quad a,\, b \in (0,\infty), \tag{16}$$

then $\lim_{t\to\infty} u(t) = \infty$ *holds if*

$$\int_1^\infty \phi^{-1}\left(\frac{1}{p(s)}\right) \mathrm{d}s = \infty. \tag{17}$$

 ISBN: 978-84-617-8694-7

4 Conclusions and example

If we combine the theorems about existence of escape solutions of the auxiliary problem (7)-(2) with one of the theorems from Section 3, we get the main existence results about unbounded solutions of (1)-(2). We will write them for Case II, being analogous for Case I.

Theorem 4.1 (Existence of unbounded solutions of problem (1)-(2), Case II, 1)**.** *Let* (3)–(6), (8), (9) *and* (12) *hold. Then there exist infinitely many unbounded solutions* u_n *of problem* (1)-(2) *on* $[0, b_n)$ *with starting values in* $\big[L_0, \bar{B}\big)$, $n \in \mathbb{N}$.

Theorem 4.2 (Existence of unbounded solutions of problem (1)-(2), Case II, 2)**.** *Assume that* (3)–(6), (8), (9) *and* (13) *hold. Then there exist infinitely many unbounded solutions* u_n *of problem* (1)-(2) *on* $[0, b_n)$ *with starting values in* $\big[L_0, \bar{B}\big)$, $n \in \mathbb{N}$.

Theorem 4.3 (Existence of unbounded solutions of problem (1)-(2), Case II, 3)**.** *Let* (3)–(6), (8), (9) *and* (14)–(17) *hold. Then there exist infinitely many unbounded solutions* u_n *of problem* (1)-(2) *on* $[0, b_n)$ *with starting values in* $\big[L_0, \bar{B}\big)$, $n \in \mathbb{N}$.

Example 4.4. Consider problem (1)-(2) with $\phi(x) = |x|^\alpha \operatorname{sgn} x$, $\alpha > 1$, $p(t) = \arctan t$ and

$$f(x) = \begin{cases} \sqrt{|x|}\, \operatorname{sgn} x(x - \phi(L_0))(\phi(L) - x) & \text{for } x \in [\phi(L_0), \phi(L)], \\ \cos(x - \phi(L)) - 1 & \text{for } x > \phi(L), \end{cases} \qquad 0 < L < -L_0.$$

Previous functions satisfy (3)–(6) and (8). As f is continuous, $0 < L < -L_0$ and ϕ is a continuous and odd function, (9) holds. From Theorem 4.1, problem (1)-(2) has infinitely many unbounded solutions with starting values in $\big[L_0, \bar{B}\big)$.

An energy method for nonlinear Riesz space-fractional wave equations

J. E. Macías-Díaz[1]

[1] *Departamento de Matemáticas y Física, Centro de Ciencias Básicas, Universidad Autónoma de Aguascalientes, Mexico*

emails: jemacias@correo.uaa.mx

Abstract

In this work, we will investigate a Riesz space-fractional wave equation with a nonlinear potential term, and approximate its solutions following an implicit finite-difference approach. Classical wave equations are susceptible of being investigated through Lagrangian and Hamiltonian formulations; however, the lack of a physically meaningful theory has been a major drawback in the investigation of fractional systems. Recently, some energy-like operators have been introduced for fractional models. Using those results, we propose a discretization for nonlinear fractional wave equations that conserves the total energy of the system. Amongst other properties, we establish that the method is a convergent and stable technique. Some comparisons against results available in the literature are provided in the way.

Key words: wave equation, Riesz space-fractional equation, Lagrangian formulation, Hamiltonian formulation, energy-preserving method, implicit finite-difference scheme

1 Introduction

Nonlinear supratransmission is a phenomenon that was thoroughly investigated in arrays of harmonic oscillators and in many other hyperbolic systems [2]. Historically, the study of energy transmission in nonlinear wave equations has been an interesting topic of investigation. These models have applications in the description of data transmission in optical fibers and in the study of the self-induced transparency of systems subject to a high-energy incident laser pulse. More generally, the behavior of continuous media subject to a continuous wave radiation is a fundamental problem that has potential applications in many nonlinear systems [6].

 ISBN: 978-84-617-8694-7

Additionally, there are many reports which investigate mathematically the occurrence of supratransmission. However, still many questions remain unanswered while other avenues of research open up with the development of new mathematical tools. For instance, models that consider fractional derivatives have attracted the attention of many researchers in recent years. Classical systems that include derivatives of integral order have been extended in this way using various inequivalent approaches [5], and interesting results have been derived in the way. Motivated by these facts, we will provide a continuous Riesz fractional extension of the model investigated in [1] for derivative orders in $(1, 2)$, and design an energy-preserving and convergent method to approximate the solutions of Riesz space-fractional wave equations with nonlinear potentials.

2 Preliminaries

The point of departure and the motivation of this work are the $(1 + 1)$-dimensional sine-Gordon and nonlinear Klein-Gordon equations from relativistic quantum mechanics and field theory, which are described by the hyperbolic partial differential equation

$$\frac{\partial^2 u}{\partial t^2}(x,t) - \frac{\partial^2 u}{\partial x^2}(x,t) + V'(u(x,t)) = 0, \tag{1}$$

where

$$V(u) = 1 - \cos u \tag{2}$$

in the case of the classical sine-Gordon system. In the case of the nonlinear Klein-Gordon equation, the potential function V takes on the form

$$V(u) = \frac{1}{2!}u^2 - \frac{1}{4!}u^4 + \frac{1}{6!}u^6. \tag{3}$$

Both equations possess a Lagrangian functional and an associated Hamiltonian which are defined for each $(x,t) \in I \times \mathbb{R}^+$, and that are given respectively by

$$\mathcal{L}(x,t) = \frac{1}{2}\left[\frac{\partial u}{\partial t}(x,t)\right]^2 - \frac{1}{2}\left[\frac{\partial u}{\partial x}(x,t)\right]^2 - V(u(x,t)), \tag{4}$$

$$\mathcal{H}(x,t) = \frac{1}{2}\left[\frac{\partial u}{\partial t}(x,t)\right]^2 + \frac{1}{2}\left[\frac{\partial u}{\partial x}(x,t)\right]^2 + V(u(x,t)). \tag{5}$$

The total energy of the system (1) at the time t is provided by

$$\mathcal{E}(t) = \int_I \mathcal{H}(x,t)dx. \tag{6}$$

 ISBN: 978-84-617-8694-7

3 Mathematical problem

In this work, we will consider a space-fractional extension of the sine-Gordon equation (1) using the Riesz fractional approach [4]. More precisely, let us define the Riesz space-fractional derivative of u of order $0 \leq \alpha \leq 2$ at the point (x,t) by

$$\frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) = \begin{cases} -\dfrac{\mathcal{D}_+^\alpha + \mathcal{D}_-^\alpha}{2\cos(\alpha\pi/2)} u(x,t), & \alpha \neq 1, \\ \left(\dfrac{d}{dx} H\right) u(x,t), & \alpha = 1. \end{cases} \tag{7}$$

Here H is the Hilbert transform in the first variable, that is,

$$Hu(x,t) = \text{p.v.} \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{u(\xi,t)}{\xi - x} d\xi, \tag{8}$$

where the principal value of the integral is understood in the sense of Cauchy.

For the sake of briefness, the Riesz space-fractional derivative of order α of $u(x,t)$ is sometimes denoted by $\mathcal{D}^\alpha u(x,t)$. In (7), $\mathcal{D}_\pm^\alpha$ denotes a Weyl fractional derivative operator of order α, which is given in terms of the Weyl fractional integrals by

$$\mathcal{D}_\pm^\alpha u(x,t) = \begin{cases} \pm \left(\dfrac{d}{dx} I_\pm^{1-\alpha}\right) u(x,t), & 0 < \alpha < 1, \\ \left(\dfrac{d^2}{dx^2} I_\pm^{2-\alpha}\right) u(x,t), & 1 < \alpha < 2. \end{cases} \tag{9}$$

For each $\beta > 0$,

$$I_+^\beta u(x,t) = \frac{1}{\Gamma(\beta)} \int_{-\infty}^{x} (x-\xi)^{\beta-1} u(\xi,t) d\xi, \tag{10}$$

$$I_-^\beta u(x,t) = \frac{1}{\Gamma(\beta)} \int_{x}^{\infty} (\xi-x)^{\beta-1} u(\xi,t) d\xi. \tag{11}$$

Let A and Ω be positive numbers, and let $I = (0,L)$ for some $L > 0$. Using the conventions introduced above, this manuscript investigates the following initial-boundary-value problem:

$$\frac{\partial^2 u}{\partial t^2}(x,t) - \gamma(x)\frac{\partial u}{\partial t}(x,t) - \frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) + V'(u(x,t)) = 0, \quad (x,t) \in I \times \mathbb{R}^+,$$
$$\text{subject to } \begin{cases} u(x,0) = u_t(x,0) = 0, & \forall x \in I, \\ u(0,t) = A\sin(\Omega t), & \forall t \in \mathbb{R}^+, \\ u_x(L,t) = 0, & \forall t \in \mathbb{R}^+. \end{cases} \tag{12}$$

Here, the function $\gamma : I \to \mathbb{R}$ represents damping and it will be used to account for an absorbing boundary at the right end of I.

 ISBN: 978-84-617-8694-7

The problem considered in this work is a non-local version of the system studied in different media [2, 3] in the context of the investigation of nonlinear supratransmission. It is important to point out that the undamped form of the fractional model (12) has the generalized fractional Hamiltonian functional

$$\mathcal{H}(x,t) = \frac{1}{2}\left[\frac{\partial u}{\partial t}(x,t)\right]^2 + \frac{1}{2}\left[\frac{\partial u}{\partial x}(x,t)\right]\left[\frac{\partial^{\alpha-1}u}{\partial|x|^{\alpha-1}}(x,t)\right] + V(u(x,t)), \tag{13}$$

for each $(x,t) \in I \times \mathbb{R}^+$ (see [5] for details). With these conventions, an energy integral associated to the undamped sine-Gordon equation of the problem (12) is defined by (6). Moreover, if we consider a finite period of time T, the total energy of the system in that periods will be defined as

$$\mathcal{E} = \int_0^T \mathcal{E}(t)dt. \tag{14}$$

4 Aim of this work

The purpose of this work is to provide a consistent finite-difference discretization of (12), together with consistent discrete forms of (13) and (14). These and more properties of our numerical techniques will be established thoroughly, and suitable applications to the investigation of nonlinear supratransmission will be proposed in the way.

Abstract

In this work, we provide a discretization of a nonlinear diffusion-reaction system that models the growth of cancer with radiotherapy. Only positive and bounded solutions are physically relevant in this context, and the discretization that we provide in this manuscript is able to preserve both properties. The method is computationally economic; some qualitative and quantitative comparisons are carried out in support of the advantages of our scheme. Moreover, the technique used in the present manuscript has the advantage over other similar methodologies that it yields no singularities. In addition, the preservation of the properties of non-negativity and boundedness of both the solution and the total mass are distinctive features which are established analytically in this work. The numerical simulations on cancer growth obtained with the exponential method are found to be in good agreement with the experimental results available in the literature.

Key words: cancer growth model, two-dimensional diffusion-reaction equation, preservation of structure, exponential finite-difference method, fast computational method

1 Introduction

The present work is motivated by various systems of partial differential equations that describe the growth of cancer. More precisely, the present work is motivated by partial

 ISBN: 978-84-617-8694-7

differential equations in the dynamics of brain cancer [1] and the effects of proliferation and motility of transforming growth factor (TGF) β on cancer cells [5]. In all these cases, the models under consideration are extensions of the classical Fisher's equation of population dynamics [2], and all of them are physically interesting in the two-dimensional scenario in view of the applications to the dynamics of growth of tumors on human tissues. Moreover, the variable of interest in either case is the density of tumor cells at each point of the tissue, whence the properties of non-negativity and boundedness naturally arise. In view of these remarks, one is immediately led to ask whether it is possible to design an efficient and dynamically consistent technique to approximate the solutions of a generalized two-dimensional form of the equations investigated in [5]. More precisely, we are interested in developing numerical methods to approximate the solutions of those equations with the following characteristics:

1. The non-negativity and the boundedness of numerical approximations is preserved.
2. The method preserves the non-negativity and the boundedness of the total mass of the cancer tumor.
3. The technique is computationally fast.
4. The method is easy to implement in any computer language.
5. The computational implementation allows to employ fine grid meshes.

2 Mathematical model

Throughout this manuscript, we assume that α, β and D_p are positive numbers and that D_m is nonnegative. Let Ω be a domain of $\mathbb{R}^2$ which is open, bounded, connected and measurable, with area given by $\mathcal{A}(\Omega)$. We let $u = u(x, y, t)$ be a real function defined on the closure of $\Omega \times \mathbb{R}^+$, which is twice differentiable in the interior of its domain and which satisfies the initial-value problem with homogeneous Neumann boundary conditions

$$\begin{gathered}\frac{\partial u}{\partial t}(x,y,t) = \nabla \cdot (D(\mu(t))\nabla u(x,y,t)) + \alpha u(x,y,t)\left(1-\beta u(x,y,t)\right), \quad \forall (x,y) \in \Omega, \forall t \in \mathbb{R}^+, \\ \begin{cases} u(x,y,0) = \phi(x,y), & \forall (x,y) \in \overline{\Omega}, \\ \dfrac{\partial u}{\partial \mathbf{n}}(x,y,t) = 0, & \forall (x,y) \in \partial\Omega, \forall t \in \mathbb{R}^+ \cup \{0\}, \end{cases}\end{gathered} \tag{1}$$

for some continuous function $\phi : \overline{\Omega} \to \mathbb{R}$ which satisfies the condition $0 \leq \phi(x, y) \leq \frac{1}{\beta}$ at each $(x, y) \in \overline{\Omega}$. Here, D is the real function defined by

$$D(z) = D_m \left(1 - \frac{z}{\mathcal{A}(\Omega)}\right) + D_p \tag{2}$$

 ISBN: 978-84-617-8694-7

for each $z \in \mathbb{R}$, and the function μ will be the function of *total mass* of the system at the time t. More precisely, for each $t \geq 0$ we let

$$\mu(t) = \mu(u(x, y, t)) = \beta \iint_{\Omega} u(x, y, t) dx dy. \tag{3}$$

3 Physical description

Following the physical context of [5], the value $u(x, y, t)$ represents the spatial density of tumor cells at the time t and at the point (x, y) on a flat surface of interior equal to Ω. Clearly, u has units $length^{-2}$. The parameter α denotes the intrinsic proliferation rate of the cells, with units given in $time^{-1}$. Meanwhile, β is given in units of $length^2$ and represents the (positive) area occupied by a single cell in average, whence the constant $1/\beta$ represents the number of cells per unit of area. Here, we impose the constraint

$$0 \leq u(x, y, t) \leq \frac{1}{\beta}, \tag{4}$$

for each $(x, y) \in \Omega$ and each $t \in \mathbb{R}^+$. Moreover, the expression

$$N(t) = \frac{\mu(t)}{\beta} \tag{5}$$

denotes the total number of cells in the region Ω.

Obviously, the maximum value of N is achieved when u is the constant $1/\beta$, in which case the number of cells is given by the value $N_{\max} = \mathcal{A}(\Omega)/\beta$. The role of the constant D_p is to account for the spatial expansion of proliferating cells, while the parameter D_m accounts for the facts that the cells undergo a random walk which follows the laws of Brownian motion, and that the cells of a cluster may break lose from the cluster [4]. Finally, it is worthwhile to notice that (1) is also a model of the growth of brain cancer when the diffusion coefficient is constant and when radiotherapy is not considered [1, 3].

The following property is recorded as a lemma for the sake of future reference.

Lemma 1 *The inequalities*

$$0 \leq \mu(t) \leq \mathcal{A}(\Omega), \tag{6}$$

$$D_p \leq D(\mu(t)) \leq D_m + D_p, \tag{7}$$

are satisfied when (4) *holds.*

 ISBN: 978-84-617-8694-7

4 Aim of this work

The purpose of this work is to provide a structure-preserving finite-difference discretization of the following initial-boundary-value problem:

$$\begin{aligned}\frac{\partial u}{\partial t}(x,y,t) &= \nabla\cdot(D(\mu(t))\nabla u(x,y,t)) + \alpha u(x,y,t)\,(1-\beta u(x,y,t)) + f(u,x,y,t),\\ &\begin{cases} u(x,y,0) = \phi(x,y), & \forall (x,y)\in\overline{\Omega},\\ \dfrac{\partial u}{\partial \mathbf{n}}(x,y,t) = 0, & \forall (x,y)\in\partial\Omega, \forall t\in\mathbb{R}^+\cup\{0\},\end{cases}\end{aligned} \tag{8}$$

This problem describes, among other physical situations, the dynamics of growth of cancer subject to a therapy function f, whence its importance is pragmatically justified.

Traveling-wave solutions of a generalized damped wave equation with time-dependent coefficients through the trial equation method

J. E. Macías-Díaz[1] and Héctor Vargas-Rodríguez[2]

[1] *Departamento de Matemáticas y Física, Centro de Ciencias Básicas, Universidad Autónoma de Aguascalientes, Mexico*

[2] *Departamento de Ciencias Exactas y Tecnología, Centro Universitario de los Lagos, Universidad de Guadalajara, Mexico*

emails: jemacias@correo.uaa.mx, hvargas@culagos.udg.mx

Abstract

In this note, we investigate the existence of exact solutions of a nonlinear partial differential equation with time-dependent coefficients that generalizes the well-known nonlinear wave model with external and internal damping. The model under consideration generalizes other classical models from physics, like the nonlinear Klein–Gordon equation, the $(1+1)$-dimensional ϕ^4-theory, the Fisher–Kolmogorov–Petrovsky–Piscounov equation from population dynamics and the Hodgkin–Huxley model used in the description of the propagation of electric signals through the nervous system. An extension of the trial equation method (also known as the direct integral method) for partial differential equations with non-constant coefficients is used in this work in order to derive traveling-wave solutions in exact form.

Key words: generalized wave equation, time-dependent coefficients, traveling-wave solutions, trial equation method, external and internal damping, direct integral method

1 Introduction

In this note, we use $\mathbb{R}^+$ to represent the set of positive numbers, and we let a, b, c, d, e, f and g be real-valued functions defined on $\mathbb{R}^+\cup\{0\}$. Throughout we suppose that u is a real function defined on $\mathbb{R}\times\mathbb{R}^+\cup\{0\}$ which has derivatives up to the third order in the interior

 ISBN: 978-84-617-8694-7

of its domain, and which satisfies the nonlinear wave equation with external damping and time-dependent coefficients

$$\frac{\partial^2 u}{\partial t^2}(x,t) - a^2(t)\frac{\partial^2 u}{\partial x^2}(x,t) = b(t)\frac{\partial^3 u}{\partial x^2 \partial t}(x,t) + c(t)\frac{\partial u}{\partial t}(x,t) + F(u(x,t),t), \tag{1}$$

for all $(x,t) \in \mathbb{R} \times \mathbb{R}^+$. Here the reaction function is given by

$$F(u,t) = d(t) + e(t)u + f(t)u^2 + g(t)u^3, \quad \forall (x,t) \in \mathbb{R} \times \mathbb{R}^+. \tag{2}$$

It is worth noting that this model is a generalization of various models appearing mathematical physics. Amongst those equations, we may quote the following:

- The classical wave equation results from (1) when the coefficient a is a constant, and when b, c and F are identically equal to zero. So (1) is a generalization of the wave equation with power-law nonlinearities.

- The classical linear Klein–Gordon equation from relativistic quantum mechanics is obtained when a is a constant, e is a positive real number, and all the other coefficients are identically equal to zero. The nonlinear Klein–Gordon equation with constant coefficients is also a particular case of Equation (1).

- Our model is also a generalization of the classical Fisher's equation investigated simultaneously and independently by R. A. Fisher and A. N. Kolmogorov, I. G. Petrovsky and N. S. Piscounov in the context of the dynamics of some populations.

- Equation (1) is an extension of the Hogdkin–Huxley model describing the propagation of electric signals through nerves.

- Finally, our model is also a continuous and damped generalization of both the α- and β-Fermi–Pasta–Ulam systems.

The presence of time-dependent coefficients in (1) accounts for the possible effects of an inhomogeneous medium. From that perspective, the model under investigation in this work may provide a more realistic description of phenomena described by constant-coefficient wave equations in the homogeneous regime. This is particularly interesting in view of the fact that wave-like equation with constant coefficients have been proposed to describe a wide range of physical phenomena, including the process of nonlinear supratransmission. Supratransmission which is a nonlinear phenomenon which was discovered in mechanical chains of oscillators described by coupled Klein-Gordon equations [2], and it was quickly studied in other nonlinear models [2, 3].

 ISBN: 978-84-617-8694-7

2 Methodology

In this work, we will derive traveling-wave solutions of the generalized damped wave equation (1) using an extension of the well-known trial equation method for partial differential equations with time-dependent coefficients. To that end, we start considering a solution of (1) of the form

$$u(x,t) = u(\xi(x,t)), \qquad \xi(x,t) = \kappa(t)x + \omega(t), \tag{3}$$

where both κ and ω are real functions defined on $\mathbb{R}^+ \cup \{0\}$. After differentiating and using these assumptions, we obtain the equations

$$\begin{aligned}
\frac{\partial u}{\partial t}(x,t) &= \left(\kappa'(t)x + \omega'(t)\right) u'(\xi), &(4)\\
\frac{\partial^2 u}{\partial t^2}(x,t) &= \left(\kappa''(t)x + \omega''(t)\right) u'(\xi) + \left(\kappa'(t)x + \omega'(t)\right)^2 u''(\xi), &(5)\\
\frac{\partial^2 u}{\partial x^2}(x,t) &= \kappa^2(t) u''(\xi), &(6)\\
\frac{\partial^3 u}{\partial x^2 \partial t}(x,t) &= 2\kappa(t)\kappa'(t)u''(\xi) + \kappa^2(t)\left(\kappa'(t)x + \omega'(t)\right) u'''(\xi). &(7)
\end{aligned}$$

In order to simplify the notation, for the remainder of this work we will convey that $u = u(\xi)$. Substituting the derivatives (4)–(7) into (1), we readily obtain the following nonlinear ordinary differential equation:

$$\Delta(x,t)u' + \Theta(x,t)u'' - \Lambda(x,t)u''' - F(u,t) = 0. \tag{8}$$

where we have employed the notation

$$\begin{aligned}
\Delta(x,t) &= \left[\kappa''(t) - c(t)\kappa'(t)\right] x + \left[\omega''(t) - c(t)\kappa'(t)\right], &(9)\\
\Theta(x,t) &= \left[\kappa'(t)x + \omega'(t)\right]^2 - a^2(t)\kappa^2(t) - 2\kappa(t)\kappa'(t)b(t), &(10)\\
\Lambda(x,t) &= \kappa^2(t)\left[\kappa'(t)x + \omega'(t)\right] b(t). &(11)
\end{aligned}$$

3 Aim of this work

In work, we will employ the trial equation method to obtain solutions of the ordinary differential equation (8). We obtain some conditions to guarantee that the parameters of the trial equation are constant real numbers. The results of our calculations will be summarized in a proposition at the end of our work. We will also derive some traveling-wave solutions of the damped wave equation (1) in exact form. To that end, we will make use of some results reported in [1]. Various cases will be considered in terms of a complete discriminant system for the polynomial resulting from the trial equation.

Abstract

In this work, we introduce a spatially discrete model that generalizes the well-known α-Fermi–Pasta–Ulam chain with damping. The system is perturbed at one end by a harmonic disturbance irradiating at a frequency in the forbidden band-gap of the classical regime, and a nonlocal coupling between the oscillators is considered using discrete Riesz fractional derivatives. We propose fully discrete expressions to approximate a pseudo-energy functional of the system, and we use them to calculate the total energy of fractional chains over a relatively long period of time. As an application, we provide evidence that the process of supratransmission is present in spatially discrete Fermi–Pasta–Ulam lattices with Riesz fractional derivatives in space.

Key words: wave equation, fractional nonlinear chains, energy-preserving method, explicit finite-difference scheme

1 Introduction

In this work, we investigate the following continuous form of the classical chain investigated by Fermi, Pasta and Ulam in [1]:

$$\frac{\partial^2 u}{\partial t^2}(x,t) = \frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t)\left[1+\epsilon\left(\frac{\partial u}{\partial x}(x,t)\right)^p\right] - \gamma\frac{\partial u}{\partial t}(x,t), \quad \forall (x,t)\in\Omega\times[0,\infty),$$
$$\begin{cases} u(x,0)=\phi(x), & \forall x\in\Omega,\\ \dfrac{\partial u}{\partial t}(x,0)=\psi(x), & \forall x\in\Omega,\\ u(a,t)=f(t), & \forall t\in[0,\infty),\\ u(b,t)=g(t), & \forall t\in[0,\infty), \end{cases} \tag{1}$$

 ISBN: 978-84-617-8694-7

where $\phi, \psi : [a, b] \to \mathbb{R}$ and $f, g : [0, \infty) \to \mathbb{R}$ are sufficiently smooth functions. In this expression, we employ the Riesz fractional derivative of order $\alpha \in (1, 2)$, which is given by

$$\frac{\partial^\alpha u}{\partial |x|^\alpha} = \frac{-1}{2\cos(\frac{\pi\alpha}{2})\Gamma(2-\alpha)} \frac{d^2}{dx^2} \int_{-\infty}^{\infty} \frac{u(\xi, t)}{|x-\xi|^{\alpha-1}} d\xi, \quad \forall (x, t) \in \Omega \times [0, \infty). \tag{2}$$

Here $\Gamma(z)$ represents the gamma function, for each $z \in \mathbb{R} \setminus \{n : -n \in \mathbb{N} \text{ or } n = 0\}$. In the absence of a physically meaningful formulation of the Euler–Lagrange formality for fractional systems, we propose the following pseudo-Hamiltonian for the undamped scenario:

$$H(x, t) = \frac{1}{2} \left[\left(\frac{\partial u}{\partial t}(x, t) \right)^2 + u(x, t) \frac{\partial^\alpha u}{\partial |x|^\alpha}(x, t) \right] + \frac{\epsilon}{(p+2)(p+1)} \left(\frac{\partial u}{\partial x}(x, t) \right)^{p+2}. \tag{3}$$

Under these circumstances, a functional for the total energy of the system would be

$$E(t) = \int_a^b H(x, t) dx, \quad \forall t \geq 0. \tag{4}$$

2 Discrete model

Motivated by the continuous space-fractional equation (1), we propose now a spatially discrete fractional array that extends the original FPU chains. Recall that for each $f : \mathbb{R} \to \mathbb{R}$, each $h > 0$ and each $\alpha > -1$ the *fractional centered difference* of order α of f at the point x and step h is

$$\Delta_h^\alpha f(x) = \sum_{k=-\infty}^{\infty} g_k^\alpha f(x - kh), \quad \forall x \in \mathbb{R}, \tag{5}$$

where

$$g_k^\alpha = \frac{(-1)^k \Gamma(\alpha + 1)}{\Gamma(\frac{\alpha}{2} - k + 1)\Gamma(\frac{\alpha}{2} + k + 1)}, \quad \forall k \in \mathbb{Z}. \tag{6}$$

In the case that $1 < \alpha < 2$ the fractional centered differences satisfy (see [3])

$$\lim_{h \to 0} \frac{-1}{h^\alpha} \Delta_h^\alpha f(x) = \frac{\partial^\alpha f}{\partial |x|^\alpha}(x), \quad \forall x \in \mathbb{R}. \tag{7}$$

In the present work, we let $h = 1/c$ for the spatially discrete scenario. For simplification purposes, we convey that $\Delta_x^\alpha = \Delta_1^\alpha$. The Riesz space-fractional FPU chain under

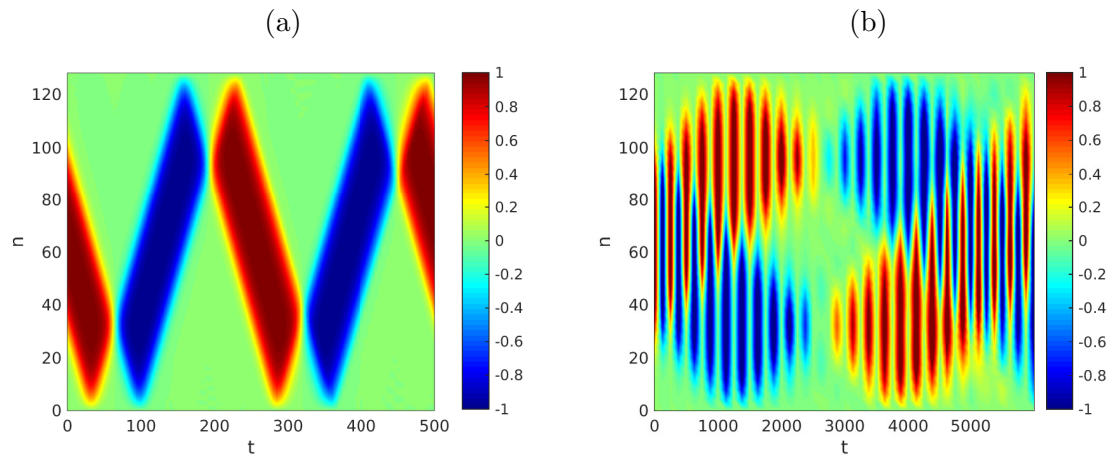

Figure 1: (Color online). Graphs of the approximate solution of a system of $N = 128$ anharmonic oscillators governed by (8) versus node number n and time t for periods of time (a) $T = 500$ and (b) $T = 6000$. The model parameters are $\alpha = 2$, $p = c = 1$, $\epsilon = 0.01$ and $\gamma = 0$, with initial-boundary data $\psi = f = g \equiv 0$ and $\phi(n) = \chi(n, 0)$ for each $n \in \{0, 1, \ldots, N\}$. The function χ is given by (12) with $\kappa = 0.1$. Computationally, we used $\tau = 0.02$.

consideration in this work is given by the system

$$\frac{d^2u_n}{dt^2}(t) = c^\alpha \Delta_x^\alpha u_n(t) + \delta_x V'(\delta_x u_{n-1}(t)) - \gamma \frac{du_n}{dt}(t), \quad \forall n \in \{0, 1, \ldots, N\}, \forall t \in [0, \infty),$$
$$\begin{cases} u_n(0) = \phi(n), & \forall n \in \{0, 1, \ldots, N\}, \\ \dfrac{du_n}{dt}(0) = \psi(n), & \forall n \in \{0, 1, \ldots, N\}, \\ u_0(t) = f(t), & \forall t \in [0, \infty), \\ u_N(t) = g(t), & \forall t \in [0, \infty). \end{cases} \tag{8}$$

Obviously, in this case $\phi, \psi : \{0, 1, \ldots, N\} \to \infty$. In the practice, we will consider a discrete domain of the form $\{0, 1, \ldots, N\}$ for some $N \in \mathbb{N}$, so

$$\Delta_x^\alpha u_n = -\frac{1}{h^\alpha} \sum_{k=n-N}^{n} g_k^\alpha u_{n-k} - \frac{1}{h^\alpha} \sum_{k=0}^{N} g_{n-k}^\alpha u_k, \tag{9}$$

for each $n \in \{1, \ldots, N-1\}$. Under these circumstances the pseudo-Hamiltonian and the

 ISBN: 978-84-617-8694-7

pseudo-energy of the undamped system will be defined respectively as

$$H_n(t) = \frac{1}{2}\left[\left(\frac{du_n}{dt}(t)\right)^2 + c^\alpha u_n(t)\Delta_x^\alpha u_n(t)\right] + V(\delta_x u_n(t)), \tag{10}$$

$$E(t) = \sum_{n=1}^{\infty} H_n(t) + \frac{c^\alpha}{2} u_0(t)\Delta_x^\alpha u_0(t) + V(\delta_x u_0(t)). \tag{11}$$

3 Numerical results

Our last example is motivated by the Toda lattice used to describe the motion of particles in one-dimensional nonlinear crystals [4]. Recall that the damped Toda lattice is described by (8) with $c = 0$, $\epsilon = 1$ and $V(u) = e^{-u} + u - 1$ for $u \in \mathbb{R}$. This system has soliton/anti-soliton solutions. In our simulations, we will use a superposition of those solutions of the form

$$\chi(n,t) = 5\ln\left\{\left(\frac{1+\exp\left[2(\kappa(n-97)+t\sinh\kappa)\right]}{1+\exp\left[2(\kappa(n-96)+t\sinh\kappa)\right]}\right)\left(\frac{1+\exp\left[2(\kappa(n-32)+t\sinh\kappa)\right]}{1+\exp\left[2(\kappa(n-33)+t\sinh\kappa)\right]}\right)\right\}, \tag{12}$$

for each $n \in \{0, 1, \ldots, N\}$ and $t \geq 0$, and $\kappa \in \mathbb{R}$.

Consider $N = 128$ nodes satisfying (8) with $\epsilon = 0.01$, $\gamma = 0$ and $\kappa = 0.1$, and let $\phi(n) = \chi(n, 0)$ for each $n \in \{0, 1, \ldots, N\}$. The approximate solutions of this chain are shown in Figure 1 for (a) $T = 500$ and (b) $T = 6000$. Again, the results are in agreement with those reported in [2].

Abstract

We consider an initial-boundary-value problem governed by a $(1+1)$-dimensional hyperbolic partial differential equation with constant damping that generalizes many nonlinear wave equations from mathematical physics. The model contemplates the presence of a spatial Laplacian of fractional order which is defined in terms of Riesz fractional derivatives, as well as the inclusion of a generic continuously differentiable potential. It is known that the undamped regime has an energy functional that is preserved throughout time under suitable boundary conditions. To approximate the solutions of this model, we propose a finite-difference discretization of our model based on fractional centered differences. Some discrete quantities are proposed here to estimate the energy functionals, and we show that the numerical method is capable of conserving the discrete energy under the same boundary conditions for which the continuous model conserves it. The method is is both stable and convergent.

Key words: sine-Gordon equation, Riesz space-fractional equation, energy-preserving method, stability and convergence analyses

1 Introduction

In this manuscript we let $T > 0$ and $\gamma \in \mathbb{R}$, and suppose that $a < b$. Throughout we will assume that $\alpha \in (1, 2)$ and $\Omega = (a, b) \times (0, T) \subset \mathbb{R}^2$. We will employ $\overline{\Omega}$ to represent the closure of Ω in $\mathbb{R}^2$. Suppose that $G : \mathbb{R} \to \mathbb{R}$, that $\phi, \psi : [a, b] \to \mathbb{R}$ and that $f, g : [0, T] \to \mathbb{R}$ are all continuously differentiable and satisfy the conditions $\phi(a) = f(0)$, $\phi(b) = g(0)$,

 ISBN: 978-84-617-8694-7

$\psi(a) = f'(0)$ and $\psi(b) = g'(0)$. Moreover, we will suppose that $u : \overline{\Omega} \to \mathbb{R}$ is a sufficiently smooth function that satisfies the initial-boundary-value problem

$$\frac{\partial^2 u}{\partial t^2}(x,t) - \frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) + \gamma \frac{\partial u}{\partial t}(x,t) + G'(u(x,t)) = 0, \quad \forall (x,t) \in \Omega,$$
$$\text{such that } \begin{cases} u(x,0) = \phi(x), & \forall x \in (a,b), \\ \dfrac{\partial u}{\partial t}(x,0) = \psi(x), & \forall x \in (a,b), \\ u(a,t) = f(t), & \forall t \in (0,T), \\ u(b,t) = g(t), & \forall t \in (0,T). \end{cases} \tag{1}$$

For convenience, we let $u(x,t) = 0$ for each $x \in (\mathbb{R} \setminus [a,b]) \times [0,T]$ and define (see [1])

$$\frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) = \frac{-1}{2\cos(\frac{\pi\alpha}{2})\Gamma(2-\alpha)} \frac{d^2}{dx^2} \int_{-\infty}^{\infty} \frac{u(\xi,t)}{|x-\xi|^{\alpha-1}} d\xi, \quad \forall (x,t) \in \Omega. \tag{2}$$

2 Numerical method

Let $h > 0$ and τ be step-sizes in space and time, respectively, and assume $N = T/\tau$ and $M = (b-a)/h$ are positive integers. Consider uniform partitions of $[a,b]$ and $[0,T]$, respectively, given by $x_j = jh$ and $t_n = n\tau$. In this work v_j^n will represent a numerical approximation to $u_j^n = u(x_j, t_n)$, for each $0 \le j \le M$ and each $0 \le n \le N$. Define

$$\mu_t u_j^n = \frac{u_j^{n+1} + u_j^n}{2} = u(x_j,t_n) + \mathcal{O}(\tau), \tag{3}$$
$$\mu_t^{(1)} u_j^n = \frac{u_j^{n+1} + u_j^{n-1}}{2} = u(x_j,t_n) + \mathcal{O}(\tau^2), \tag{4}$$
$$\delta_t u_j^n = \frac{u_j^{n+1} - u_j^n}{\tau} = \frac{\partial u}{\partial t}(x_j,t_n) + \mathcal{O}(\tau), \tag{5}$$
$$\delta_t^{(1)} u_j^n = \frac{u_j^{n+1} - u_j^{n-1}}{2\tau} = \frac{\partial u}{\partial t}(x_j,t_n) + \mathcal{O}(\tau^2), \tag{6}$$
$$\delta_t^{(2)} u_j^n = \frac{u_j^{n+1} - 2u_j^n + u_j^{n-1}}{\tau^2} = \frac{\partial^2 u}{\partial t^2}(x_j,t_n) + \mathcal{O}(\tau^2), \tag{7}$$

for each $1 \le j \le K-1$ and $1 \le n \le N-1$. Obviously, the right-hand sides of (3)–(7) denote the consistency properties of each of discrete operator. In addition, the following operator estimates $G'(u(x_j,t_n))$ with an order of consistency equal to $\mathcal{O}(\tau^2)$:

$$\delta_{u,t}^{(1)} G(u_j^n) = \frac{G(u_j^{n+1}) - G(u_j^{n-1})}{u_j^{n+1} - u_j^{n-1}}, \tag{8}$$

 ISBN: 978-84-617-8694-7

Definition 1. For any function $f : \mathbb{R} \to \mathbb{R}$, any $h > 0$ and any $\alpha > -1$ we define the *fractional centered difference* of order α of f at the point x as (see [2])

$$\Delta_h^\alpha f(x) = \sum_{k=-\infty}^{\infty} g_k^\alpha f(x - kh), \quad \forall x \in \mathbb{R}, \tag{9}$$

where

$$g_k^\alpha = \frac{(-1)^k \Gamma(\alpha + 1)}{\Gamma(\frac{\alpha}{2} - k + 1)\Gamma(\frac{\alpha}{2} + k + 1)}, \quad \forall k \in \mathbb{Z}. \tag{10}$$

Note that the series in the right-hand side of (9) converges absolutely for any bounded function $f \in L_1(\mathbb{R})$. It is easy to see that any function $f \in \mathcal{C}^5(\mathbb{R})$ for which all of its derivatives up to order five belong to $L_1(\mathbb{R})$, if $1 \leq j \leq M-1$ and $1 \leq n \leq N-1$ then

$$\frac{\partial^\alpha u}{\partial |x|^\alpha}(x_j, t_n) = -\frac{1}{h^\alpha} \sum_{k=(b-x_j)/h}^{(x_j-a)/h} g_k^\alpha u(x_j - kh, t_n) + \mathcal{O}(h^2) = \delta_h^\alpha u_j^n + \mathcal{O}(h^2), \tag{11}$$

where

$$\delta_h^\alpha u_j^n = -\frac{1}{h^\alpha} \sum_{k=0}^{M} g_{j-k}^\alpha u_k^n. \tag{12}$$

The finite-difference method to approximate the solution of (1) on Ω is given by

$$\begin{gathered} \delta_t^{(2)} v_j^n - \delta_h^\alpha v_j^n + \gamma \delta_t^{(1)} v_j^n + \delta_{v,t}^{(1)} G(v_j^n) = 0, \quad \forall j \in \{1, \ldots, M\}, \forall n \in \{1, \ldots, N\}, \\ \text{such that } \begin{cases} v_j^0 = \phi(x_j), & \forall j \in \{1, \ldots, M-1\}, \\ \delta_t v_j^0 = \psi(x_j), & \forall j \in \{1, \ldots, M-1\}, \\ v_0^n = f(t_n), & \forall n \in \{1, \ldots, N-1\}, \\ v_M^n = g(t_n), & \forall n \in \{1, \ldots, N-1\}. \end{cases} \end{gathered} \tag{13}$$

3 Energy invariants

In this section we would like to show that the finite-difference method (13) satisfies physical properties similar to those satisfied by (1) (see [3], for instance). For that reason we will suppose that the initial-boundary conditions satisfy the constraints

$$\begin{cases} f(t) = g(t) = 0, & \forall t \in [0, T], \\ \phi(x) = \psi(x) = 0, & \text{for } x = a, b. \end{cases} \tag{14}$$

Throughout this section, we will employ the spatial mesh

$$R_h = \left\{ (x_j)_{j=1}^{M-1} \in \mathbb{R}^{M-1} | x_j = a + jh \text{ for each } 1 \leq j \leq M-1 \right\}. \tag{15}$$

 ISBN: 978-84-617-8694-7

Let $\mathcal{V}_h$ be the vector space of all real grid functions on R_h. For any $u \in \mathcal{V}_h$ and $j \in \{1, \ldots, M-1\}$ convey that $u_j = u(x_j)$. Moreover, define respectively the inner product $\langle \cdot, \cdot \rangle : \mathcal{V}_h \times \mathcal{V}_h \to \mathbb{R}$ and the norm $\| \cdot \|_1 : \mathcal{V}_h \to \mathbb{R}$ by

$$\langle u, v \rangle = h \sum_{j=1}^{M-1} u_j v_j, \quad \|u\|_1 = h \sum_{j=1}^{M-1} |u_j|, \tag{16}$$

for any $u, v \in \mathcal{V}_h$. The Euclidean norm induced by $\langle \cdot, \cdot \rangle$ will be denoted by $\| \cdot \|_2$.

In the following, we will represent the solutions of the finite-difference method (13) by $(v^n)_{n=0}^N$, where we convey that $v^n = (v_1^n, \ldots, v_{M-1}^n)$ for each $0 \leq n \leq N$. We will also need the following real matrix of size $(M-2) \times (M-2)$:

$$A = \begin{pmatrix} g_0^\alpha & g_{-1}^\alpha & \cdots & g_{2-M}^\alpha \\ g_1^\alpha & g_0^\alpha & \cdots & g_{3-M}^\alpha \\ \vdots & \vdots & \ddots & \vdots \\ g_{M-2}^\alpha & g_{M-3}^\alpha & \cdots & g_0^\alpha \end{pmatrix}. \tag{17}$$

We will require the following lemma.

Lemma 2. *There exists a unique linear positive operator $\Lambda^\alpha : \mathcal{V}_h \to \mathcal{V}_h$ such that*

$$\langle -\delta_h^\alpha u, v \rangle = \langle \Lambda_h^\alpha u, \Lambda_h^\alpha v \rangle, \quad \forall u, v \in \mathcal{V}_h. \tag{18}$$

The next theorem establishes the existence of invariants for the discrete system (13).

Theorem 3. *Let $(v^n)_{n=0}^N$ be solution of the system* (13) *under the conditions* (14)*. Let*

$$E^n = \frac{1}{2} \|\delta_t v^n\|_2^2 + \frac{1}{2} \left\langle \Lambda^\alpha v^n, \Lambda^\alpha v^{n+1} \right\rangle + \|\mu_t G(v^n)\|_1, \quad \forall n \in \{1, \ldots, N-1\}. \tag{19}$$

Then for each $1 \leq n \leq N-1$ the following identity holds: $\delta_t E^n = -\gamma \|\delta_t^{(1)} v^{n+1}\|_2^2$. In particular, the quantities E^n are invariants of (13) *if $\gamma = 0$ and the conditions* (14) *hold.* □

Abstract

In this work, we depart from the well-known one-dimensional Fisher's equation from population dynamics, and consider an extension of this model using Riesz fractional derivatives in space. Positive and bounded initial-boundary data are imposed on a closed and bounded domain, and a fully discrete form of this fractional initial-boundary-value problem is provided next using fractional centered differences. The fully discrete population model is implicit and linear, so a convenient vector representation is readily derived. Under suitable conditions, the matrix representing the implicit problem is an inverse-positive matrix. Using this fact, we establish that the discrete population model is capable of preserving the positivity and the boundedness of the discrete initial-boundary conditions. Moreover, the computational solubility of the discrete model is tackled in the closing remarks.

Key words: discrete fractional Huxley's equation, fractional centered differences, discrete fractional population model, inverse-positive matrices, positivity preservation, boundedness preservation

1 Introduction

Throughout we will assume that $a, b \in \mathbb{R}$ satisfy $a < b$, and that κ, λ, K and T are positive numbers. Let $\phi : [a, b] \to \mathbb{R}$ and $\psi_1, \psi_2 : [0, T] \to \mathbb{R}$ be continuously differentiable functions whose ranges are subsets of $[0, K]$. Assume additionally that the compatibility conditions $\phi(a) = \psi_1(0)$ and $\phi(b) = \psi_2(0)$ are satisfied. Let $1 < \alpha < 2$ and define $\Omega = (a, b) \times (0, T)$.

ISBN: 978-84-617-8694-7

In this work, we will suppose that $u : \overline{\Omega} \to \mathbb{R}$ is a sufficiently smooth function that satisfies the initial-boundary-value problem

$$\begin{gathered}\frac{\partial u}{\partial t}(x,t) - \kappa \frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) = \lambda u(x,t)(1-u(x,t)/K), \\ \text{such that } \begin{cases} u(x,0) = \phi(x), & \forall x \in (a,b), \\ u(a,t) = \psi_1(t), & \forall t \in (0,T), \\ u(b,t) = \psi_2(t), & \forall t \in (0,T), \end{cases}\end{gathered} \tag{1}$$

for each $(x,t) \in \Omega$.

For the sake of convenience, we will define $u(x,t) = 0$ for each $x \in (-\infty, a) \cup (b, \infty)$ and each $t \in [0,T]$. Using this convention, the space-fractional operator in (1) is the Riesz fractional derivative of order α, which is given by

$$\frac{\partial^\alpha u}{\partial |x|^\alpha}(x,t) = \frac{-1}{2\cos(\frac{\pi\alpha}{2})\Gamma(2-\alpha)} \frac{d^2}{dx^2} \int_{-\infty}^{\infty} \frac{u(\xi,t)}{|x-\xi|^{\alpha-1}} d\xi, \tag{2}$$

for each $(x,t) \in \Omega$. Here Γ is the gamma function, which is defined in $\mathbb{R} \setminus \{n : -n \in \mathbb{N} \text{ or } n = 0\}$ by

$$\Gamma(z) = \int_0^\infty s^{z-1} e^{-s} ds. \tag{3}$$

Note that the partial differential equation of (1) is actually a space-fractional extension of the model from population dynamics investigated simultaneously and independently by R. A. Fisher [2] and A. N. Kolmogorov, I. G. Petrovskii and N. Piskunov [3] in 1937.

2 Preliminary results

In this work we follow a fractional difference approach to approximate the solutions of (1), and use fractional centered differences to approximate Riesz space-fractional derivatives. For any function $f : \mathbb{R} \to \mathbb{R}$, any $h > 0$ and any $\alpha > -1$, the fractional centered difference of order α of f at the point x is defined as

$$\Delta_h^\alpha f(x) = \sum_{k=-\infty}^{\infty} g_k^\alpha f(x - kh), \quad \forall x \in \mathbb{R}, \tag{4}$$

where

$$g_k^\alpha = \frac{(-1)^k \Gamma(\alpha+1)}{\Gamma(\frac{\alpha}{2} - k + 1)\Gamma(\frac{\alpha}{2} + k + 1)}, \quad \forall k \in \mathbb{Z}. \tag{5}$$

In the case that $1 < \alpha \leq 2$, the fractional centered differences satisfy (see [4])

$$\lim_{h \to 0} \frac{-1}{h^\alpha} \Delta_h^\alpha f(x) = \frac{\partial^\alpha f}{\partial |x|^\alpha}(x), \quad \forall x \in \mathbb{R}. \tag{6}$$

 ISBN: 978-84-617-8694-7

Lemma 1 (See [1]). *If $1 < \alpha < 2$ then the coefficients $(g_k^\alpha)_{k=-\infty}^{\infty}$ satisfy:*

(a) $g_0^\alpha \geq 0$,

(b) $g_k^\alpha = g_{-k}^\alpha < 0$ *for all* $k \geq 1$, *and*

(c) $\sum_{k=-\infty}^{\infty} g_k^\alpha = 0$. □

Lemma 2 (See [1]). *Let $f \in \mathcal{C}^5(\mathbb{R})$, and assume that all its derivatives up to order five belong to $L_1(\mathbb{R})$. If $1 < \alpha < 2$ then*

$$-\frac{\Delta_h^\alpha f(x)}{h^\alpha} = \frac{\partial^\alpha f(x)}{\partial |x|^\alpha} + \mathcal{O}(h^2). \tag{7}$$

□

3 Numerical methodology

For the remainder of this work, we assume that $M, N \in \mathbb{N}$ and use partition norms $h = (b-a)/M$ and $\tau = T/N$ for the intervals $[a, b]$ and $[0, T]$, respectively. For each $j \in \{0, 1, \ldots, M\}$ and each $n \in \{0, 1, \ldots, N\}$ we define

$$x_j = a + jh, \tag{8}$$
$$t_n = n\tau, \tag{9}$$
$$u_j^n = u(x_j, t_n). \tag{10}$$

Under these circumstances, note that

$$\begin{aligned} \frac{\partial^\alpha u}{\partial |x|^\alpha}(x_j, t_n) &= -\frac{1}{h^\alpha} \sum_{k=j-M}^{j} g_k^\alpha u_{j-k}^n + \mathcal{O}(h^2) \\ &= -\frac{1}{h^\alpha} \sum_{k=0}^{M} g_{j-k}^\alpha u_k^n + \mathcal{O}(h^2), \end{aligned} \tag{11}$$

for each $j \in \{1, \ldots, M-1\}$ and each $n \in \{1, \ldots, N-1\}$. In the following, we will consider the discrete operators

$$\delta_t u_j^n = \frac{u_j^{n+1} - u_j^n}{\tau}, \tag{12}$$
$$\Delta_h^\alpha u_j^n = -\frac{1}{h^\alpha} \sum_{k=0}^{M} g_{j-k}^\alpha u_k^n. \tag{13}$$

 ISBN: 978-84-617-8694-7

Using this nomenclature, the fully discrete population model used in this work to approximate the solutions of (1) is given by the discrete system of equations

$$\begin{gathered}\delta_t u_j^n - \kappa \Delta_h^\alpha u_j^{n+1} = \lambda u_j^{n+1}(1 - u_j^n/K), \\ \text{such that } \left\{ \begin{array}{ll} u_j^0 = \phi(x_j), & \forall j \in \{0, 1, \ldots, M\}, \\ u_0^n = f(a), & \forall n \in \{0, 1, \ldots, N\}, \\ u_M^n = g(b), & \forall n \in \{0, 1, \ldots, N\}, \end{array} \right.\end{gathered} \tag{14}$$

for each $j \in \{1, \ldots, M-1\}$ and $n \in \{1, \ldots, N-1\}$. In this work, we will derive various analytical and numerical properties of (14).

Abstract

In this paper a model for the spread of TB between wild herbivores and their predators is presented and analysed. The most important system parameters are identified: vertical and horizontal disease transmission among the prey, the influence that intraspecific competition between healthy and diseased prey has on the infected prey population. Removal of diseased-prey may be the most effective strategy to free the ecosystem from the disease.

Key words: herd behavior, disease transmission
MSC 2000: AMS 92D25, 92D30, 92D40

1 Introduction

Bovine Tuberculosis (TB) is a threat to wildlife health. The transmission of TB between herd individuals occurs most frequently by aerosol, [4] and predators contract the disease mostly by ingestion of tuberculoses tissues [16]. It directly impacts animal productivity and fitness and can lead to an increase in the mortality rate.

Wild animals appear to be able to harbour mycobacteria for months to years. As infection progresses, there is evidence that TB may decrease reproductive and other fitness

 ISBN: 978-84-617-8694-7

parameters. However, it may not significantly affect them unless they experience other stressors, such as drought or concurrent disease, suggesting that infected animals may remain in the population for prolonged periods [16, 17]. For instance, buffalo herds with a higher prevalence of bovine TB had worse body condition in the dry season than those with lower bovine TB prevalence. Consequently, affected buffalo might be more susceptible to predation by lions, [7]. In addition the loss of these prey animals may influence the predators. A simulation over 50 years of the the impact of bovine TB on lions shows a scenario suggesting a serious threat to the species survival, [17].

To study the impact of TB on wild animals, we present a predator-prey model involving buffalos and lions, both subject to the disease, which is horizontally as well as vertically transmitted. Because the wild buffalo congregates in huge herds, the border individuals are usually captured. Mathematically, this can be modeled via a square root response function, [1, 2, 25, 6]. Indeed since the total population of prey, say P, occupies a certain area A on the ground, the number of the individuals who are found at the border is proportional to the length of the perimeter of the patch A, which in turn is proportional to $\sqrt{P}$.

The paper is organized as follows. In the next section, we formulate the model, show that trajectories are bounded and adimensionalize it. The feasibility and stability analysis are in Section 3. Section 4 contains a study about the basic reproduction number $\mathcal{R}_0$ where we focus the discussion on conditions for the eradication of the disease. Transcritical and Hopf bifurcations are investigated in Section 5. Section 6 shows that the parameter m is crucial for the feasibility and stability of points E_1 and E_2, respectively. The establishment of the disease is directly related to the value of $\mathcal{R}_0$ at both points. To investigate the behavior of model (4) in relation to the parameters, we first separate the simulations in two specific cases. In the first case, E_1 is stable and E_2 is unstable, that is, $m > a$. The second case is obtained when $a/\sqrt{3} < m < a$, in which E_1 is unstable and E_2 is feasible. A final discussion concludes the paper.

2 Model Formulation

We consider a model for species interactions, subject to a TB that can infect both the buffalos and lions. Once infected, an animal remains infected for its life, so that the disease is of type SI. Infected prey $\widehat{I}$ become weak and are left behind the herd. Let further $\widehat{R}$ denote the susceptible prey population, $\widehat{F}$ and $\widehat{W}$ respectively the susceptible and infected predators. The prey have a highly socialized "herd behavior", in that they live together wandering in search of pastures. They are generally followed in their wanderings by the predators. If the hunt is successful for the predator, generally the prey individuals residing on the boundary of herd are harmed. The model, accounting for all the possible population

 ISBN: 978-84-617-8694-7

interactions described below, reads as follows:

$$\frac{d\widehat{R}}{d\tau} = \tilde{r}\widehat{R} + \bar{r}\,(1-\widehat{\alpha})\,\widehat{I} - k\widehat{R}\left(\widehat{R}+\widehat{g}\widehat{I}\right) - \widehat{\lambda}\widehat{R}\widehat{I} - \widehat{cp}\sqrt{\widehat{R}}\widehat{W} - \widehat{a}\sqrt{\widehat{R}}\widehat{F} - \widehat{\theta}\,(1-\widehat{p})\,\widehat{c}\sqrt{\widehat{R}}\widehat{W}, \quad (1)$$

$$\frac{d\widehat{I}}{d\tau} = \bar{r}\widehat{\alpha}\widehat{I} + \widehat{I}\left(\widehat{\lambda}\widehat{R} - \widehat{b}\widehat{F} - \widehat{\mu} - \widehat{\ell}\widehat{W}\right) + \widehat{\theta}(1-\widehat{p})\widehat{c}\sqrt{\widehat{R}}\widehat{W} - k\widehat{I}(\widehat{u}\widehat{R}+\widehat{q}\widehat{I}),$$

$$\frac{d\widehat{F}}{d\tau} = \widehat{ae}\sqrt{\widehat{R}}\widehat{F} + (1-\widehat{\sigma})\widehat{b}\widehat{e}\widehat{I}\widehat{F} + (1-\widehat{\gamma})\widehat{W}(\widehat{ce}\widehat{p}\sqrt{\widehat{R}} + \widehat{\ell}\widehat{e}\widehat{I}) - \widehat{m}\widehat{F} - \widehat{\beta}\widehat{F}\widehat{W},$$

$$\frac{d\widehat{W}}{d\tau} = \widehat{W}\left(\widehat{\gamma}\widehat{ce}\widehat{p}\sqrt{\widehat{R}} + \widehat{\gamma}\widehat{\ell}\widehat{e}\widehat{I} - \widehat{\nu}\right) + \widehat{\sigma}\widehat{b}\widehat{e}\widehat{I}\widehat{F} + \widehat{\beta}\widehat{F}\widehat{W}.$$

The first equation describes the dynamics of $\widehat{R}$ (susceptible prey). The term $\tilde{r}\widehat{R}$ expresses growth rate of $\widehat{R}$ due to their own reproduction and $\bar{r}(1-\widehat{\alpha})\widehat{I}$ is the fraction of $\widehat{I}$ that are born healthy (vertical transmission). The term $k\widehat{R}\left(\widehat{R}+\widehat{g}\widehat{I}\right)$ is the mortality by intraspecific competition between $\widehat{R}$ individuals among themselves and with $\widehat{I}$ individuals. The term $\widehat{\lambda}\widehat{R}\widehat{I}$ represents the susceptible prey, that become infected (horizontal transmission). The term $\widehat{cp}\sqrt{\widehat{R}}\widehat{W}$ represents the prey individuals that are captured by infected predators and $\widehat{a}\sqrt{\widehat{R}}\widehat{F}$ is the capture rate of $\widehat{R}$ by $\widehat{F}$. Finally, $\widehat{\theta}\,(1-\widehat{p})\,\widehat{c}\sqrt{\widehat{R}}\widehat{W}$ are the new infections by an unsuccessful attack of infected predator $\widehat{W}$ on healthy prey $\widehat{R}$, and then latter gets disease. Note that, we have a fraction $(1-\widehat{\theta})(1-\widehat{p})$ of healthy prey that are not captured, but do not get the disease from predators.

The second equation describes the dynamics of $\widehat{I}$ (infected prey). The term $\bar{r}\widehat{\alpha}\widehat{I}$ is the fraction of the reproduction rate of $\widehat{I}$ that is born infected (possibility of vertical transmission), $\widehat{\lambda}\widehat{R}\widehat{I}$ represents the susceptibles prey, that become infected (horizontal transmission), $\widehat{b}\widehat{I}\widehat{F}$ is the predation of $\widehat{I}$ by $\widehat{F}$, $\widehat{\mu}\widehat{I}$ is the mortality of $\widehat{I}$ (disease-related) and $\widehat{\ell}\widehat{I}\widehat{W}$ is the predation of $\widehat{I}$ by $\widehat{W}$. Finally, $\widehat{\theta}\,(1-\widehat{p})\,\widehat{c}\sqrt{\widehat{R}}\widehat{W}$ are the new infections by an unsuccessful attack of infected predator $\widehat{W}$ on healthy prey $\widehat{R}$, and then latter gets disease and $k\widehat{I}(\widehat{u}\widehat{R}+\widehat{q}\widehat{I})$ is the mortality by intraspecific competition of $\widehat{I}$ among themselves and with $\widehat{R}$. Note that, in the model, infected prey do not benefit from the effects of herd behavior.

The third equation describes the dynamics of $\widehat{F}$ (susceptible predator). The term $\widehat{ae}\sqrt{\widehat{R}}\widehat{F}$ expresses the increase of $\widehat{F}$ due to the consumption of $\widehat{R}$ on the boundary with conversion factor $0 < \widehat{e} < 1$. The term $(1-\widehat{\sigma})\widehat{b}\widehat{e}\widehat{I}\widehat{F}$ represents the growth rate of $\widehat{F}$ due to the consumption of $\widehat{I}$, that is, predators that consume infected prey but do not become infected. The term $(1-\widehat{\gamma})\widehat{W}(\widehat{ce}\widehat{p}\sqrt{\widehat{R}})$ expresses the fraction of the reproduction rate of $\widehat{W}$ that is born as a healthy predator due to the consumption $\widehat{R}$ on boundary. Besides that, $(1-\widehat{\gamma})\widehat{W}(\widehat{\ell}\widehat{e}\widehat{I})$ is the analogous term, but due to the consumption of infected prey $\widehat{I}$. Now, the term $\widehat{m}\widehat{F}$ is the mortality of $\widehat{F}$, $\widehat{\beta}\widehat{F}\widehat{W}$ represents the predator who moves from one class to another, that is, susceptibles become infected by contact with another infected predator $\widehat{W}$ (horizontal transmission).

 ISBN: 978-84-617-8694-7

The fourth equation describes the dynamics of $\widehat{W}$ (infected predator). The term $\widehat{\gamma}\widehat{c}\widehat{e}\widehat{p}\sqrt{\widehat{R}}\widehat{W}$ represents the vertical transmission of $\widehat{W}$ in converting captured $\widehat{R}$ on boundary in infected predators $\widehat{W}$. The term $\widehat{\gamma}\widehat{\ell}\widehat{e}\widehat{I}\widehat{W}$ is the vertical transmission of $\widehat{W}$ due to the consumption of $\widehat{I}$, $\widehat{\nu}\widehat{W}$ is the mortality of $\widehat{W}$ (disease-related) and $\widehat{\sigma}\widehat{b}\widehat{e}\widehat{I}\widehat{F}$ is the fraction of healthy predators that gives birth to infected offspring by eating $\widehat{I}$ (vertical transmission). Finally, $\widehat{\beta}\widehat{F}\widehat{W}$ represents the predator who moves from one class to another, that is, susceptibles become infected by contact with another infected predator $\widehat{W}$ (horizontal transmission). All parameters are non-negative and listed in Table 2.

2.1 Boundedness

Following closely [25], the system's trajectories are confined within a compact set. For the total environment population $\varphi(\tau) = \widehat{R}(\tau) + \widehat{I}(\tau) + \widehat{F}(\tau) + \widehat{W}(\tau)$, summing equations (1),

$$\begin{aligned}\frac{d\varphi(\tau)}{dt} = & \left(\tilde{r}\widehat{R} + \bar{r}\widehat{I}\right) - k\widehat{R}\left(\widehat{R} + \widehat{g}\widehat{I}\right) - k\widehat{I}\left(\widehat{u}\widehat{R} + \widehat{q}\widehat{I}\right) \\ & + (\widehat{e} - 1)\left(\widehat{c}\widehat{p}\sqrt{\widehat{R}}\widehat{W} + \widehat{a}\sqrt{\widehat{R}}\widehat{F} + \widehat{\ell}\widehat{I}\widehat{W}\right) - \left(\widehat{\mu}\widehat{I} + \widehat{m}\widehat{F} + \widehat{\nu}\widehat{W}\right).\end{aligned} \tag{2}$$

Using $(\widehat{e} - 1) \leq 0$ we can drop the term that contains it, to get

$$\frac{d\varphi(\tau)}{d\tau} \leq (\tilde{r}\widehat{R} + \bar{r}\widehat{I}) - k\widehat{R}(\widehat{R} + \widehat{g}\widehat{I}) - k\widehat{I}(\widehat{u}\widehat{R} + \widehat{q}\widehat{I}) - (\widehat{\mu}\widehat{I} + \widehat{m}\widehat{F} + \widehat{\nu}\widehat{W})$$

Letting M be the maximum value of the parabola $\Phi(\widehat{R}+\widehat{I}) = -k\eta_2(\widehat{R}+\widehat{I})^2+(\eta_1+\eta_2)(\widehat{R}+\widehat{I})$, with $\eta_1 = \max\{\tilde{r}, \bar{r}\}$, $\eta_2 = \min\{1, \widehat{g}, \widehat{u}, \widehat{q}\}$, $\eta_3 = \min\{\widehat{\mu}, \widehat{m}, \widehat{\nu}\}$, we find the estimate

$$\frac{d\varphi(t)}{dt} + \eta_3\varphi(t) \leq \Phi(\widehat{R} + \widehat{I}) \leq \bar{M} = \frac{(\eta_1 + \eta_3)^2}{4\eta_2 K},$$

from which we establish the boundedness result

$$\varphi(t) \leq (\widehat{e})^{\eta_3 t}\frac{M}{\eta_3} + \varphi(0)(\widehat{e})^{-\eta_3 t} \leq \frac{M}{\eta_3} + \varphi(0) = \bar{M}$$

Note also that from below, the coordinate hyperplanes cannot be crossed toward negative values, although the system is not homogeneous. For instance, the first equation for $\widehat{R} = 0$ gives $\widehat{R}'(\tau) = \bar{r}\,(1 - \widehat{\alpha})\,\widehat{I} \geq 0$ because the parameters are nonnegative and $1 - \widehat{\alpha} \geq 0$.

The model (1) can be nondimensionalized via $R(t) = \frac{k}{\tilde{r}}\widehat{R}(\tau)$, $I(t) = \frac{k}{\tilde{r}}\widehat{I}(\tau)$, $F(t) = \frac{k}{e\tilde{r}}\widehat{F}(\tau)$, $W(t) = \frac{k}{e\tilde{r}}\widehat{W}(\tau)$, $t = \tilde{r}\tau$, and

$$\begin{aligned} r = \frac{\bar{r}}{\tilde{r}}, \quad g = \widehat{g}, \quad \lambda = \frac{\widehat{\lambda}}{k}, \quad c = \frac{\widehat{c}\widehat{e}}{\sqrt{\tilde{r}k}}, \quad a = \frac{\widehat{a}\widehat{e}}{\sqrt{\tilde{r}k}}, \quad b = \frac{\widehat{b}\widehat{e}}{k}, \\ \mu = \frac{\widehat{\mu}}{\tilde{r}}, \quad \ell = \frac{\widehat{\ell}\widehat{e}}{k}, \quad u = \widehat{u}, \quad q = \widehat{q}, \quad m = \frac{\widehat{m}}{\tilde{r}}, \quad \frac{\widehat{\beta}\widehat{e}}{k}, \end{aligned} \tag{3}$$

 ISBN: 978-84-617-8694-7

Table 1: Parameters of model (1) and their biological meanings

Parameter	Biological meaning
$\tilde{r}$	Specific growth rate of healthy prey $\widehat{R}$
$\bar{r}$	Specific growth rate of infected prey I ($\bar{r} \leq \tilde{r}$)
$\widehat{\alpha}$	Non-dimensional parameter that represents the fraction of prey $\widehat{R}$ that born infected (vertical transmission)
$1-\widehat{\alpha}$	Non-dimensional parameter that represents the fraction of prey $\widehat{R}$ that born no infected
k	Mortality of healthy prey $\widehat{R}$ due intraspecific competition ($k = \frac{r}{K}$)
K	Carrying capacity of prey $\widehat{R}$ in absence of predator
$\widehat{g}$	Non-dimensional parameter that regulates competition among infected prey $\widehat{I}$ with healthy prey $\widehat{R}$
$\widehat{\lambda}$	Infection rate in healty prey $\widehat{R}$ (horizontal transmission)
$\widehat{\theta}$	Probability that healthy prey $\widehat{R}$, not captured by infected predator $\widehat{W}$, becomes infected
$\widehat{p}$	Probability that represents the fraction of captured prey $\widehat{R}$
$1-\widehat{p}$	Probability that represents the fraction of no captured prey $\widehat{R}$
$\widehat{a}$	Predation rate of healthy prey $\widehat{R}$ by healthy predator $\widehat{F}$
$\widehat{c}$	Predation rate of healthy prey $\widehat{R}$ by infected predator $\widehat{W}$
$\widehat{b}$	Predation rate of infected prey $\widehat{I}$ by healthy predator $\widehat{F}$
$\widehat{\mu}$	Mortality rate of infected prey $\widehat{I}$
$\widehat{\ell}$	Predation rate of infected prey $\widehat{I}$ by infected predator $\widehat{W}$
$\widehat{u}$	Non-dimensional parameter that regulates how infected prey $\widehat{I}$ compete with healthy prey $\widehat{R}$
$\widehat{q}$	Non-dimensional parameter that regulates how infected prey $\widehat{I}$ compete with infected prey $\widehat{I}$
$\widehat{e}$	Efficiency of the predator in converting captured prey into reproductive success
$\widehat{\sigma}$	Non-dimensional parameter that regulates the infection rate in predator $\widehat{F}$ (vertical transmission)
$1-\widehat{\sigma}$	Non-dimensional parameter that represents the fraction of no infection of $\widehat{F}$ in the vertical transmission for the case where there is consumption of infected prey
$\widehat{m}$	Mortality rate of healthy predator $\widehat{F}$
$\widehat{\beta}$	Infection rate in healty predator $\widehat{F}$ (horizontal transmission)
$\widehat{\gamma}$	Probalility of vertical transmission in predator $\widehat{F}$
$1-\widehat{\gamma}$	Non-dimensional parameter that describes the fraction that rate of no infection in $\widehat{F}$ (no infected individual)
$\widehat{\nu}$	Mortality rate of infected predator $\widehat{W}$

 ISBN: 978-84-617-8694-7

to get re-scaled system:

$$\frac{dX}{dt} = f(X), \quad X = (R, I, F, W)^T, \quad f = (f_1, f_2, f_3, f_4)^T, \tag{4}$$

$$\begin{aligned} f_1 &= R + r\,(1-\alpha)\,I - R\,(R + gI) - \lambda RI - cp\sqrt{R}W - a\sqrt{R}F - \theta\,(1-p)\,c\sqrt{R}W, \\ f_2 &= \alpha I + I\,(\lambda R - bF - \mu - \ell W) + \theta(1-p)c\sqrt{R}W - I(uR + qI), \\ f_3 &= a\sqrt{R}F + (1-\sigma)bIF + (1-\gamma)cp\sqrt{R}W - mF + (1-\gamma)\ell IW - \beta FW, \\ f_4 &= \gamma cp\sqrt{R}W + \gamma\ell IW - \nu W + \sigma bIF + \beta FW. \end{aligned}$$

3 System's equilibria

Model (4) has five equilibria. The origin E_0, two disease-free equilibria, $E_1 = (1, 0, 0, 0)$, and $E_2 = (R_2, 0, F_2, 0)$, the predator-free $E_3 = (R_3, I_3, 0, 0)$ and coexistence $E_4 = (R_4, I_4, F_4, W_4)$ which is studied numerically. Their components are:

$$R_2 = \frac{m^2}{a^2}, \quad F_2 = \frac{m^2}{a^2}\left(\frac{1}{m} - \frac{m}{a^2}\right), \quad I_3 = \frac{\alpha - \mu}{q} + \frac{\lambda - u}{q}R_3 \tag{5}$$

and R_3 given by the roots of the quadratic equation

$$\Phi(R_3) = \alpha_2 R_3^2 + \alpha_1 R_3 + \alpha_0 = 0 \tag{6}$$

with

$$\alpha_2 = \frac{(g+\lambda)(u-\lambda) - q}{q}, \quad \alpha_0 = \frac{r(\alpha-1)(\mu-\alpha)}{q}, \quad \alpha_1 = \frac{(1-\alpha)r(\lambda-u) + (\mu-\alpha)(\lambda+g) + q}{q}.$$

3.1 Feasibility

Feasibility for E_2 is ensured by

$$m \le a \tag{7}$$

and in case of E_3 the feasibility conditions are for $I_3 \ge 0$

$$\alpha + \lambda R_3 \ge \mu + uR_3 \tag{8}$$

and for $R_3 \ge 0$ two positive roots exist if

$$\Delta = \alpha_1^2 - 4\alpha_2\alpha_0 > 0, \quad -\alpha_1\alpha_2^{-1} > 0, \quad \alpha_0\alpha_2^{-1} > 0$$

while at least one positive root is ensured by

$$\Delta = \alpha_1^2 - 4\alpha_2\alpha_0 > 0, \quad \alpha_0\alpha_2^{-1} < 0.$$

 ISBN: 978-84-617-8694-7

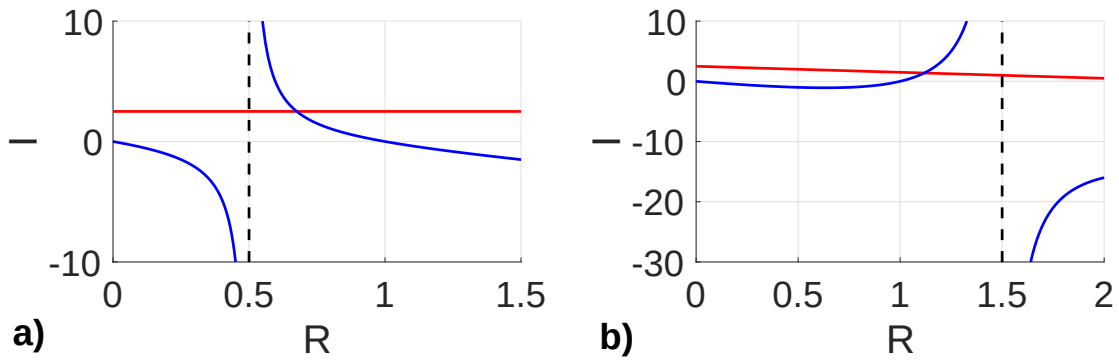

Figure 1: Nullclines in the plane $R-I$, considering $F=W=0$. If $\lambda+\alpha>u+\mu$ ($\lambda_1^{E_1}>1$), there is a unique feasible equilibrium point in the form $(R_3, I_3, 0, 0)$. a) Parameter values: $\alpha=0.5$, $q=g=0.1$, $r=0.75$ and $u=\mu=0.25$ we obtain $p^*=0.5$. b) Parameter values: $\alpha=0.5$, $q=g=0.1$, $r=0.75$ and $u=\mu=0.25$ we obtain $p^*=0.5$.

A feasible equilibrium solution for system (4) with $F=0$ and $W=0$ is an intersection in the first quadrant of the two curves:

$$f(R)=\frac{(R-1)R}{(1-\alpha)r-(g+\lambda)R}, \quad h(R)=\frac{(\alpha-\mu)+(\lambda-u)R}{q}. \tag{9}$$

Note that the function $f(R)$ has an asymptote in $R=p^*=r(1-\alpha)/(g+\lambda)$, thus there are two cases: $p^*>1$ and $p^*<1$, which respectively give:

$$f(R):\begin{cases}<0 & \text{if } 0<R<p^*\\ >0 & \text{if } p^*<R<1\\ <0 & \text{if } 1<R\end{cases} \qquad f(R):\begin{cases}<0 & \text{if } 0<R<1\\ >0 & \text{if } 1<R<p^*\\ <0 & \text{if } p^*<R\end{cases}. \tag{10}$$

Assume

$$\lambda+\alpha>\mu+u. \tag{11}$$

It follows thay $f(1)=0$ and f is unbounded around $(p^*-\epsilon, p^*+\epsilon)$, $\epsilon>0$, since $h(R)$ is bounded in any closed interval in $(0,\infty)$ it follows that $f(R)$ and $h(R)$ must intersect at a point in $(p^*,1)$ if $p^*<1$ or in the interval $(1,p^*)$ if $p^*>1$. Since $f(R)$ is convex in such intervals and negative outside them, uniqueness of the intersection is assured. In Figure 1 we present a sketch with the two cases.

3.2 Local Stability Analysis

The Jacobian of the system (4) is given by

$$J = \begin{pmatrix} J_{11} & -\lambda R - gR + (1-\alpha)r & -a\sqrt{R} & -\theta(1-p)c\sqrt{R} - cp\sqrt{R} \\ J_{21} & J_{22} & -bI & \theta(1-p)c\sqrt{R} - \ell I \\ J_{31} & J_{32} & J_{33} & (1-\gamma)(\ell I + cp\sqrt{R}) - \beta F \\ \frac{c\gamma pW}{2\sqrt{R}} & \ell\gamma W + b\sigma F & \beta W + b\sigma I & cp\gamma\sqrt{R} + \gamma\ell I + \beta F - \nu \end{pmatrix} \tag{12}$$

with

$$J_{11} = -\lambda I - \frac{\theta(1-p)cW}{2\sqrt{R}} - \frac{cpW}{2\sqrt{R}} - 2R - \frac{aF}{2\sqrt{R}} - gI + 1, \quad J_{21} = \lambda I + \frac{\theta(1-p)cW}{2\sqrt{R}} - uI,$$

$$J_{22} = \lambda R - \ell W - 2qI - uR - bF + \alpha - \mu, \quad J_{31} = \frac{c(1-\gamma)pW}{2\sqrt{R}} + \frac{aF}{2\sqrt{R}},$$

$$J_{32} = (1-\gamma)\ell W + b(1-\sigma)F, \quad J_{33} = -\beta W + a\sqrt{R} + b(1-\sigma)I - m,$$

3.2.1 Stability Analysis of E_0

The origin for this model presents a particular behavior. Although unstable in the Lyapunov sense [19], it is still capable of attracting trajectories over a set of initial condition with positive measure in $\mathbb{R}^4$. The instability of the origin can be seen, by observing that any trajectory starting in the line defined by $I = F = W = 0$ remains in it, since $\dot{I} = \dot{F} = \dot{W} = 0$. The equation for $\dot{R}$ on the line is simply $\dot{R} = R(1-R)$ which implies that the origin is unstable, since any trajectory with initial condition $0 < \epsilon = R_0 < 1$ moves away from the origin.

This particular behavior of the origin is caused by the predation term which is proportional to the square root of the healthy prey population. When $R \to 0$, such term has a higher order when compared to the reproduction term (R). In fact such proportionality to the square root of R is adequate for "large" population, since the group defense effect is negligible when the population is "small". Also, in the present model we seek to analyze the biological situations which are relevant to the analysis to the spread of the disease, that is, the scenarios where at least one of the populations is present.

However, a particular phenomenon has been observed in similar models in these conditions, [26, 11, 12, 3]. The right hand side of the system is not Lipschitz-continuous because of the presence of the square root in every component, so that the uniqueness theorem does not hold. In [26] this has been investigated, showing that trajectories lying in a narrow stripe may well end up on the prey axis in finite time, and from there they move toward the origin, with ecosytem collapse. This has been further investigated in [11, 12, 3], showing that it entails a wealth of bifurcation phenomena. For a generalization to an arbitrary power instead of the square root, see [5].

 ISBN: 978-84-617-8694-7

At E_1 the eigenvalues are easily found and given by $\lambda_1 = cp\gamma - \nu$, $\lambda_2 = a - m$, $\lambda_3 = -1$ and $\lambda_4 = \lambda + \alpha - \mu - u$. E_1 is stable if and only if

$$cp\gamma < \nu, \quad a < m, \quad \lambda + \alpha < \mu + u. \tag{13}$$

For E_2 the product of two quadratic equations is obtained. The first one has the Routh-Hurwitz conditions $\mathrm{tr}(\overline{J}^1_{E_2}) = (a^2 - 3m^2)(2a)^{-2} < 0$, $\det(\overline{J}^1_{E_2}) = (ma^2 - m^3)(2a)^{-2} > 0$, the stability conditions

$$\frac{a}{\sqrt{3}} < m < a. \tag{14}$$

The second quadratic has more complicated Routh-Hurwitz conditions that provide the second set of stability conditions

$$a^4\nu + a^2m^2u + a^4\mu + \beta m^3 + bma^2 > am^2\lambda + cmp\gamma a^3 + bm^3 + \beta ma^2 + \alpha a^4 \tag{15}$$

and

$$\begin{aligned} a^5c\gamma m^3p\lambda + a^4\beta m^3\lambda + a^6m^2u\nu + a^8\mu\nu + a^6bm\nu + a^2\beta m^5u + a^5bcpm^2\theta\sigma + a^3bcm^4\theta\sigma \\ +a^3bcpm^4\gamma + a^7cmp\alpha\gamma + a^4\beta m^3\mu + a^2 2b\beta m^4 + a^6\beta m\alpha > a^6m^2\nu\lambda + a^2\beta m^5\lambda \\ +a^4bm^3\nu + a^8\alpha\nu + a^5cpu\gamma m^3 + a^3bcpm^4\theta\sigma + a^4\beta m^3u + a^5bcm^2\theta\sigma + a^7cmp\mu\gamma \\ +a^5bcpm^2\gamma + a^6\beta m\mu + \beta bm^6 + a^4\beta m^3\alpha + a^4\beta bm^2. \end{aligned} \tag{16}$$

At E_3 again the characteristic equation factorizes into the product of two quadratic equations, that have the Routh-Hurwitz conditions

$$\begin{aligned} \mathrm{tr}(\overline{J}^1_{E_3}) &= (\lambda R_3 - \lambda I_3 - 2qI_3 - gI_3 - uR_3 - 2R_3 + \alpha + 1 - \mu < 0, \\ \det(\overline{J}^1_{E_3}) &= -2\lambda {R_3}^2 + \lambda R_3 + 2q\lambda {I_3}^2 + 2gq{I_3}^2 - 2r\lambda I_3 - g\mu I_3 - 2u{R_3}^2 + 4qR_3I_3 - 2qI_3 \\ &\quad -rukR_3 - r\alpha uI_3 - ruI_3 - 2\mu R_3 - r\lambda I_3 + \mu\lambda I_3 - \alpha\lambda I_3 - g\alpha I_3 - 2\alpha r - \mu + \alpha > 0, \end{aligned}$$

from which the stability conditions follow

$$\begin{aligned} \lambda I_3 + 2qI_3 + gI_3 + uR_3 + 2R_3 + \mu > \lambda R_3 + \alpha + 1, \\ 2\lambda {R_3}^2 + \lambda R_3 + 2q\lambda {I_3}^2 + 2gq{I_3}^2 + 4qR_3I_3 + \mu\lambda I_3 + \alpha \\ > 2r\lambda I_3 + g\mu I_3 + 2u{R_3}^2 + 2qI_3 + rukR_3 + r\alpha uI_3 \\ +ruI_3 + 2\mu R_3 + r\lambda I_3 + \alpha\lambda I_3 + g\alpha I_3 + 2\alpha r + \mu. \end{aligned} \tag{17}$$

The second quadratic instead gives the Routh-Hurwitz conditions

$$\begin{aligned} \mathrm{tr}(\overline{J}^2_{E_3}) &= cp\gamma\sqrt{R_3} + a\sqrt{R_3} - b\sigma I_3 + \gamma\ell I_3 + bI_3 - \nu - m < 0, \\ \det(\overline{J}^2_{E_3}) &= acp\gamma R_3 - bcp\sigma\sqrt{R_3}I_3 + bc\gamma p\sqrt{R_3}I_3 + a\gamma\ell\sqrt{R_3}I_3 - a\nu\sqrt{R_3} \\ &\quad -cmp\gamma\sqrt{R_3} - b\sigma\ell {I_3}^2 + b\ell\gamma {I_3}^2 + b\sigma\nu I_3 - b\nu I_3 - m\ell\gamma I_3 + m\nu > 0, \end{aligned}$$

 ISBN: 978-84-617-8694-7

once again providing the stability conditions

$$\begin{aligned} b\sigma I_3+\nu+m > cp\gamma\sqrt{R_3}+a\sqrt{R_3}+\gamma\ell I_3+bI_3 \\ acp\gamma R_3+bc\gamma p\sqrt{R_3}I+a\gamma\ell\sqrt{R_3}I_3+b\ell\gamma {I_3}^2+b\sigma\nu I_3+m\nu \\ > bcp\sigma\sqrt{R_3}+a\nu\sqrt{R_3}I_3+cmp\gamma\sqrt{R_3}+b\sigma\ell {I_3}^2+b\nu I_3+m\ell\gamma I_3. \end{aligned} \tag{18}$$

4 The basic reproduction number

Conditions for the eradication of the disease can be obtained from the basic reproduction number $\mathcal{R}_0$, the spectral radius of the next generation matrix at each disease-free equilibrium [24]. Let F_I, F_W be the corresponding new infectious rates and V_I, V_W the analogous flows, the dynamics of the infectious classes I and W can be written as:

$$\frac{dI}{dt}=F_I-V_I=F_I-(V_I^- - V_I^+), \quad \frac{dW}{dt}=F_W-V_W=(V_W^- - V_W^+), \tag{19}$$

where

$$\begin{aligned} F_I=\bar{r}\alpha I+\lambda RI+\theta(1-p)c\sqrt{R}W, \quad F_W=be\sigma IF+\beta FW+cep\gamma\sqrt{R}W+el\gamma IW, \\ {V_I}^-=bIF+\mu I+lIW+ukRI+qkI^2, \quad {V_I}^+=0, \quad {V_W}^-=vW, \quad {V_W}^+=0. \end{aligned}$$

Letting

$$F=\begin{pmatrix} \frac{\partial F_I}{\partial I} & \frac{\partial F_W}{\partial I} \\ \frac{\partial F_I}{\partial W} & \frac{\partial F_W}{\partial W} \end{pmatrix}=\begin{pmatrix} \alpha+\lambda R & \gamma\ell W+b\sigma F \\ \theta(1-p)c\sqrt{R} & pc\gamma\sqrt{R}+\ell\gamma I+\beta F \end{pmatrix}$$

$$V=\begin{pmatrix} \frac{\partial V_I}{\partial I} & \frac{\partial V_W}{\partial I} \\ \frac{\partial V_I}{\partial W} & \frac{\partial V_W}{\partial W} \end{pmatrix}=\begin{pmatrix} bF+\mu+\ell W+uR+2qI & 0 \\ \ell I & \nu \end{pmatrix}.$$

the next generation matrix is

$$G=FV^{-1}=\begin{pmatrix} \frac{\alpha\nu+\lambda\nu R-\ell\gamma IW-b\ell\sigma IF}{\nu(\ell W+uR+2qI+bF+\mu)} & \frac{\ell\gamma W+b\sigma F}{\nu} \\ \frac{\theta(1-p)c\nu\sqrt{R}-pc\ell\gamma I\sqrt{R}-\ell^2\gamma I^2-\beta\ell IF}{\nu(\ell W+uR+2qI+bF+\mu)} & \frac{\beta F+\ell\gamma I+cp\gamma\sqrt{R}}{\nu} \end{pmatrix}.$$

$\mathcal{R}_0$ is defined in each disease-free equilibrium as the spectral radius of G. For model (4) the only feasible disease-free equilibria are E_0, E_1 and E_2. Therefore, we proceed the analysis of the disease-free equilibria.

 ISBN: 978-84-617-8694-7

4.1 Stability analysis of disease-free equilibria

The methodology requires five conditions to be applied [24], one of them is that disease-free equilbrium should be stable if the number of new cases are set to zero. Considering $F_I = 0$ and $F_W = 0$ in model (4) we obtain:

$$\begin{aligned}
\frac{dR}{dt} = \quad & rR + \bar{r}\,(1-\alpha)\,I - kR\,(R+gI) - \lambda RI - cp\sqrt{R}W \\
& -a\sqrt{R}F - \theta\,(1-p)\,c\sqrt{R}W, \\
\frac{dI}{dt} = \quad & -bIF - \mu I - lIW - ukRI - qkI^2, \\
\frac{dF}{dt} = \quad & ae\sqrt{R}F + (1-\sigma)beIF + (1-\gamma)W(cep\sqrt{R} + \ell eI) \\
& -mF - \beta FW, \\
\frac{dW}{dt} = \quad & -vW.
\end{aligned} \tag{20}$$

The Jacobian of the system (20) is given by

$$J = \begin{pmatrix} J_{11} & -\lambda R - gR + (1-\alpha)r & -a\sqrt{R} & J_{14} \\ -uI & J_{22} & -bI & -\ell I \\ \frac{cp(1-\gamma)W + aF}{2\sqrt{R}} & J_{32} & J_{33} & J_{34} \\ 0 & 0 & 0 & -v \end{pmatrix} \tag{21}$$

with

$$J_{11} = -\lambda I - \frac{\theta(1-p)cW}{2\sqrt{R}} - \frac{cpW}{2\sqrt{R}} - gI - 2R - \frac{aF}{2\sqrt{R}} + 1,$$

$$J_{14} = -\theta(1-p)c\sqrt{R} - cp\sqrt{R}, \quad J_{22} = -bF - \mu - \ell W - uR - 2qI,$$

$$J_{32} = (1-\gamma)\ell W + b(1-\sigma)F,$$

$$J_{33} = a\sqrt{R} + (1-\sigma)bI - m - \beta W, \quad J_{34} = (1-\gamma)(\ell I + cp\sqrt{R}) - \beta F,$$

4.1.1 Disease-free equilibrium E_1

For this point the stability condition under $F_I = F_W = 0$ is

$$m > a. \tag{22}$$

The eigenvalues of G in E_1 are:

$$\lambda_1^{E_1} = \frac{\alpha + \lambda}{u + \mu}, \quad \lambda_2^{E_1} = \frac{cp\gamma}{\nu}. \tag{23}$$

 ISBN: 978-84-617-8694-7

Since $\lambda_1^{E_1}$ and $\lambda_2^{E_1}$ are both positive, the value of $\mathcal{R}_0$ in E_1 is simply $\mathcal{R}_0^{E_1} = \max\{\lambda_1^{E_1}, \lambda_2^{E_1}\}$. Disease-induced instability occurs if $\mathcal{R}_0 > 1$.

If $\nu \geq m$, that is, the rate of mortality of infected predators is greater than non-infected ones, then we can write:

$$\nu \geq m > a \geq c \geq cp\gamma,$$

because we consider $a \geq c$ (healthy predators are more efficient in hunting than infected ones) and $p, \gamma \leq 1$. Therefore, $\lambda_2^{E_1} < 1$ if E_1 is stable in the absence of disease.

The condition for $\mathcal{R}_0 < 1$ coming from $\lambda_1^{E_1}$ can be written as

$$\alpha + \lambda < u + \mu.$$

The left side of the inequality represents rates that are favorable to the permanence of the disease, i.e, reproduction rate of infectious prey and generation of new infectious cases at the equilibrium. In the right side of inequality are the factors that contribute to the eradication of the disease, i.e, the mortality rates of infected prey and mortality due to competition with healthy prey at the equilibrium. In this case stability in the absence of the disease does not imply $\lambda_1^{E_1} < 1$. For instance, even if $\alpha = 0$ it is sufficient to take $\lambda > u + \mu$ to obtain $\mathcal{R}_0 > 1$.

4.1.2 Disease-free equilibrium E_2

Considering $F_I = F_W = 0$, the viability condition for the equilibrium E_2 is given by

$$m \leq a \tag{24}$$

and the stability conditions for it are

$$\frac{a}{\sqrt{3}} < m < a. \tag{25}$$

The matrix G in E_2 is

$$G(E_2) = \begin{pmatrix} \dfrac{\alpha a^4 + \lambda m^2 a^2}{um^2a^2 + bma^2 - bm^3 + \mu a^4} & \dfrac{\sigma ba^2 m - \sigma bm^3}{\nu a^4} \\ \dfrac{(-cpma^3 + cma^3)\theta}{a^2m^2u + \mu a^4 - bm^3 + bma^2} & \dfrac{cpm\gamma a^3 - \beta m^3 + \beta ma^2}{\nu a^4} \end{pmatrix} \tag{26}$$

The formulas for eigenvalues of $G(E_2)$ do not provide any immediate insight on the behavior of $\mathcal{R}_0$, but through numerical simulations we can state that both $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$ can have absolute values greater than one.

5 Bifurcations

In this section we will use Sotomayor theorem [19, 18].

5.1 Transcritical bifurcation

Note that the general second order term of the Taylor expansion of f, recall (4), is given by

$$D^2 f(X,m)(U,U) = (D_{11}, D_{21}, D_{31}, D_{41})^T, \tag{27}$$

taking m as any bifurcation parameter and $U = (\xi_1, \xi_2, \xi_3, \xi_4)^T$ being the vector of variations in R, I, F and W, with

$$\begin{aligned} D_{11} &= \frac{\theta(1-p)cW{\xi_1}^2 + cpW{\xi_1}^2 + aF{\xi_1}^2}{4R\sqrt{R}} - 2{\xi_1}^2 - 2g\xi_1\xi_2 - 2\lambda\xi_1\xi_2 \\ &- \frac{a}{\sqrt{R}}\xi_1\xi_3 - \frac{cp}{\sqrt{R}}\xi_1\xi_4 - \frac{\theta(1-p)c}{\sqrt{R}}\xi_1\xi_4, \end{aligned}$$

$$D_{21} = -\frac{\theta(1-p)cW}{4R\sqrt{R}}{\xi_1}^2 + 2(\lambda-u)\xi_1\xi_2 - 2b\xi_2\xi_3 - 2\ell\xi_2\xi_4 - 2q{\xi_2}^2 + \frac{\theta(1-p)c}{\sqrt{R}}\xi_1\xi_4,$$

$$\begin{aligned} D_{31} &= -\frac{c(1-\gamma)pW{\xi_1}^2 - aF{\xi_1}^2}{4R\sqrt{R}} + \frac{a}{\sqrt{R}}\xi_1\xi_3 + \frac{c(1-\gamma)p}{\sqrt{R}}\xi_1 l\xi_4 \\ &+ 2b(1-\sigma)\xi_2\xi_3 + 2(1-\gamma)\ell\xi_2\xi_4 - 2\beta\xi_3\xi_4, \end{aligned}$$

$$D_{41} = -\frac{cpW}{4R\sqrt{R}}{\xi_1}^2 + \frac{cp\gamma}{\sqrt{R}}\xi_1\xi_4 + 2b\sigma\xi_2\xi_3 + 2\gamma\ell\xi_2\xi_4 + 2\beta\xi_3\xi_4.$$

5.1.1 Bifurcation between E_1 and E_2

Comparing the second inequality in (13) given by $m > a$ for the equilibrium point E_1 and, the inequality in (7) and the right inequality in (14) for equilibrium point E_2, we find that E_2 becomes feasible and stable exactly when E_1 becomes unstable. There is thus a transcritical bifurcation for which E_2 emanates from E_1 when the bifurcation parameter m crosses the critical value $m^\dagger$ given by

$$m^\dagger = a. \tag{28}$$

The simulation presented in Figure 2 (a) shows it explicitly for the chosen parameter values $m^\dagger = a = 1$. We prove that there is a transcritical bifurcation between points E_1 and E_2, according to the following proposition

 ISBN: 978-84-617-8694-7

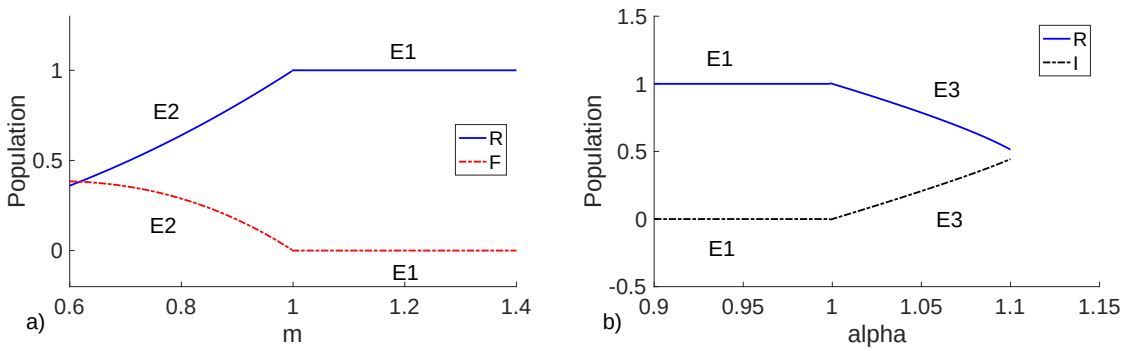

Figure 2: a) Transcritical bifurcation between E_1 and E_2 for the parameter values $\lambda = \beta = \ell = \alpha = \sigma = \gamma = \theta = q = c = p = r = g = b = 0.5$, $a = 1$, $u = \mu = 0.75$, $\nu = 2m$. Initial conditions $R_0 = I_0 = F_0 = W_0 = 0.1$. b) Transcritical bifurcation between E_2 and E_3. In this case, we have same parameter value and initial conditions, except for $m = 0.5$.

Proposition 1 Assuming that $\alpha + \lambda < u + \mu$ and $cp\gamma < \nu$, when m passes through the value $m^\dagger = a$, model (4) near the disease-free equilibrium $E_1 = (1, 0, 0, 0)$ has:

- no saddle-node bifurcation;
- a transcritical bifurcation;
- no pitchfork bifurcation.

Proof Since $\alpha + \lambda < u + \mu$, $cp\gamma < \nu$ and $m > a$, the equilibrium point E_1 is stable. The Jacobian matrix of model (4) evaluated at E_1 with $m^\dagger = a$, is given by

$$J_{E_1}(m^\dagger) = \begin{pmatrix} -1 & -\lambda - g + (1-\alpha)r & -a & -\theta(1-p)c - cp \\ 0 & \lambda - u - \mu + \alpha & 0 & \theta(1-p)c \\ 0 & 0 & 0 & c(1-\gamma)p \\ 0 & 0 & 0 & cp\gamma - \nu \end{pmatrix}. \tag{29}$$

In this case, we have one eigenvalue equal zero in (29), in which the corresponding eigenvector is $V_1 = \varphi_1(1, 0, -\frac{1}{a}, 0)^T$, where φ_1 is any nonzero real number.

Similarly, $Z_1 = \omega_1(0, 0, 1, -p(c\gamma - c)(\nu - c\gamma p)^{-1})^T$ represents the eigenvector corresponding to eigenvalue equal zero of $(J_{E_1}(m^\dagger))^T$, where ω_1 is any nonzero real number. Differentiating partially the right hand sides of the equations of system (4) with respect to $m^\dagger = a$, we find

$$\frac{df}{dm} = f_m(E_1, a) = (0, 0, 0, 0)^T, \tag{30}$$

 ISBN: 978-84-617-8694-7

which gives $Z_1^T f_m(E_1, a) = 0$. Thus, according to Sotomayor's theorem for local bifurcation, model (4) has no saddle-node bifurcation near disease-free equilibrium at $m^\dagger = a$. Besides that,

$$Df_m(E_1, a) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{31}$$

then, $Z_1^T[Df_m(E_1, a).V_1] = \varphi_1\omega_1/a \neq 0$. Now, considering E_1, $m^\dagger = a$ and V_1 in (27) we get

$$D^2 f(E_1, a).(V_1, V_1) = \varphi_1^2 (-1, 0, -1, 0)^T . \tag{32}$$

Therefore,

$$Z_1^T[D^2 f(E_1, a).(V_1, V_1)] = -\omega_1\varphi_1^2 \neq 0. \tag{33}$$

According to Sotomayor's theorem model (4) has a transcritical bifurcation at E_1 with parameter $m^\dagger = a$, while the pitchfork bifurcation cannot occur.

5.1.2 Bifurcation between E_1 and E_3

Comparing the third inequality in (13) for the equilibrium point E_1 and, the inequality in (11) for equilibrium point E_3, we find that E_3 becomes feasible exactly when E_1 becomes unstable. There is thus a transcritical bifurcation for which E_3 emanates from E_1 when the bifurcation parameter α crosses the critical value $\alpha^\dagger$ given by

$$\alpha^\dagger = u + \mu - \lambda \tag{34}$$

The simulation presented in Figure 2 (b) shows it explicitly for the chosen parameter values $\alpha^\dagger = u + \mu - \lambda = 1$. We prove that there is a transcritical bifurcation between points E_1 and E_3, according to the following proposition

Proposition 2 Assuming that $\alpha + \lambda < u + \mu$ and $cp\gamma < \nu$, when α passes through the value $\alpha^\dagger = u + \mu - \lambda$, model (4) near the disease-free equilibrium E_1 has:

- no saddle-node bifurcation;
- a transcritical bifurcation;
- no pitchfork bifurcation.

Proof

Since $\alpha + \lambda < u + \mu$, $cp\gamma < \nu$ and $m > a$, the equilibrium point E_1 is stable. The Jacobian matrix of model (4) evaluated at E_1, with $\alpha^\dagger = u + \mu - \lambda$ is

 ISBN: 978-84-617-8694-7

$$J_{E_1}(\alpha^\dagger) = \begin{pmatrix} -1 & \lambda(r-1)+r(1-u-\mu)-g & -a & -\theta(1-p)c-cp \\ 0 & 0 & 0 & \theta(1-p)c \\ 0 & 0 & a-m & c(1-\gamma)p \\ 0 & 0 & 0 & cp\gamma-\nu \end{pmatrix}. \tag{35}$$

in which has one eigenvalue equal zero and the corresponding eigenvector is $V_2 = \varphi_2(1, (\lambda - ru+r-r\mu-g)^{-1}, 0, 0)^T$. For $J_{E_1}(\alpha^\dagger))^T$, the eingenvector is $Z_2 = \omega_2(0, 1, 0, ((cp-c)\theta)(c\gamma p-\nu)^{-1})^T$. We have φ_2 and ω_2 are any nonzero real number.

Differentiating partially the right hand sides of the equations of system (4) with respect to $\alpha^\dagger = u + \mu - \lambda$, we find

$$\frac{df}{d\alpha} = f_\alpha(E_1, \alpha^\dagger) = (0, 0, 0, 0)^T, \tag{36}$$

which gives $Z_2^T.f_\alpha(E_1, \alpha^\dagger) = 0$. Thus, according to Sotomayor's theorem for local bifurcation, model (4) has no saddle-node bifurcation near disease-free equilibrium at $\alpha^\dagger = u+\mu-\lambda$.

Moreover,

$$Df_\alpha(E_1, \alpha^\dagger) = \begin{pmatrix} 0 & -r & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0, \end{pmatrix} \tag{37}$$

then, $Z_2^T[Df_m(E_1, \alpha^\dagger)V_2] = \varphi_2\omega_2(\lambda - ru + r - r\mu - g)^{-1} \neq 0$. Now, considering E_1, $\alpha^\dagger$ and V_2 in (27) we get with $\Lambda = \lambda - ru + r - r\mu - g$

$$D^2 f(E_1, \alpha^\dagger).(V_2, V_2) = \varphi_2^2 \left(\frac{-4\lambda - 2r + 2ru - 2r\mu}{\Lambda}, \frac{2(\lambda - u)}{\Lambda} - \frac{2q}{\Lambda^2}, 0, 0 \right)^T. \tag{38}$$

Therefore,

$$Z_2^T[D^2 f(E_1, \alpha^\dagger).(V_2, V_2)] = \frac{2\omega_2\varphi_2^2(\lambda - u)(\lambda - ru + r - r\mu - g)}{(\lambda - ru + r - r\mu - g)^2} \neq 0. \tag{39}$$

So, according to Sotomayor's theorem model (4) has a transcritical bifurcation at E_1 with parameter $\alpha^\dagger = u + \mu - \lambda$, while the pitchfork bifurcation cannot occur.

5.2 Hopf bifurcations

We now try to establish whether there are parameter combinations giving sustained population oscillations. For E_1 it is not the case, since the eigenvalues are all real.

At E_2, see Figure 3, we have

 ISBN: 978-84-617-8694-7

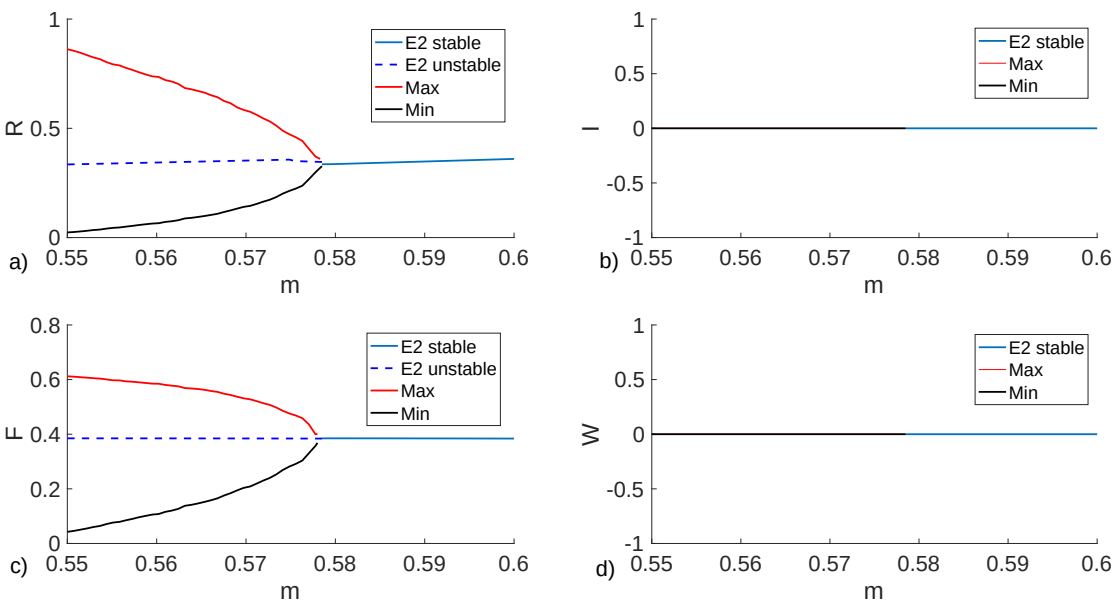

Figure 3: Hopf bifurcation for point E_2 for parameter values $\lambda = \beta = \ell = \alpha = \sigma = \gamma = \theta = q = c = p = r = g = b = 0.5$, $a = 1$, $u = \mu = 0.75$, $\nu = 1.157$. Initial conditions $R_0 = I_0 = F_0 = W_0 = 0.1$.

 ISBN: 978-84-617-8694-7

Proposition 3 Assuming that conditions (15) and (16) hold, then model (4) undergoes Hopf bifurcation around the equilibrium point E_2 when parameter m crosses the critical positive value $m^* = a/\sqrt{3}$.

Proof For systems in four-dimensional spaces, for a Hopf bifurcation to occur, the following conditions should be satisfied [10, 27, 18]:

- The characteristic equation at E_2 has two real and negative eigenvalues and two complex eigenvalues;
- $\tau_1(m^*) = 0$;
- $(\frac{d}{dm}\tau_1(m))|_{m=m^*}$ (The transversality condition).

The stability analysis of E_2 showed that we obtain two real and negative eigenvalues and another two given by:

$$\Lambda_\pm = \tau_1 \pm \sqrt{P(m)}, \quad \tau_1 = 3m^2 - a^2, \quad P(m) = 9m^4 + 8a^2m^3 - 6a^2m^2 - 8a^4m + a^4.$$

Thus, since $P(m)$ is continuous, and $P(m^*) = -16a^5(3\sqrt{3})^{-1} < 0$, there is an interval $T = (m^* - \epsilon, m^* + \epsilon)$ around m^* , such that, $P(x) < 0$ whenever $x \in T$ and further $\tau_1(m^*) = 0$. Finally, the transversality condition is satisfied because

$$\frac{d}{dm}\tau_1(m^*) = \frac{3}{2a\sqrt{3}} \neq 0.$$

At E_4 we can only perform numerical simulations. We present two different bifurcation scenarios. In the first, when parameter m crosses from above the critical value $m_1^\star \approx 0.71462$ there is a transcritical bifurcation between E_4 losing feasibility and E_2 becoming stable. Then when $m_2^\star \approx 0.578$ we find a Hopf bifurcation in E_2. With a further decrease of m a four-dimensional limit cycle arises when $m_3^\star \approx 0.56884$, Figure 4. The second situation is simply a Hopf bifurcation in E_4 when m crosses from above the critical value of $m_4^\star \approx 0.4626875$, Figure 5.

6 Numerical results

The analysis of model (4), shows that the parameter m is crucial for the feasibility and stability of points E_1 and E_2, respectively. The establishment of the disease is directly related to the value of $\mathcal{R}_0$ at both points. Thus, we conduct an exploration of the parameter space with relation to those fundamental quantities. As it will be shown in this section, the results of the majority of the simulations can be predicted simply by the analysis of m, $\mathcal{R}_0^{E_1}$ and $\mathcal{R}_0^{E_2}$.

 ISBN: 978-84-617-8694-7

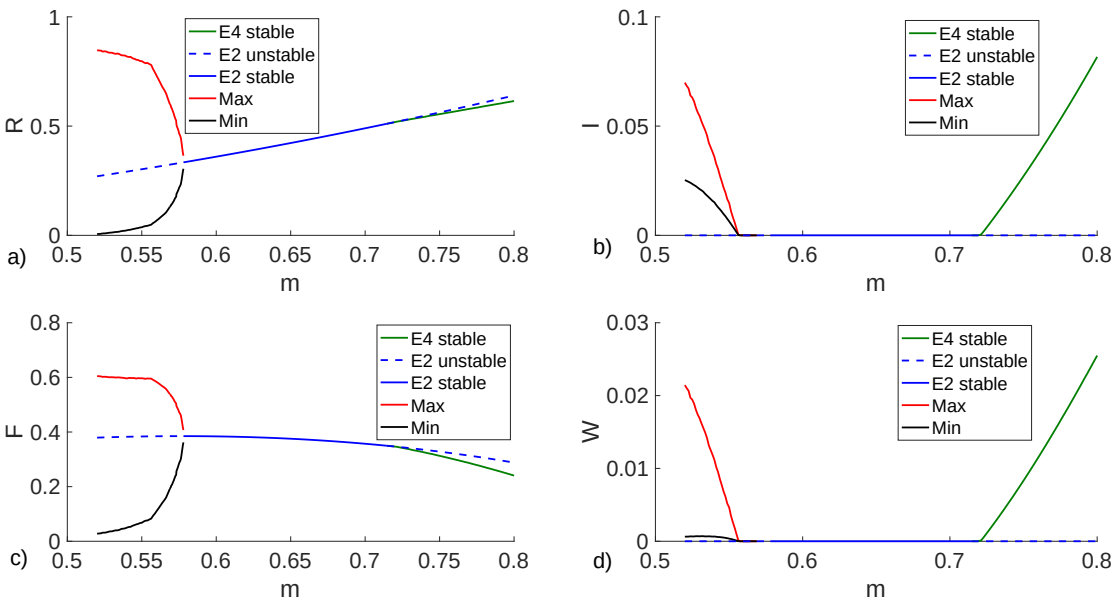

Figure 4: a), b), c) and d) illustrate a transcritical bifurcation between E_4 and E_2 for $m_1^\star \approx 0.71462$; Hopf bifurcation for E_2 when $m_2^\star \approx 0.578$; Loss of stability of the two-dimensional limit cycle and creation of a four-dimensional limit cycle when $m_3^\star \approx 0.56884$. The parameter values are: $\lambda = \sigma = \theta = r = q = g = \mu = 0.5$, $a = 1$, $\alpha = 0.6$, $c = 0.8289$, $\beta = 0.2056$, $\gamma = \ell = 0.99$, $b = 0.5066$, $\nu = 0.8$, $p = 0.7389$ and $u = 0.4$. Initial conditions $R_0 = I_0 = F_0 = W_0 = 0.1$.

 ISBN: 978-84-617-8694-7

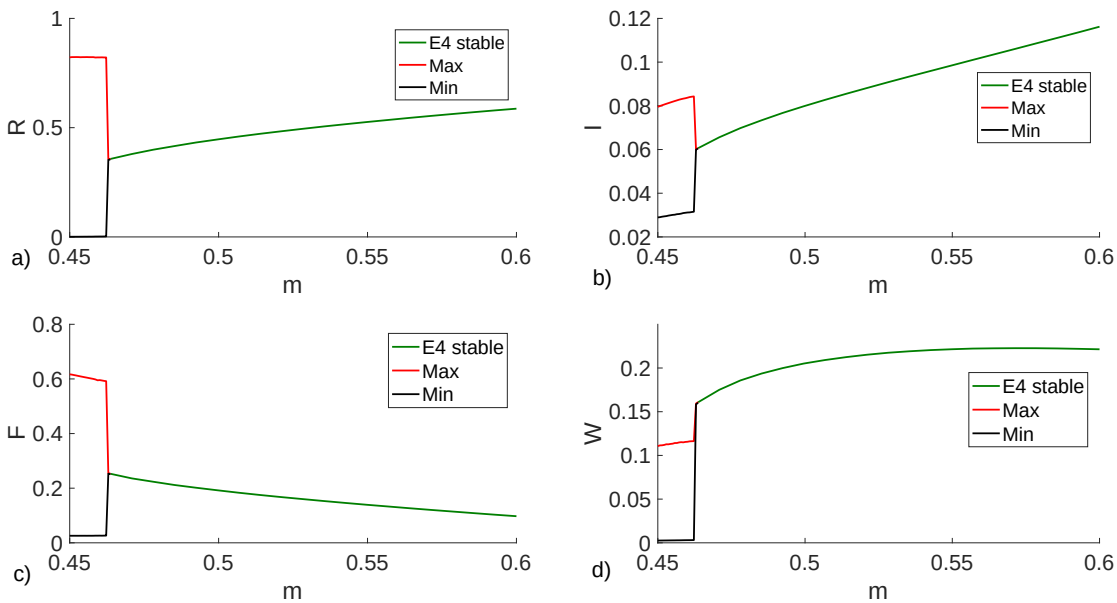

Figure 5: Hopf bifurcation for point E_4 for parameter values $\lambda = \sigma = \theta = r = q = g = \mu = 0.5$, $a = 1$, $\alpha = 0.61$, $c = 0.8289$, $\beta = 0.9433$, $\gamma = \ell = 0.99$, $b = 0.5066$, $\nu = 0.6833$, $p = 0.7389$ and $u = 0.4$.

 ISBN: 978-84-617-8694-7

6.1 Details about the numerical implementation

To investigate the behavior of model (4) in relation to the parameters, we first separate the simulations in two specific cases. In the first case, E_1 is stable and E_2 is unstable, that is, $m > a$. The second case, is obtained when $a/\sqrt{3} < m < a$, in which E_1 is unstable and E_2 is feasible. The reason for the adoption of such thresholds comes from the analysis of the analogous predator-prey model without the presence of disease [5]. In our model a transcritical bifurcation E_1 and E_2 is observed when $m = a$ and Hopf bifurcation occurs when $m = a/\sqrt{3}$ as we can see in subsection 5.

Given the high number of parameters (18), we opt for a random exploration of the space. In Table 2 represent the distributions adopted for each parameter.

Table 2: Distribution for the parameters in simulations using Matlab. Here, we make a random exploration of the space to each parameter. $\mathcal{U}(x, y)$ stands for an uniform distribution between x and y.

Parameters	Distribution
$u, \quad q, \quad g$	50% $\mathcal{U}(0.5, 1)$; 50% $\mathcal{U}(1, 2)$
$\mu, \quad \beta, \quad \lambda$	50% $\mathcal{U}(0.1, 1)$; 50% $\mathcal{U}(1, 10)$
$a, \quad b$	50% $\mathcal{U}(0.1, 1)$; 50% $\mathcal{U}(1, 2)$
c	$\mathcal{U}(0.1, a)$
$m > a$ (case 1)	$\mathcal{U}(1.1a, (2 - 1.1/\sqrt{3})a)$
$a/\sqrt{3} < m < a$ (case 2)	$\mathcal{U}(1.1a/\sqrt{3}, 0.9a)$
ν	$\mathcal{U}(m, 3m)$
ℓ	$\mathcal{U}(0.1, b)$
$\alpha, \quad \sigma, \quad \gamma, \quad \theta, \quad p$	$\mathcal{U}(0.05, 0.95)$
r	$\mathcal{U}(0.05, 1)$

When non-dimensional parameters cross the threshold 1, it usually means a transition between two qualitatively distinct scenarios. For this reason, the random sampling is chosen to be half of the time in each situation. For biological reasons, some parameters are linked. For instance, the mortality of diseased predators (ν) is greater than or equal to the mortality of healthy predators (m).

For the numerical simulation of the system of differential equations we use the Matlab ode45 routine. For each random combination of parameters, a random initial condition was chosen with the distributions: $R_0 \sim \mathcal{U}(0.2, 1)$, $I_0 \sim \mathcal{U}(0.2, 0.6)$, $F_0 \sim \mathcal{U}(0.05, 1.05)$ and $W_0 \sim \mathcal{U}(0.05, 0.1)$ ($\mathcal{U}(x, y)$ stands for an uniform distribution between x and y). The choice of initial conditions with smaller predator populations is made in order to avoid trajectories that converge to the origin, in which the approximation of the predation term by $\sqrt{R}$ is not valid. Given the initial conditions, the system is simulated in the time interval

 ISBN: 978-84-617-8694-7

$I_{t_1} = [0, 200]$, if such interval is not enough to find an equilibrium, another try is attempted with $I_{t_2} = [0, 2000]$.

Also, for each combination of parameters the equilibrium points E_1, E_2, E_3 and E_4 are estimated. For E_1 and E_2 the analytical formulae of section (3) are used. For the equilibrium point E_3 the quadratic equation (6) is numerically solved using the routine ROOTS of Matlab. In sequence, the equation for I_3 (5) is employed to establish if there was any feasible equilibrium solution E_3.

For the equilibrium point E_4 we do not have analytic formulae. Thus, we used the routine FMINCON of Matlab, to minimize the sum of the squares of the derivatives subject to the conditions: $R_4 > 2^{-8}$, $I_4 > 2^{-8}$, $F_4 > 2^{-8}$, e $W_4 > 2^{-8}$. Since the results of the minimization process depend on the initial guess, 10 starting points are taken for each parameter combination. The distributions of the initial guesses are taken as: $R_g \sim \mathcal{U}(0, 1)$, $I_g \sim \mathcal{U}(0, 1)$, $F_g \sim \mathcal{U}(0, 1)$ and $W_g \sim \mathcal{U}(0, 1)$. Each time, if the routine obtained with success a solution for the minimization problem, it is stored as a candidate for equilibrium point E_4. After the 10 executions of the routine FMINCON, redundant solutions are removed from the list of equilibrium candidates. Two solutions x_1, $x_2 \in \mathbb{R}^4$ are considered redundant if

$$\frac{\|x_1 - x_2\|}{\|x_1\|} < 0.01.$$

After obtaining the list of all equilibrium candidates (from E_1 to E_4), again all redundant solutions are removed, using the same criterion. For the equilibrium points E_1 and E_2 the values of $\lambda_1^{E_1}$, $\lambda_2^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$ are computed. For points E_3 and E_4 (possibly multiple) the stability (eigenvalues of the Jacobian) are computed numerically.

The remaining list of candidates is then used to be compared with the result of the numerical simulation. The relative error between all the candidate solutions and the result of the numerical simulation is calculated. If the smallest error between the simulated solution and the candidate solutions is smaller than 0.001, then the simulation is classified as a success and said to converge to the candidate solution closest to the simulated solution. In figure 6 we present a scheme on how each simulation is conducted.

As we shall show, from the results of the numerical simulations, the majority of the results of the simulations can be predicted only by analyzing the values of m (which is a critical ecological parameter) and the values related to the spread of the epidemy: $\lambda_1^{E_1}$, $\lambda_2^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$. We divide the discussion according to the values of those variables.

6.2 Case 1: m > a

We ran 10,000 simulations with random parameters as in Table 2, in which $m > a$. Of this total, 9870 (98.7%) were concluded with success in the sense defined in section 6.1 and Figure 6. The results can be subdivided in two main cases, one when $\mathcal{R}_0^{E_1} < 1$ and the

 ISBN: 978-84-617-8694-7

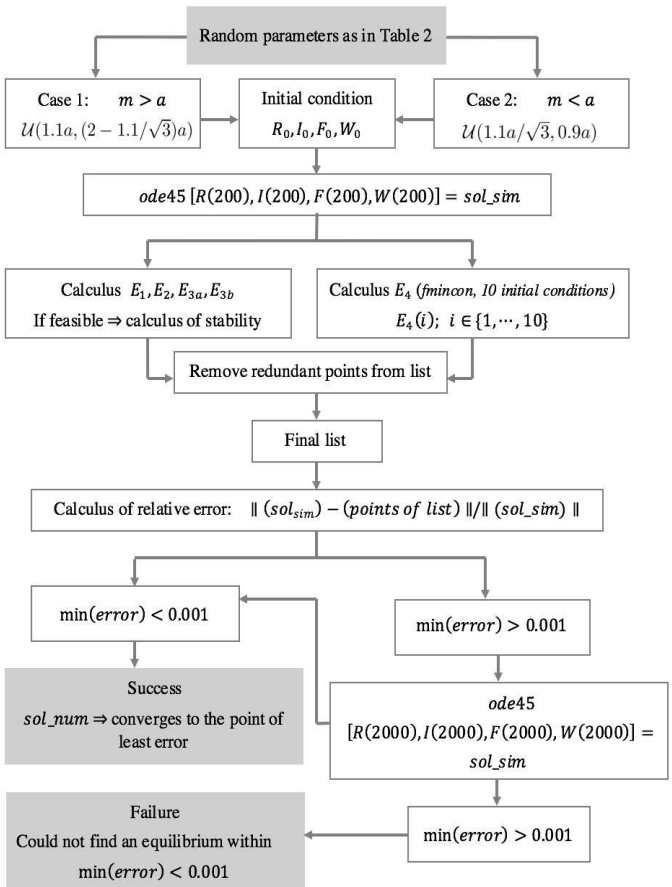

Figure 6: Scheme for a numerical simulation of the system. The equilibrium points, their stability and a simulated solution is computed. If the numerical solution converges to any of the computed candidate equilibrium points, the simulation is classified as a success.

 ISBN: 978-84-617-8694-7

other when $\mathcal{R}_0^{E_1} > 1$.

6.2.1 $\mathcal{R}_0^{E_1} < 1$:

In 6155 (63,26%) of the total 9870 successful simulations, $\mathcal{R}_0^{E_1} < 1$. Of those, in 6143 (99.81%) the system converged to E_1 while in 12 (0.19%) cases it converged to E_3. To understand these results, we analyzed also the feasibility and stability of the other equilibrium points under these conditions.

We have shown that if $m > a$, E_2 is unfeasible, therefore, besides E_1, the system could converge to E_3 or E_4. We map the behavior of those other two points in the simulations. For each simulation, we classify three possible states for the points E_3 and E_4:

- State 1: There are no feasible points of this type of equilibrium.
- State 2: There is at least one feasible point of this type of equilibrium, but it is unstable.
- State 3: There is at least a feasible and stable point of this type of equilibrium.

In table 3 we present the distribution of the results for points E_3 and E_4. It is easy to note that, for the vast majority of the simulations, the only feasible and stable point is E_1, in agreement with the result that 99.81 % of the simulations with $\mathcal{R}_0^{E_1} < 1$ converged to E_1.

Table 3: Distribution of states of points E_3 and E_4 when $m > a$ and $\mathcal{R}_0^{E_1} < 1$. The rows and columns represent the number of times the points E_3 and E_4, respectively, were in the states 1, 2 or 3. State 1: No feasible points of this type are found in the simulation. State 2: there is at least one feasible point of this type, but it is unstable. State 3: There is at least a feasible and stable point of this type.

E_3 \ E_4	1	2	3
1	5285 (85.87%)	652 (10.59%)	199 (3.23 %)
2	0	0	2 (0.03 %)
3	16 (0.26%)	1 (0.02%)	0

The results for point E_3 can be summarized as follows: in 6136 (99.69%) we have two unfeasible points, in two (0.02%) we have two feasible and unstable points and in 17 (0.28 %) we have two feasible points of which one is stable.

The behavior of E_4 can be summarized as follows. The 6155 simulations with $\mathcal{R}_0^{E_1} < 1$ are distributed as follows: 5301 (86.13 %) no feasible points are found, 628 (10.2%) one feasible and unstable point, 25 (0.41%) two feasible and unstable points, 130 (2.11%) one

 ISBN: 978-84-617-8694-7

feasible and stable point, 59 (0.96%) two feasible points with one stable and 12 (0.19%) three feasible points with one stable. Thus, in the vast majority of the simulations, E_4 is either unfeasible or unstable. We may also observe that, since E_4 is calculated numerically it can be very close to other equilibria, but not enough to be eliminated as redundant from the candidate list.

6.2.2 $\mathcal{R}_0^{E_1} > 1$:

In this particular case it is possible to show that there exists a unique feasible point E_3 in the form $(R_3, I_3, 0, 0)$ (see section 3.2).

In 3715 (37.64%) of the total 9870 successful simulations, $\mathcal{R}_0^{E_1} > 1$. Of those, in 3567 (96.02%), the system converges to E_3 and in 148 (3.98%) it converges to E_4. In this case, E_1 is unstable, E_2 is unfeasible and the equilibria for which the solution could converge are only E_3 or E_4.

In Table 4 we present the distribution of the results for points E_3 and E_4, observing that E_3 can never be unfeasible in this case. It is easy to note that, for the vast majority of the simulations, the only feasible and stable point is E_3, in agreement with the result that 96.02 % of the simulations with $\mathcal{R}_0^{E_1} > 1$ converges to E_3. The only cases in which we have convergence for E_4 is in when E_3 is unstable.

Table 4: Distribution of states of points E_3 and E_4 when $m > a$ and $\mathcal{R}_0^{E_1} > 1$.

E_3 \ E_4	1	2	3
2	0	0	148 (3.98%)
3	3050 (82.10%)	302 (8.13%)	215 (5.79%)

The results for point E_3 can be summarized as follows: in 148 (3.98%) simulations we have one feasible and unstable point and in the other 3567 (96.02%) we obtain one feasible and stable point.

The behavior of E_4 can be summarized as follows. Of the total 3715 simulations with $\mathcal{R}_0^{E_1} > 1$ we have: 3050 (82.10%) no feasible point found, 282 (7.59 %) one feasible and unstable point, 14 (0.38 %) two feasible and unstable points, 6 (0.16%) three feasible and unstable points, 306 (8.24%) one feasible and stable point, 50 (1.35%) two feasible points with one stable, 2 (0.05%) three feasible points with one stable, 3 (0.08 %) four feasible points with one stable and 2 (0.05%) two stable and feasible points.

6.2.3 Sensitivity analysis

Since $\mathcal{R}_0^{E_1}$ has a fundamental role in the determination of the behavior of the system, we can discuss its sensibility in relation to the parameters. In the first place, it is worth to

 ISBN: 978-84-617-8694-7

note that, as shown in section 4.1 in this case, $\lambda_2^{E_1} < 1$. Therefore, point E_1 can only be destabilized through $\lambda_1^{E_1}$. The explicit relation of equation (23) indicates that $\lambda_1^{E_1}$ should be sensible to parameters α and λ with a positive correlation and to parameters u and μ with a negative correlation.

For each of the 9870 successful simulations, $\lambda_1^{E_1}$ is computed. Using this collection of values, we calculate the slope of the linear regression of $\lambda_1^{E_1}$ with each of the parameters. In table 5 we present the coefficients. As expected, the strongest correlations are those of parameters α, λ, u and μ.

Table 5: Regression slopes of $\lambda_1^{E_1}$ for each parameter.

Parameter	α	σ	γ	q	u	g
Slope	0.4576	0.0642	0.1734	-0.0188	-0.6930	-0.0080
Parameter	p	a	c	θ	r	m
Slope	-0.0013	0.0899	0.0503	0.0202	0.0720	0.0643
Parameter	λ	β	ν	μ	ℓ	b
Slope	0.4156	0.0045	0.0283	-0.2584	-0.0103	-0.0153

6.3 Case 2: $\mathbf{a/\sqrt{3} < m < a}$

We ran 10,000 simulations with random parameters as in table 2, in which $m < a$. Of this total, 9001 (90.1%) are successul in the sense defined in section 6.1 and Figure 6. In this case, E_1 is always unstable, the stability of E_2 hinges on $\mathcal{R}_0^{E_2}$ and the distribution of the convergences is more complex than when $m > a$. Again, we discuss separately the two cases $\mathcal{R}_0^{E_2} < 1$ and $\mathcal{R}_0^{E_2} > 1$.

6.3.1 $\mathcal{R}_0^{E_2} < 1$:

In 4598 (51,08%) of the total 9001 successful simulations, $\mathcal{R}_0^{E_2} < 1$. Of those, in 4581 (99.63%) the system converges to E_2, in 16 (0.35%) cases it converges to E_3 and in 1 (0.02%) case it converges to E_4. To understand these results, we analyze also the feasibility and stability of the other equilibrium points under these conditions.

We have shown that if $m < a$, E_1 is unstable, therefore, besides E_2, the system could converge to E_3 or E_4. Just as in the examples above, we map the behavior of those other two points in the simulations. In table 6 we present the distribution of the results for points E_3 and E_4. It is easy to note that, for the vast majority of the simulations, the only feasible and stable point is E_2, in agreement with the result that 99.63 % of the simulations with $\mathcal{R}_0^{E_2} < 1$ converged to E_2.

The results for point E_3 can be summarized as follows. Of the total 4598 simulations with $\mathcal{R}_0^{E_2} < 1$ we obtain: 4028 (87.60%) two unfeasible points, 544 (11.83%) one feasible

 ISBN: 978-84-617-8694-7

Table 6: Distribution of states of points E_3 and E_4 when $m < a$ and $\mathcal{R}_0^{E_2} < 1$.

E_3 \ E_4	1	2	3
1	3600 (78.29%)	273 (5.94%)	155 (3.37 %)
2	406 (8.83 %)	63 (1.37 %)	78 (1.70 %)
3	2 (0.04%)	20 (0.43%)	1 (0.02%)

and unstable point, 12 (0.26 %) one feasible and stable point, 3 (0.07%) two feasible and unstable points and 11 (0.24%) two feasible points with one stable.

The behavior of E_4 can be summarized as follows. The 4598 simulations with $\mathcal{R}_0^{E_2} < 1$ are distributed in this form: 4008 (87.17 %) no feasible points are found, 346 (7.53%) one feasible and unstable point, 9 (0.2%) two feasible and unstable points, 1 (0.02%) three feasible and unstable points, 207 (4.5%) one feasible and stable point, 26 (0.57%) two feasible points with one stable and 1 (0.02%) two feasible and stable points. Thus, in the vast majority of the simulations, E_4 is either unfeasible or unstable.

6.3.2 $\mathcal{R}_0^{E_2} > 1$:

In 4403 (48.92%) of the total 9001 successful simulations, $\mathcal{R}_0^{E_2} > 1$. Of those, in 2255 (51.22%) the system converges to E_4, in 2137 (48.54%) cases it converges to E_3 and in 12 (0.25%) case it converges to E_2. In the cases where the solution converge to E_2, despite its instability, were due to the fact that $\mathcal{R}_0^{E_2}$ is close to one, so the numerical solution remains quasi-stationary close to E_2 for a long period of time, in that time the relative error between E_2 and the numerical solution is estimated and found to be smaller than 0.001. Below, we present the analysis of the stability of the other equilibrium points in those simulations.

In table 7 we present the distribution of the results for points E_3 and E_4.

Table 7: Distribution of states of points E_3 and E_4 when $m < a$ and $\mathcal{R}_0^{E_2} > 1$.

E_3 \ E_4	1	2	3
1	0	8 (0.18%)	1518 (34.48 %)
2	0	0	622 (14.13 %)
3	1483 (33.68%)	346 (7.86%)	426 (9.68%)

The results for point E_3 can be summarized as follows. Of the total 4403 simulations with $\mathcal{R}_0^{E_2} > 1$ we obtain: 1526 (34.66%) two unfeasible points, in 620 (14.08%) one feasible and unstable point, 2248 (51.06%) one feasible and stable point, 2 (0.05%) two feasible and unstable points and 7 (0.16%) two feasible points with one stable.

 ISBN: 978-84-617-8694-7

The behavior of E_4 can be summarized as follows. The 4403 simulations with $\mathcal{R}_0^{E_2} > 1$ are distributed in this form: 1483 (33.68 %) no feasible points are found, 331 (7.52%) one feasible and unstable point, 20 (0.45) two feasible and unstable points, 2 (0.05%) three feasible and unstable points, 1 (0.02%) 5 feasible and unstable points, 2032 (46.15%) one feasible and stable point, 493 (11.20%) two feasible points with one stable, 28 (0.64%) three feasible points with one stable, 4 (0.09%) four feasible points with one stable, 1 (0.02%) five feasible points with one stable, 4 (0.09%) two feasible and stable points, 3 (0.07%) three feasible points with two stable ones and 1 (0.02%) four feasible points with two stable ones.

6.3.3 Sensitivity analysis

In this case, there is not a clear behavior of convergence dependent only on the value of $\mathcal{R}_0^{E_2}$. In fact, it is possible to predict the vast majority of the results (see section 6.4) if we analyze the three eigenvalues $\lambda_1^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$. Therefore, we present in Tables 8 and 9, the analysis of sensitivity for $\lambda_1^{E_2}$, $\lambda_2^{E_2}$. The sensitivity results for $\lambda_1^{E_1}$ are very similar to the case were $m > a$ (case 1).

Table 8: Regression slopes of $\lambda_1^{E_2}$ for each parameter.

Parameter	α	σ	γ	q	u	g
Slope	0.4764	0.2535	-1.0134	0.1274	-0.1382	0.1062
Parameter	p	a	c	θ	r	m

6.4 Behavior based on m, $\lambda_1^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$

Based on the results of the simulations and the stability analysis of the equilibrium points it is possible to suggest a prediction rule based on the values of $\lambda_1^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$. In Figure

 ISBN: 978-84-617-8694-7

(7) we present the way in which the behavior of the system can be classified. We show that, for the vast majority of the parameter space that was explored in this work, a simple analysis of the values of m, $\lambda_1^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$ is enough to predict the model's behavior. The scheme was successful in predicting the outcome of the numerical simulations in 96.35% of the simulations.

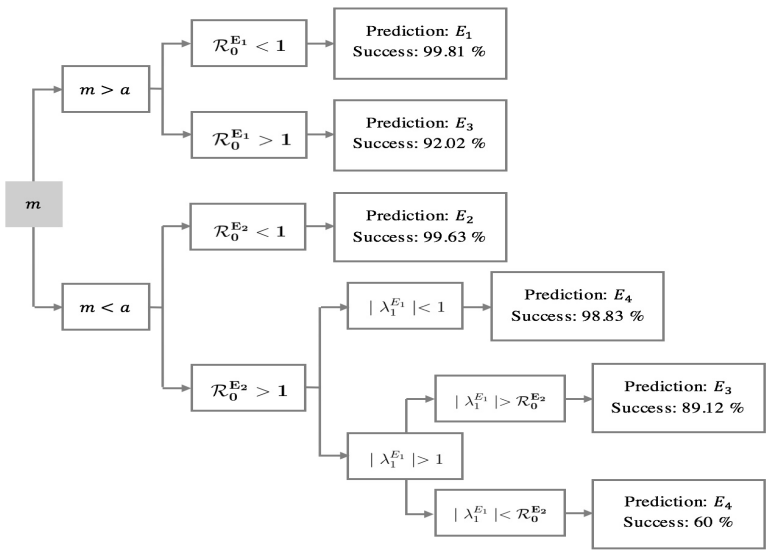

Figure 7: Scheme for a numerical simulation of the system. The equilibrium points, their stability and a simulated solution is computed. If the numerical solution converges to any of the computed candidate equilibrium points, the simulation is classified as a success.

7 Conclusions

In this work we presented an model for the study of prey-predator dynamics with the presence of disease and herd behavior. The theoretical analysis and the numerical simulations suggest that, in the majority of the parameter combinations studied, the behavior of the model can be predicted by the analysis of just four fundamental quantities in the system (m, $\lambda_1^{E_1}$, $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$).

The first fundamental quantity is the natural mortality rate of predators, which is crucial to define the survival of the predator species. Since the mortality of diseased predators is supposed to be equal or higher than the the mortality of healthy ones, parameter m plays a determinant role in the dynamics of the system.

 ISBN: 978-84-617-8694-7

The second, third and fourth fundamental quantities are the values of $\mathcal{R}_0$ (basic reproduction number) calculated in the two disease-free equilibria of the system (E_1 and E_2): $\mathcal{R}_0^{E_1}$ and $\mathcal{R}_0^{E_2}$. Sensitivity analysis through linear regression between the parameters has shown that the parameter with the strongest influence is $\mathcal{R}_0^{E_1}$.

Parameters α and λ are related to the vertical and horizontal transmission rates, respectively, and have a positive correlation with $\mathcal{R}_0^{E_1}$. Parameters u (influence intra-specific competition between healthy and diseased prey on the infected prey population) has a negative effect on the spread of the disease. Therefore, it is clear that a species with the behavior of marginalizing or being hostile to the diseased individuals reduces the chance of permanence of an epidemics in the population.

The analysis of sensitivity for $\mathcal{R}_0^{E_2}$, involves two eigenvalues $\lambda_1^{E_2}$ and $\lambda_2^{E_2}$. The strongest positive correlation between the first one and the parameters occurs for parameters α and β. Thus, again, vertical transmission in prey plays an important role in the maintenance of the disease. Interestingly, the horizontal transmission in the predator population (β) plays a more important role in the destabilization of the disease-free coexistence than the horizontal transmission between prey (λ). Strong negative correlations were observed for parameters a and m. For the sensitivity of $\lambda_2^{E_2}$, again, α displayed a strong positive correlation, followed by parameters m and λ (horizontal transmission). Parameters u and b (mortality of diseased predators) displayed the strongest negative correlation.

Given the importance of parameters α, λ and u, our results suggest that the removal of diseased-prey may be the most effective strategy to lead the system to a disease-free equilibrium.

Abstract

We study the local convergence of a Newton-like method of convergence order six to approximate a locally unique solution of a nonlinear equation. Earlier studies show convergence under hypotheses on the seventh derivative or even higher. The convergence in this study is shown under hypotheses on the first derivative although only the first derivative appears in these methods. Hence, the applicability of the method is expanded.

1 Introduction

In this study we are concerned with the problem of approximating a locally unique solution ξ of equation

$$F(x) = 0, \tag{1.1}$$

where F is a differentiable function defined on a convex subset D of S with values in S, where S is $\mathbb{R}$ or $\mathbb{C}$.

Many problems from Applied Sciences including engineering can be solved by means of finding the solutions of equations in a form like (1.1) using Mathematical Modelling [4, 5]. For example, dynamic systems are mathematically modeled by difference or differential

 ISBN: 978-84-617-8694-7

equations, and their solutions usually represent the states of the systems. Except in special cases, the solutions of these equations can be found in closed form. This is the main reason why the most commonly used solution methods are usually iterative. The convergence analysis of iterative methods is usually divided into two categories: semilocal and local convergence analysis. The semilocal convergence matter is, based on the information around an initial point, to give criteria ensuring the convergence of iteration procedures. A very important problem in the study of iterative procedures is the convergence domain. In general the convergence domain is small. Therefore, it is important to enlarge the convergence domain without additional hypothesis. Another important problem is to find more precise error estimates on the distances $\|x_{n+1}-x_n\|$, $\|x_n-\xi\|$. These are with the study of the dynamical behavior our objectives in this paper.

The most popular method for approximating a simple solution ξ of equation (1.1) is undoubtedly Newton's method defined for all $n=0,1,2,\ldots$ by

$$x_{n+1} = x_n - \frac{F(x_n)}{F'(x_n)}, \tag{1.2}$$

where x_0 is an initial point. Newton's method converges quadratically to ξ [4, 5] provided that F' does not vanish in D and x_0 is close enough to ξ. To obtain higher order of convergence many third order methods have been proposed [1]– [6].

These methods look like

$$x_{n+1} = x_n - \frac{F(x_n)}{F'(x_n)}\Gamma(s(x_n)), \tag{1.3}$$

where

$$s=s(x)=\frac{F'\left(x-\frac{F(x)}{F'(x)}\right)}{F'(x)}$$

and only differ in the choice of function Γ.

Recently the method defined for all $n=0,1,2,\ldots$ by

$$x_{n+1} = x_n - B(x_n)\tfrac{F(x_n)}{F'(x_n)}, \tag{1.4}$$

where

$$B(x_0)=\Gamma\left(s(x_0)\right)+\frac{F\left(x_0-\frac{F(x_0)}{F'(x_0)}\Gamma\left(s(x_0)\right)\right)\left[F'\left(x_0-\frac{F(x_0)}{F'(x_0)}\right)+F'(x_0)\right]}{F(x_0)\left[3F'\left(x_0-\frac{F(x_0)}{F'(x_0)}\right)-F'(x_0)\right]}$$

was studied in [7]. The sixth order of convergence was shown under hypotheses reauhing up to the seventh derivative of the function F. In terms of the computational cost, method (1.4) require two function evaluations and two first derivative evaluations per iterations.

 ISBN: 978-84-617-8694-7

Therefore, the efficiency index is $6^{1/4} \approx 1.56508$ provided that evaluations of functions such as exp, ln or mth root are negleited.

In the present study we first study the local convergence of method (1.4) using hypotheses up to the first derivative of function F. We also provide the radius of the convergence ball, computable error bounds on the distances involved and a uniqueness of the solution result. Such results were not given in [7] or the earlier related studies [8], [9]. This way we expand the applicability of method (1.4). It is convenient for us to simplify method (1.4) and study the equivalent method defined for all $n = 0, 1, 2, \ldots$ by

$$\begin{aligned} y_n &= x_n - \frac{F(x_n)}{F'(x_n)}, \\ z_n &= x_n - \frac{F(x_n)}{F'(x_n)}\Gamma\left(s(x_n)\right), \\ x_{n+1} &= z_n - \frac{s(x_n)+1}{3s(x_n)-1}\frac{F(z_n)}{F'(x_n)}, \end{aligned} \tag{1.5}$$

where $s(x_n)$ is defined in method (1.3).

2 Main result

Let $F : D \subset X \to Y$ be a continuously Fréchet-differentiable operator, X, Y be Banach spaces and D an open, convex subset of X. Consider (1.1) rewritten

$$\begin{aligned} y_n &= x_n - F'(x_n)^{-1}F(x_n), \\ z_n &= x_n - \Gamma(F'(x_n)^{-1}(F'(x_n - F'(x_n)^{-1}F(x_n))F'(x_n)^{-1}F(x_n), \\ x_{n+1} &= z_n - (3s(x_n) - I)^{-1}(s(x_n) + I)F'(x_n)^{-1}F(z_n), \end{aligned} \tag{2.1}$$

where $s(x) = F'(x)^{-1}F'(x - F'(x)^{-1}F(x))$ and $\Gamma(\cdot) : X \to \mathbb{L}(Y, X)$ is a linear operator.

Next, using the preceding notation we can show the local convergence result for method (2.1).

Theorem 1 *Let F: $U(\xi, R_0) \subseteq X \to Y$ be Fréchet-differentiable. Suppose that there exist $\xi \in D$, $L_0 > 0$ such that for each $x \in U(\xi, R_0)$:*

$$F(\xi) = 0 \tag{2.2}$$

$$F'(\xi) \neq 0, \tag{2.3}$$

$$\left\| F'(\xi)^{-1}\left(F'(x) - F'(\xi)\right)\right\| \leqslant L_0 \|x - \xi\|. \tag{2.4}$$

Moreover, suppose that there exist $L > 0$, $M \geq 1$, $\{s_n\}$ and functions $\Gamma(\cdot) : X \to L(Y, X)$, A:$\left[0, \frac{1}{L_0}\right) \to \left[0, \frac{1}{M}\right)$ continuous and non-decreasing such that for each $x, y \in U(\xi, \frac{1}{L_0}) \cap U(\xi, R_0)$

$$\left\| F'(\xi)^{-1}\left(F'(x) - F'(y)\right)\right\| \leqslant L \|x - y\|, \tag{2.5}$$

 ISBN: 978-84-617-8694-7

$$\left\|F'(\xi)^{-1}F'(x)\right\| \leqslant M, \tag{2.6}$$

and

$$|1-\Gamma\left(s(x)\right)| \leqslant A(\|x-\xi\|)\|x-\xi\|. \tag{2.7}$$

Then, sequence $\{x_n\}$ *generated by method* (1.5) *for* $x_0 \in U\left(\xi,r\right)\backslash\{\xi\}$ *remains in* $U\left(\xi,r\right)$ *for each* $n=0,1,2,\ldots$ *and converges to* ξ *where* r *is defined in* (2.1). *Moreover, the following estimates for each* $n=0,1,2,\ldots$

$$\|y_n-\xi\| \leqslant g_1\left(\|x_n-\xi\|\right)\|x_n-\xi\| \leq \|x_n-\xi\| < r, \tag{2.8}$$

$$\|z_n-\xi\| \leqslant g_2\left(\|x_n-\xi\|\right)\|x_n-\xi\| \leq \|x_n-\xi\| \tag{2.9}$$

$$\left\|\left(3F'(y_n)-F'(x_n)\right)^{-1}\left(2F'\left(\xi\right)\right)\right\| \leqslant \tfrac{1}{1-g_0(\|x_n-\xi\|)} \tag{2.10}$$

and

$$\|x_{n+1}-\xi\| \leqslant g_3\left(\|x_n-\xi\|\right)\|x_n-\xi\| \leq \|x_n-\xi\|, \tag{2.11}$$

where

$$g_1(t)=\frac{Lt}{2\left(1-L_0t\right)},\quad g_2(t)=\frac{Lt+2MA(t)}{2\left(1-L_0t\right)},\quad h_2(t)=g_2(t)-1$$

$$r_1=\frac{2}{2L_0+L}<\frac{1}{L_0}g_0(t)=\frac{L_0}{2}\left(\frac{3}{2}Lt+1\right)th_0(t)=g_0(t)-1$$

$$r_0=\frac{4L_0L}{L_0+\sqrt{L_0^2+12L_0L}}$$

$$g_3(t)=\left[1+\frac{ML_0\left(1+g_1(t)\right)}{2(1-L_0t)(1-g_0(t))}\right]g_2(t)=\frac{1}{2(1-L_0t)}\left[1+\frac{ML_0\left(1+g_1(t)\right)t}{2(1-L_0t)(1-g_0(t))}\right](Lt+2MA(t))$$

$$h_3(t)=g_3(t)-1.$$

$$r=\min\left\{r_i\right\},i=0,1,2,3.$$

and

$$R_0:=sup\{t\in[0,R):U(\xi,t)\subseteq D\}.$$

Furthermore for $T\in[r,\frac{2}{L_0})$, *the vector point* ξ *is the only solution of equation* $F(x)=0$ *in* $U\left(\xi,R_0\right)\cap\overline{U}(\xi,T)$.

Abstract

The principle aim of this manuscript is to propose a scheme that can be applied to any optimal iteration function of order eight or a family of eighth-order methods to further develop new interesting optimal method/family of iterative methods of order sixteen. The proposed scheme requires four evaluations of the involved function and one evaluation of its first-order derivative, being optimally consistent with the conjecture of Kung-Traub. In addition, theoretical and computational properties are fully investigated along with a main theorem describing the order of convergence of the proposed scheme. Moreover, the conjugacy maps and the strange fixed points of some iterative methods are discussed, their basins of attractions are also given to show their dynamical behavior around the simple roots. From the numerical experiments, we find that our proposed schemes perform better than the existing ones when we checked the performance of the proposed methods on a variety of nonlinear equations.

1 Introduction

The conceptualization and construction of multi-point solution techniques have always been a paramount importance in the field of numerical analysis that provide more accurate

and efficient approximate solution ξ of nonlinear equation of the form

$$f(x) = 0, \tag{1.1}$$

where $f : \mathbb{D} \subseteq \mathbb{R} \to \mathbb{R}$ is a nonlinear sufficiently differentiable function in an interval $\mathbb{D}$. This topic has attracted the attention of many researchers from the worldwide, when Traub [9] initiated the qualitative as well as the quantitative analysis of iterative methods.

In the past, Ostrowski was the first mathematician who proposed an optimal fourth-order multi-point method which requires only three functional evaluations. On the other hand, Jarratt [3,4], in 1966 and King [6], in 1975, had also proposed various optimal fourth-order multi-point methods. King further showed that Ostrowski's method a particular case of his proposed family.

Due to the advancement of digital computer, advanced computer arithmetics and symbolic computation, with in the last two decade a large number of optimal eighth-order methods have been proposed by various authors. Most of them are the extension of Newton's method or Newton like method at the expense of additional functional evaluations or increase the sub step of the original methods.

In recent years, some researchers like Guem and Kim [1, 2], Sharma et al. [8], Ullah et al. [10], have also proposed optimal sixteen order extension of Newton's method. Kung and Traub [7], proposed two general classes of m-point iterative methods with optimal convergence order of 2^{m-1} with first-order derivative and without derivative. Nowadays, obtaining new four-step optimal methods of order sixteen not requiring the computation of second derivative, is very important and interesting task from the computational point of view because the efficiency indices of all the proposed methods is $E = \sqrt[5]{16} \approx 1.741$, far better than the classical Newton's method $E \approx 1.414$ and they converge very fast towards the required root. Sharma et al. [8] and Ullah et al. [10], have proposed sixteen-order modification of fourth-order King's method. On the other hand, Guem and Kim [1, 2] have given sixteen-order modification of of a particular fourth and eight-order iterative methods. However, Kung-Traub [7] also given two general classes of m-point iterative methods with optimal convergence order of 2^{m1}. But that is the modification of Newton's method at every step. According to our knowledge, no one given a general scheme which will be applicable on any optimal eight-order methods to further extend sixteenth-order optimal method whose first sub step should be Newton's method.

In order to develop a new scheme, it is quite often to approximate functions. Several types of approximations are available in the literature for e.g. Functional approach, Sampling approach, Geometric approach, Weight function approach, Adomain approach, Composition approach and Rational function approach. Every approach have some advantageous and disadvantageous because it's dependent on the considered problem. The choice of suitable approximation approach can save considerable amount of computation. Rational function approach is one of the most important techniques in numerical analysis for approximating the function or to find the next approximation.

 ISBN: 978-84-617-8694-7

According to our knowledge, Jarratt and Nudds [5] were the first persons who used this approach for developing new schemes with higher-order convergence. The rational function operator have the property of being unitary. The reason behind this, we have to find the same number of undermined constants in the same number of linear independent equations. These linear independent equations can be formed with the help of tangency conditions. In general, the number of tangency conditions are equal to number of undetermined constants. Further, we will get an improved method with higher-order convergence as we increase the number of undetermined constants in the rational function.

Therefore, we are interested to develop a scheme that can be applied on any eighth-order optimal method/family of methods whose first sub -step should be Newton's method to get further optimal family of sixteen-order method instead of applying that approach only on any particular iterative method. The derivation of the proposed scheme is based on the concept of the rational approximations. The beauty of the proposed scheme is that it is applicable to every optimal scheme of order eight whose first sub step should be Newton's method.

2 Development of sixteenth-order optimal scheme

We propose an optimal sixteenth-order family of iterative methods. Therefore, we consider a eighth-order scheme in the following way

$$\begin{aligned} y_n =& x_n - \frac{f(x_n)}{f'(x_n)}, \\ z_n =& \psi_4(x_n,\ y_n), \\ t_n =& \phi_8(x_n,\ y_n,\ z_n). \end{aligned} \tag{2.1}$$

For getting the next approximation x_{n+1} to a root, we consider the following rational function

$$w(x) = \frac{(x - x_n) + \alpha_1}{\alpha_2(x - x_n)^3 + \alpha_3(x - x_n)^2 + \alpha_4(x - x_n) + \alpha_5}, \tag{2.2}$$

where $\alpha_1,\ \alpha_2,\ \alpha_3,\ \alpha_4$ and α_5 can be determined by imposing the following tangency conditions

$$w(x_n) = f(x_n),\ \ w'(x_n) = f'(x_n),\ \ w(y_n) = f(y_n),\ \ w(z_n) = f(z_n),\ \ w(t_n) = f(t_n). \tag{2.3}$$

Now, we shall find the next approximation x_{n+1} by using the above rational function (2.2). Further, let us assume that this function meets the x – axis at $x = x_{n+1}$, we have

$$w(x_{n+1}) = 0, \tag{2.4}$$

which further yields

$$x_{n+1} = x_n - \alpha_1. \tag{2.5}$$

 ISBN: 978-84-617-8694-7

It is straight forward to say that from the above equation (2.5), that if we get the value of disposable parameter α_1 then our main target is achieved. In order to achieve this, we impose the first two tangency conditions defined in equation (2.3), to obtain

$$\alpha_1 = \alpha_5 f(x_n), \;\; \alpha_4 = \frac{1-\alpha_5 f'(x_n)}{f(x_n)}. \tag{2.6}$$

From the last three tangency conditions, we get

$$\begin{aligned}
&f(y_n)\big[f'(x_n)\left(f'(x_n)\left(2\alpha_5 f'(x_n)-1\right)+\alpha_3 f(x_n)^2\right)-\alpha_2 f(x_n)^3\big] = f'(x_n)^2 f(x_n)\left(\alpha_5 f'(x_n)-1\right),\\
&f(z_n)\left[\frac{(1-\alpha_5 f'(x_n))(z_n-x_n)}{f(x_n)}+\alpha_2(z_n-x_n)^3+\alpha_3(x_n-z_n)^2+\alpha_5\right] = \alpha_5 f(x_n)+z_n-x_n,\\
&f(t_n)\left[\frac{(1-\alpha_5 f'(x_n))(t_n-x_n)}{f(x_n)}+\alpha_2(t_n-x_n)^3+\alpha_3(t_n-x_n)^2+\alpha_5\right] = \alpha_5 f(x_n)+t_n-x_n.
\end{aligned} \tag{2.7}$$

By eliminating α_2 and α_3 from the above equations, we obtain the following value of α_5

$$\alpha_5 = \frac{a_n b_n\big(u_1 f(x_n)^2 f(y_n)+u_2 f'(x_n) f(t_n) f(z_n)\big)}{v_1 f(x_n)^3+v_2 f'(x_n) f(t_n) f(z_n)} \tag{2.8}$$

where
$u_1 = f(t_n)\big(b_n^2 f'(x_n)+b_n f(x_n)-c_n f(z_n)\big)+a_n\big(f(x_n)-a_n f'(x_n)\big)f(z_n)$, $u_2 = a_n b_n c_n f'(x_n)\big(f(y_n)-f(x_n)\big)+c_n f(y_n) f(x_n)(a_n-b_n)$, $v_1 = f(y_n)\big[b_n f(t_n)\left(b_n^2 f'(x_n)+b_n f(x_n)-c_n f(z_n)\right)+\big(a_n^3 f'(x_n)+c_n a_n f(t_n)-a_n^2 f(x_n)\big)f(z_n)\big]$, $v_2 = a_n^2 b_n^2 c_n f'(x_n)^2\big(2f(y_n)-f(x_n)\big)+a_n b_n c_n(2a_n-c_n)f'(x_n) f(y_n) f(x_n)+c_n\big(a_n b_n-a_n c_n-b_n^2\big)f(y_n) f(x_n)^2$, $a_n = x_n - z_n$, $b_n = t_n - x_n$, $c_n = t_n - z_n$.
Finally, we obtain the new optimal scheme of order sixteen by using the equation (2.8), we yield

$$\begin{aligned}
y_n &= x_n - \frac{f(x_n)}{f'(x_n)},\\
z_n &= \psi_4(x_n,\, y_n),\\
t_n &= \phi_8(x_n,\, y_n,\, z_n),\\
x_{n+1} &= x_n - \alpha_5 f(x_n).
\end{aligned} \tag{2.9}$$

where α_5 is previously defined in equation (2.8). The following theorem 1 demonstrates that the order of convergence will reach at the optimal eighth-order without using any more functional evaluations.

Theorem 1 *Let $f : \mathbb{R} \to \mathbb{R}$ has a simple zero ξ and is a sufficiently differentiable function an interval containing ξ. Further, assume that $\phi_4(x_n,\, y_n)$ and $\psi_8(x_n,\, y_n,\, z_n)$ are any optimal scheme of order four and eight-order, respectively. In addition, we also consider that initial guess $x = x_0$ is sufficiently close to ξ for the guaranteed convergence. Then, the*

 ISBN: 978-84-617-8694-7

iterative scheme defined by (2.9) *has an optimal sixteenth-order convergence and satisfy the following error equation*

$$\begin{aligned} e_{n+1} =& c_2\left(c_2^4 - 3c_3c_2^2 + 2c_4c_2 + c_3^2 - c_5\right) A_0B_0e_n^{16} + \left[c_2^5(c_1B_0 + c_0B_1) - 4c_2^6c_0B_0 + 16c_3c_2^4c_0B_0\right. \\ & - c_2^3\{10c_4c_0B_0 + 3c_3(c_1B_0 + c_0B_1)\} + 2c_2^2\{(-7c_3^2c_0B_0 + 3c_5c_0B_0 + c_4(c_1B_0 + c_0B_1)\} \\ & + c_2\{c_3^2(c_1B_0 + c_0B_1) + 8c_4c_3c_0B_0 - 2c_6c_0B_0 - c_5(c_1B_0 + c_0B_1)\} + 2c_3(c_3^2 - c_5)c_0B_0\big]e^{17} \\ & + O(e_n^{18}), \end{aligned} \tag{2.10}$$

where $e_n = x_n - \xi$ *and* $c_j = \frac{f^{(j)}(\xi)}{j!f'(\xi)}$ *for* $j = 2, 3, \ldots, 16$.

Expansions of ratios of gamma functions – an application to the distribution of the likelihood ratio test statistic used to test the equality of several covariance matrices

Filipe J. Marques[1]

emails: fjm@fct.unl.pt

Abstract

In this work the problem of testing the equality of several covariance matrices is addressed. Using an expansion of the ratio of two gamma functions, new approximations for the distribution of the test statistic are derived. These approximations are obtained using a new representation of the Fourier transform of the density function the logarithm of the test statistic which is based on products of ratios of gamma functions. The approximations developed are simple, precise and easy to implement.

Key words: asymptotic expansions, Fourier transforms, gamma function, generalized Bernoulli polynomials, likelihood ratio test, mixtures, ratio of gamma functions

1 Introduction

The ratio of two gamma functions appears in different problems and applications of mathematics. In statistics, among other possible applications, we show that it is possible to represent the Fourier transform of the density of the logarithm of the likelihood ratio test statistic used to test the equality of several covariance matrices in the form of products of ratios of gamma functions. Using an expansion for the ratio of two gamma functions given in [10] it is possible obtain a representation for the product of ratios of gamma functions which will enable us to derive simple and precise approximations for the distribution of the likelihood ratio test statistic. A similar procedure was also used in related problems in [3] and [7]. For other interesting results on the ratio of two gamma functions please see [1, 4, 5, 9]. A simple illustration of the procedure used will be given in the next sections.

 ISBN: 978-84-617-8694-7

2 Expansion for the ration of two gamma functions

In 1951, Tricomi and A. Erdélyi, obtained a representation, for the ratio of two gamma functions, in terms of generalized Bernoulli polynomials, which is given by (see [6] and [10])

$$\frac{\Gamma(z+a)}{\Gamma(z+b)} = z^{a-b}\sum_{k=0}^{M-1}\frac{(-1)^k B_k^{a-b+1}(a)(b-a)_k}{k!}z^{-k} + z^{a-b}O(z^{-M}) \tag{1}$$

with $|arg(z+a)| \leq \pi - \epsilon$, $\epsilon > 0$ and where $B_n^y(x)$ are the generalized Bernoulli polynomials which can be defined through the equality (see [6])

$$\frac{t^y \mathrm{e}^{xt}}{(\mathrm{e}^t-1)^y} = \sum_{k=0}^{\infty}\frac{t^k}{k!}B_k^y(x), \quad |t| < 2\pi\,.$$

The expansion in (1) may be used to developed a representation for the product of ratios of gamma functions which will enable the development of approximations for the likelihood ratio test statistic used to test the equality of several covariance matrices. The procedure is briefly illustrate in Section 3.

3 Asymptotic approximations for the likelihood ratio test statistic

Let us assume we have q independent samples, $N_1, \ldots, N_q$, from q multivariate Normal populations, $N_p\big(\underline{\mu}, \Sigma\big)$. As it is referred in [2] the multivariate normal distribution assumption can be extended to a more general assumption of elliptically contoured distributions. The null hypothesis is

$$H_0 : \Sigma_1 = \ldots = \Sigma_q\,.$$

The modified likelihood ratio test statistic is given by (see [8])

$$\Lambda = \frac{N^{Np/2}}{\prod_{k=1}^{q} n_k^{n_k p/2}}\,\frac{\prod_{k=1}^{q}|A_k|^{n_k/2}}{|A|^{N/2}} \quad \text{with} \quad N = \sum_{k=1}^{q} n_k\,, \quad n_k = N_k - 1\,, \quad k = 1, \ldots, q\,, \tag{2}$$

and where A_k is the matrix of corrected sums of squares and products formed from the k-th sample and $A = A_1 + \ldots + A_q$. For our purposes it is useful to consider the random variable $W = -\log\Lambda$, and it can be shown that its characteristic function can be written in the following form

$$\Phi_W(t) = \prod_{j=1}^{p}\prod_{k=1}^{q}\prod_{\ell=1}^{n_k}\frac{\Gamma\left(\alpha_{jk\ell}+\beta_{jk\ell}\right)\Gamma\left(\alpha_{jk\ell}-\frac{\mathrm{i}t}{2}\right)}{\Gamma\left(\alpha_{jk\ell}\right)\Gamma\left(\alpha_{jk\ell}+\beta_{jk\ell}-\frac{\mathrm{i}t}{2}\right)} \tag{3}$$

 ISBN: 978-84-617-8694-7

for some parameters $\alpha_{jk\ell}$ and $\beta_{jk\ell}$. If these parameters were all positive the expression in (3) would correspond to the characteristic function of the sum of independent logbeta distributions, however these parameters are not all positive. Nevertheless, it is possible to observe that the representation in (3) is based on products of ratios of gamma functions and thus, using the expansion in (1), it is possible to obtain a new representation for the characteristic function which is a mixture of gamma distributions with the same rate parameter. This feature together with the well known matching moments technique, will enable the derivation of asymptotic approximations in the form of mixture gamma of distributions, all with the same rate parameter, λ, with shape parameters r_j and with weights π_j, $j = 1, \ldots, m$, that is

$$\sum_{j=0}^{m} \pi_j \, \lambda^{r_j} \left(\lambda - \frac{\mathrm{i}t}{2}\right)^{-r_j} . \tag{4}$$

The matching moments technique will be used to determine the parameters in (4). One should note that in [2] the authors already developed very impressive and precise near-exact distributions for the test statistic. However, in the unbalanced case, the approximations obtained using the procedure described in this paper are much simpler and even more precise.

4 Conclusion

The approximations obtained using procedure described in this paper are simple and of easy computational implementation, since they are standard mixtures of gamma distributions and, in addition, they are extremely precise. The main contribution of these results is for the unbalanced case (the case where the samples may not have the same size) where is possible to obtain a significant improvement of the results already available in the literature, however even in the balanced case these approximations are very precise.

emails: almudena.marquez@uca.es, m.bruzon@uca.es, tamara.garrido@uca.es, elena.recio@uca.es

Abstract

In this work we study a viscous Cahn-Hilliard equation from the point of view of Lie symmetries in partial differential equations. A classification of Lie symmetries is found applying the classical Lie method. These symmetries allow the obtaining of travelling wave solutions. On the other hand, we analyze conservation laws using multipliers method proposed by Anco and Bluman. Afterwards, it is possible to calculate potential symmetries of the equation from the corresponding conserved systems.

Key words: nonlinear partial differential equation, Lie symmetries, Conservation laws, travelling wave solutons, multipliers method

In [8] the authors investigated different singular limits of an initial–boundary value problem of the viscous Cahn–Hilliard equation

$$\nu u_t = \Delta(\varphi(u) - \alpha\Delta u + \beta u_t), \tag{1}$$

where u is the solute concentration at point x, t is the time, $\varphi(u)$ is a "homogeneous free energy" and $\alpha/2$ is the gradient energy coefficient describing the contribution of the diffuse interface to the decomposition, βu_t is the viscous term and $\nu = 1 - \beta$.
If $\nu = 1$ and $\beta = 0$, then the Cahn–Hilliard equation is

$$u_t = \Delta(\varphi(u) - \alpha\Delta u). \tag{2}$$

This equation was introduced to study phase separation in binary alloys glasses and polymers and is a good approach to spinodal decomposition [7]. In [6], the authors obtained

 ISBN: 978-84-617-8694-7

classical and nonclassical symmetries of the equation and reduced the equation to ordinary differential equations.

In this paper we solve a group classification problem for equation (1), by studying those diffusion coefficients $f(u)$ which admit classical symmetries. Both the symmetry group and the diffusion coefficients will be found through consistent applications of the Lie-group formalism. We determine conservation laws of equation (1) by using the general multipliers method for this equation.

1 Lie symmetries

Lie group analysis [1, 2, 3, 4, 5, 10] is the most powerful tool to find the general solution of partial differential equations. We consider a one-parameter Lie group of infinitesimal transformations in (x, t, u). The associated Lie algebra of infinitesimal symmetries is the set of vector fields of the form

$$V = \xi(x,t,u)\frac{\partial}{\partial x} + \tau(x,t,u)\frac{\partial}{\partial t} + \phi(x,t,u)\frac{\partial}{\partial u}, \tag{3}$$

where $\xi(x,t,u)$, $\tau(x,t,u)$ and $\phi(x,t,u)$ are the infinitesimals. By requiring that this transformation leaves invariant the set of solutions of (1) we obtain an overdetermined, linear system of equations for the infinitesimals. This transformation leaves invariant the set of solutions of (1). After solving the determining equations, we give the following classification:

- For $f(u)$ arbitrary, the only symmetries admitted by equation (1) are the groups of space and time translations, which are defined by the infinitesimal generators

  $$V_1 = \frac{\partial}{\partial x}, \qquad V_2 = \frac{\partial}{\partial t}.$$

  In this case, we obtain travelling wave reductions,

  $$z = x - \lambda t, \qquad u = h(z),$$

  where $h(z)$, after integrating once with respect to z, satisfies

  $$\alpha\, h'''' + \lambda\beta\, h''' - \varphi_h\, h'' - \varphi_{hh}\, \left(h'\right)^2 - \lambda\nu\, h' = 0. \tag{4}$$

  Equation (4) is invariant under translations, what allows us to reduce the order by one.

- For $\beta = 0$, the only functional forms of $f(u)$, with $f(u) \neq$ const., for which equation (1) has extra symmetries are $f(u) = (au + b)^n$ and $f(u) = de^{au}$, where a, b, d, n are constants, $a \neq 0$, $d \neq 0$. These symmetries were obtained in [6]. For equation (4) it is possible to determine the form of the function f for which we can apply the simplest equation method. This method enables us to obtain exact travelling wave solutions for this class of nonlinear partial differential equations containing polynomial nonlinearities.

 ISBN: 978-84-617-8694-7

2 Conservation laws

We apply the direct method of the multipliers to set up the standard determining equations for finding the conservation laws admitted by equation (1) [1, 2, 3, 4, 5]. We find all multipliers by solving the determining equation

$$\frac{\delta}{\delta u}\Big((\nu u_t - \Delta(\varphi(u) + \alpha\Delta u - \beta u_t))Q\Big) = 0. \tag{5}$$

The nontrivial conservation laws are characterized by the multiplier Q satisfying

$$\hat{E}[u]\left(Q(\nu u_t - \Delta(\varphi(u) + \alpha\Delta u - \beta u_t))\right) = 0,$$

where

$$\hat{E}[u] := \frac{\partial}{\partial u} - D_t\frac{\partial}{\partial u_t} - D_x\frac{\partial}{\partial u_x} + D_x^2\frac{\partial}{\partial u_{xx}} + \ldots.$$

The conservation laws can be written

$$D_t T + D_x X = 0. \tag{6}$$

Given a multiplier Q, we can obtain the conserved density using a standard method

$$T = \int_0^1 dQ\ uQ(x, t, Qu, Qu_x, Qu_{xx}, ...)$$

and the flux X by

$$\begin{aligned} X &= -D_x^{-1}(Q(\nu u_t - \Delta(\varphi(u) + \alpha\Delta u - \beta u_t)) - \frac{\partial T}{\partial u_x}(\nu u_t - \Delta(\varphi(u) + \alpha\Delta u - \beta u_t) \\ &\quad +(\nu u_t - \Delta(\varphi(u) + \alpha\Delta u - \beta u_t)D_x\left(\frac{\partial T}{\partial u_{xx}}\right) + \ldots. \end{aligned}$$

From conservation laws, by using the corresponding conserved (potential) systems we can obtain potential symmetries of equation (1).

[3] *Department of Mathematics "Giuseppe Peano, University of Torino*

emails: iuliam@live.it, acesteves@ua.pt, ezio.venturino@unito.it

Abstract

In this paper a three dimensional non linear ODE system is analysed. The model describes the interaction between the orange tree and two different microorganisms present on it: a pathogen fungus *Guignardia citricarpa* and a beneficial one *Trichoderma harzianum T1A*. Five different equilibrium points are found plus the trivial one. The feasibility conditions are needed only for the coexistence equilibrium. Their stability is analysed, only the pathogen fungus-free point and the coexistence equilibrium point are conditionally asymptotically stable while the remaining equilibrium points are unstable.

Key words: orange tree, Guignardia citricarpa, Trichoderma harzianum T1A, mathematical model

1 Introduction

We consider a mathematical model that describes the behaviour of a biological system composed by an orange tree, a pathogen fungus, *Guignardia citricarpa*, and a beneficial one, *Trichoderma harzianum T1A*. We assume that the orange tree is attacked by the pathogen fungus, this attack can be less disastrous if there is a beneficial fungus that secretes proteins related to the control of *G. citricarpa*. Furthermore we assume that the beneficial fungus has a good influence on the reduction of damage of the tree due to the pathogen fungus, [1].

 ISBN: 978-84-617-8694-7

2 The model

Let us denote the various variables considered in the model by

- O: Orange tree fruits
- P: Pathogen fungus,*G. citricarpa*
- F: Beneficial fungus, *T. harzianum T1A*

the three populations of the mathematical model.
The model reads:

$$\begin{aligned} \frac{dO}{dt} &= rO\left(1-\frac{O}{K}\right) - h(F)OP, \quad h(F) = \frac{1}{q+F} \\ \frac{dP}{dt} &= eh(F)OP - aPF \\ \frac{dF}{dt} &= baPF + sF\left(1-\frac{F}{H}\right) \end{aligned} \tag{1}$$

First equation: describes the evolution of the orange tree. It grows logistically with net reproduction rate r and carrying capacity K, and is negatively affected by the pathogen fungus, with a variable rate $h(F)$. We take $h(F)$ so that it is a decreasing function depending on F, this meaning that the beneficial fungus helps to reduce the damage of the tree, O, due to P. The more F there are on the tree the less will be the damage due to P. In fact *T. harzianum T1A* secrets proteins related to the control of *G. citricarpa*.

Second equation: we describe the evolution of the pathogen fungus. P feed on the tree parts, ($e < 1$), and are degraded by the good fungi, at rate a, in the sense that *Trichoderma*, F, is able to produce extracellular enzymes able to degrade the cell wall of the pathogenic fungi, P.

Third equation: the beneficial fungus gets food from degrading the bad fungi ($b < 1$) and we assume that it has other food resources for which in their presence it can grow logistically with net reproduction rate s and carrying capacity H also in the absence of the bad fungi.

3 The qualitative analysis of the model

Solving the system

 ISBN: 978-84-617-8694-7

$$\begin{cases} rO\left(1-\dfrac{O}{K}\right)-\dfrac{OP}{q+F}=0 \\ e\dfrac{OP}{q+F}-aPF=0 \\ baPF+sF\left(1-\dfrac{F}{H}\right)=0 \end{cases} \tag{2}$$

we get five different equilibrium points plus the trivial one:

- the trivial equilibrium point, $E_0=(0,0,0)$, is always feasible
- the pathogen fungus-beneficial fungus-free point, i.e. the healthy fruit-only equilibrium $E_1=(K,0,0)$ is always feasible
- the orange-beneficial fungus-free point $E_2=(0,P,0)$ is always feasible
- the orange-pathogen fungus-free point $E_3=(0,0,H)$ is always feasible
- the pathogen fungus-free point $E_4=(K,0,H)$ is always feasible
- the coexistence equilibrium point $E_*=(O^*,P^*,F^*)$ is feasible if $O^*>0$ and $P^*>0$

To study the stability of the equilibrium points we compute the characteristic polynomial evaluating each equilibrium point at the Jacobian of (1):

$$J=\begin{bmatrix} r-\dfrac{2rO}{K}-\dfrac{P}{q+F} & -\dfrac{O}{q+F} & \dfrac{OP}{(q+F)^2} \\ \dfrac{eP}{q+F} & \dfrac{eO}{q+F}-aF & -\dfrac{eOP}{(q+F)^2}-aP \\ 0 & baF & baP+s-\dfrac{2sF}{H} \end{bmatrix} \tag{3}$$

Proposition 1 The trivial equilibrium point, $E_0(0,0,0)$ as well as $E_1=(K,0,0)$, $E_2=(0,P,0)$ and $E_3=(0,0,H)$ are unconditionally unstable.

Proof. We evaluate E_0, E_1, E_2 and E_3 at the Jacobian matrix (3), and we get

- E_0 is unstable, in fact the characteristic polynomial is

$$\lambda(\lambda-s)(\lambda-r)=0$$

and has two positive eigenvalues $\lambda_1=s$ and $\lambda_2=r$ plus an eigenvalue equal to zero.

 ISBN: 978-84-617-8694-7

- E_1 is unstable, in fact the characteristic polynomial is

$$(\lambda - s)(\lambda + r)\left(\lambda - \frac{Ke}{q}\right) = 0$$

and has two positive eigenvalues $\lambda_1 = s$ and $\lambda_2 = Keq^{-1}$ plus a negative eigenvalue $\lambda_1 = -r$.

- E_2 is unstable, in fact the characteristic polynomial is

$$\lambda(\lambda - Pab - s)\left(\lambda + \frac{qr - P}{q}\right) = 0$$

and has one positive eigenvalue $\lambda_1 = Pab + s$, an eigenvalue equal to zero and one with indefinite sign $\lambda_3 = (qr - P)q^{-1}$.

- E_3 is unstable, in fact the characteristic polynomial is

$$(\lambda + s)(\lambda - r)(\lambda + Ha) = 0$$

and has one positive eigenvalue $\lambda_1 = Pab + s$, and two negative ones $\lambda_2 = -s$ and $\lambda_3 = -Ha$, respectively.

□

Proposition 2 The pathogen fungus-free point $E_4 = (K, 0, H)$ is stable if the condition

$$K < \frac{aH(q + H)}{e} \tag{4}$$

holds.

Proof. The characteristic polynomial associated to E_4 is

$$(\lambda + r)(\lambda + s)\left(\lambda + \frac{aH(q + H) - eK}{q + H}\right) = 0,$$

thus we have two negative eigenvalues $\lambda_1 = -r$ and $\lambda_2 = -s$. Requiring the negativity of

$$\lambda_3 = \frac{eK - aH(q + H)}{q + H},$$

we get condition (4). □

 ISBN: 978-84-617-8694-7

Proposition 3 There exists at least one feasible coexistence equilibrium $E_* = (O^*, P^*, F^*)$ if the following conditions hold:

$$\frac{s - Hbar}{s + barq} < \frac{H}{F} < 1 \tag{5}$$

and furthermore whenever it exists, it is stable if the Routh-Hurwitz conditions hold $R_3 > 0$ and $R_1 R_2 > R_3$ where these quantities are defined below in (13).

Proof. To get O_*, P_* and F_* we solve the system

$$\begin{cases} Krq + KrF - rqO - rFO - KP = 0 \\ eO - aqF - aF^2 = 0 \\ HbaP + Hs - sF = 0 \end{cases} \tag{6}$$

From the third equation of (6) we get

$$P_* = \frac{sF_* - Hs}{Hba} \tag{7}$$

and we substitute it in the first equation of (6) and we get

$$O_* = \frac{HKbarq + HKs + F_*(HKbar - Ks)}{Hba(rq + eF_*)} \tag{8}$$

where F_* is the real root of the third degree polynomial

$$\Psi(F) := AF^3 + BF^2 + CF + D = 0, \tag{9}$$

with

$$\begin{aligned} A &= Ha^2br > 0 \\ B &= 2Ha^2bqr > 0 \\ C &= Ha^2bq^2r - HKaber + Kes \\ D &= -(HKabeqr + sHKe) < 0. \end{aligned} \tag{10}$$

One can see that (9) has at least one positive root, in fact the limit for $F \to +\infty$ is $+\infty$ and $\Psi(0) = D < 0$ (i.e. (9) evaluated for $F = 0$). The continuity of this polynomial function $\Psi(F)$ ensures the existence of a positive root, then.

Furthermore to study the stability of the coexistence equilibrium we compute the characteristic polynomial associated at it evaluating E_* at (3) we get

$$J = \begin{bmatrix} -\frac{rO}{K} & -\frac{O}{q+F} & \frac{OP}{(q+F)^2} \\ \frac{eP}{q+F} & 0 & -\frac{eOP}{(q+F)^2} - aP \\ 0 & baF & -\frac{sF}{H} \end{bmatrix} \tag{11}$$

 ISBN: 978-84-617-8694-7

thus

$$det(J-\lambda) = \lambda^3 + R_1\lambda^2 + R_2\lambda + R_3 = 0 \tag{12}$$

with

$$\begin{aligned} R_1 &= \frac{HrO + KsF}{KH} > 0 \\ R_2 &= \frac{(q+F)^2 rsOF + KHbaeOPF + KHba^2FP + KHeOP}{KH(q+F)^2} > 0 \\ R_3 &= \frac{HbaerO^2PF + H(q+F)^2ba^2rOPF + KesOPF - HKbaeOP^2F}{HK(q+F)^2} \end{aligned} \tag{13}$$

As one can see the condition $R_1 > 0$ is satisfied, while the positivity of R_3 and $R_1R_2 > R_3$ must be requested for the stability of E_*.

□

4 Conclusions

A three dimensional mathematical model was introduced, that describes the evolution in time of an orange tree, O, and two different fungi *Guignardia citricarpa*, P, and *Trichoderma harzianum T1A*, F. Five equilibrium points are always feasible, while for the coexistence equilibrium feasibility conditions needs to be required. Between six equilibrium points only the pathogen fungus-free point and the coexistence equilibrium are conditionally asymptotically stable and the remaining four are unstable.

The mathematical analysis is instrumental in defining strategies for the biological control of this infestant. In the future we plan to devise policies to possibly add the beneficial fungus to orange cultures in order to fight the *Guignardia citricarpa* damages to these fruits and reduce economic losses for the farmers.

Abstract

We consider the problem of finding an appropriate preconditioner for the PCG method in the solution of sequences of SPD linear systems. We investigate several preconditioning strategies that incorporate partial approximated spectral information. In our approach, a number of approximated eigenvectors are computed for a given coefficient matrix in the sequence of linear systems to be solved and used to obtain an efficient preconditioner for the subsequents sytems in the sequence. We apply these techniques to the efficient numerical solution of a branched transport model whose long time solution for specific parameter settings is equivalent to the solution of the Monge-Kantorovich equations of optimal transport [7]. Galerkin FEM discretization combined with explicit Euler time stepping yield a linear system to be solved at each time step, characterized by a large sparse very ill conditioned symmetric matrix A. Extreme cases even prevent the convergence of PCG with standard preconditioners such as an IC (with partial fill-in) factorization of A, which can not always be computed. We present numerical evidence that the proposed techniques are efficient in reducing the condition number of the preconditioned systems, thus decreasing the number of PCG iterations and the CPU time.

Key words: linear systems solving, PCG method, preconditioning, optimal transport.

1 Introduction

Sequences of linear systems in which the coefficient matrix slightly change are very common in many applications such as those requiring the discretization of a time-dependent PDE or

the solution by Newton's method of a nonlinear set of equations. We consider the iterative solution of a sequence of large and sparse (and possibly ill-conditioned) SPD matrices by the Preconditioned Conjugate Gradient (PCG) method. Finding a good preconditioner is mandatory to assure convergence of iterative methods. In the solution of sequences of linear systems like

$$A\boldsymbol{x}_i = \boldsymbol{b}_i$$

a number of paper have investigated the benefits of using spectral information from matrix A to accelerate the iterative solution of such systems by deflation. Among the others we mention [13, 9] and also [14]. Another approach consists in using the partial spectral information to update a given preconditioner (such as an incomplete Cholesky factorization) computed for matrix A. This approach has been described in several papers such as [5, 6, 10]. In all these papers the authors start with an initial preconditioner P_0 and use an approximation of a few eigenvectors of the preconditioned matrix to update P_0 with a low-rank matrix. Another characteristic shared by all these previous papers is that the coefficient matrix of the linear systems to be solved remains unchanged throughout the whole sequence. This allow the incremental refinement of the set of eigenvectors used to update the low-rank correction matrix.

In a slightly different framework, i.e. acceleration of the linear systems within iterative inner-outer eigensolvers, a number of updating strategies that incorporate partial spectral information of A, have been proposed and discussed in [2, 12].

In this paper we consider sequences of linear systems in which the coefficient matrices slightly vary from one system to another. We propose a preconditioning technique based on the knowledge of a set of (roughly) approximated eigenvectors of the coefficient matrix (or the preconditioned matrix) at a given linear system in the sequence. This information is used to update a given initial preconditioner to produce an efficient preconditioner for the subsequent systems in the sequence. We will test our approach to the efficient numerical solution of a branched transport model whose long time solution for specific parameter settings is equivalent to the solution of the Monge-Kantorovich equations of optimal transport [7]. Galerkin FEM discretization combined with explicit Euler time stepping yield a linear system to be solved at each time step, characterized by a large sparse very ill conditioned symmetric matrix A. Extreme cases even prevent the convergence of PCG with standard preconditioners such as an IC (with partial fill-in) factorization of A, which can not always be computed.

We present numerical evidence that the proposed techniques are efficient in reducing the condition number of the preconditioned systems, thus decreasing the number of PCG iterations and the CPU time.

The remaining of the paper is organized as follows: Section 2 introduces the spectral preconditioner and two different strategies to obtain an approximated set of eigenvectors needed to form the low rank updating matrix. Section 3 describes the implementation details

 ISBN: 978-84-617-8694-7

regarding the construction of the preconditioner. We also include in this section detailed algorithms of the iterative solution phase by the PCG method for the two different spectral information recovering techniques. Numerical results are shown in Section 4. Section 5 summarizes the main conclusions.

2 The spectral preconditioner

In this paper we consider sequences of linear systems of the form

$$A_i \boldsymbol{x}_i = \boldsymbol{b}_i. \tag{1}$$

For a given linear system in the sequence $Ax = b$, we study the acceleration of the PCG solver provided by the following spectral preconditioner:

$$P = P_0 + V_p \Lambda_p^{-1} V_p^T, \tag{2}$$

where $V_p = [v_1, \ldots, v_p]$ and $v_j, j = 1, \ldots, p$ are approximate eigenvectors either of $P_0 A$ or of A; $\Lambda_p = \mathrm{diag}(\lambda_1, \ldots, \lambda_p)$, and $\lambda_j,\ j = 1, \ldots, p$ are the corresponding smallest eigenvalues, and P_0 is a standard preconditioner computed for A. When V_p contains eigenvectors of $P_0 A$, the effect of the low-rank correction is easily shown to be:

$$PAv_j = (\lambda_j + 1)v_j, \qquad j = 1, \ldots, m.$$

so that some of the eigenvalues of the new preconditioned matrix are incremented by 1 with an obvious reduction of the condition number.

We propose two different ways to obtain the approximated eigenvectors needed to construct the spectral preconditioner.

2.1 Approximating some of the smallest eigenpairs by DAGC

Following [2], we propose to approximate some of the leftmost eigenvectors of a given coefficient matrix A by performing some preliminary iterations of an eigenvalue solver. We chose the Deflation-Accelerated Conjugate Gradient (DACG) eigensolver [1], which is based on the preconditioned conjugate gradient (nonlinear) minimization of the Rayleigh Quotient (RQ) $q(\boldsymbol{x}) = \dfrac{\boldsymbol{x}^T A \boldsymbol{x}}{\boldsymbol{x}^T \boldsymbol{x}}$. The leftmost eigenpairs are computed sequentially, by minimizing the RQ over a subspace orthogonal to the previously computed eigenvectors. This method, which applies only to symmetric positive definite matrices, has been proven very efficient in the solution of eigenproblems arising from discretization of PDEs in [4]. DACG also proved very suited to parallel implementation as documented in [3] where an efficient parallel matrix vector product has been employed.

 ISBN: 978-84-617-8694-7

Convergence of DACG is strictly related to the relative separation between consecutive eigenvalues, namely $\xi_j = \dfrac{\lambda_j}{\lambda_{j+1} - \lambda_j}$. Also DACG takes advantage of preconditioning which can be chosen to be the IC factorization.

Once a small number of leftmost eigenvectors has been computed and stored as columns of V_p, different low-rank corrections of a given preconditioner P_0 can be defined as e.g. described in [12]. For example a BFGS-style preconditioner can be written as

$$\begin{aligned} P &= V_p(V_p^T A V_p)^{-1} V_p^T + \left(I - V_p(V_p^T A V_p)^{-1} V_p^T A\right) P_0 \left(I - A V_p(V_p^T A V_p)^{-1} V_p^T\right) \\ &\approx V_p \Lambda_p^{-1} V_p^T + \left(I - V_p V_p^T\right) P_0 \left(I - V_p V_p^T\right) \end{aligned} \tag{3}$$

In the previous paper, however, a simplified version of the BFGS preconditioner (3) has been defined, which neglects the left and right projector on P_0 and therefore takes the same form as (2):

$$P = V_p \Lambda_p^{-1} V_p^T + P_0.$$

In the above mentioned paper it is also shown that the preconditioned matrix PA has a better spectral distribution than $P_0 A$.

2.2 Recovering spectral information by the Lanczos process

Another strategy to obtain a set of approximated eigenvectors is to recover them from the Krylov subspace built by the linear solver. Denoting again by P_0 a preconditioner for matrix A, during the PCG method we save the first m preconditioned residuals as columns of a matrix W_m:

$$W_m = \left[\frac{P_0 r_0}{\sqrt{r_0^T P_0 r_0}}, \frac{P_0 r_1}{\sqrt{r_1^T P_0 r_1}}, \ldots, \frac{P_0 r_{m-1}}{\sqrt{r_{m-1}^T P_0 r_{m-1}}.} \right]$$

Matrix W_m thus satisfies: $W_m^T P_0^{-1} W_m = I_m$, in view of the P_0-orthogonality of the residuals generated by the PCG method. Moreover we form the Lanczos tridiagonal matrix using the PCG coefficients α_k, β_k as

$$T_m = \begin{bmatrix} \frac{1}{\alpha_0} & -\frac{\sqrt{\beta_1}}{\alpha_0} & & & \\ -\frac{\sqrt{\beta_1}}{\alpha_0} & \frac{1}{\alpha_1} + \frac{\beta_1}{\alpha_0} & -\frac{\sqrt{\beta_2}}{\alpha_1} & & \\ & & \ddots & & \\ & & & -\frac{\sqrt{\beta_{m-1}}}{\alpha_{m-2}} & \\ & & -\frac{\sqrt{\beta_{m-1}}}{\alpha_{m-2}} & \frac{1}{\alpha_{m-1}} + \frac{\beta_{m-1}}{\alpha_{m-2}} & \end{bmatrix}$$

 ISBN: 978-84-617-8694-7

Matrices W_m and T_m obey to the classical Lanczos relation i.e.: $W_m^T A W_m = T_m$. After eigensolving T_m we obtain $T_m = Q\Lambda_m Q^T$, where the diagonal coefficients of the diagonal matrix Λ_m approximate the eigenvalues of $P_0 A$ while the columns of $V_p = W_m Q_q$ (where Q_p contains the first p columns of Q) are approximations of the p leftmost eigenvectors of $P_0 A$.

In fact we have, first, that $V_p^T A V = Q_p^T W_m^T A W_m Q_p = Q_p^T T_m Q_p = \Lambda_p \equiv \mathrm{diag}(\lambda_1, \ldots, \lambda_p)$. Then, by setting $U = P_0^{-1/2} V_p$ we obtain U and Λ_p satisfying

$$U^T U = V_p^T P_0^{-1} V_p = I_m \tag{4}$$

$$\Lambda_p = V_m^T A V_m = U^T P_0^{1/2} A P_0^{1/2} U \tag{5}$$

which correspond to the Lanczos process applied to matrix $P_0^{1/2} A P_0^{1/2}$. Hence the columns of U approximate the eigenvectors of $P_0^{1/2} A P_0^{1/2}$ that is

$$P_0^{1/2} A P_0^{1/2} U \approx U\Lambda_p \iff P_0 A P_0^{1/2} U \approx P_0^{1/2} U \Lambda_p \Longleftrightarrow P_0 A V_p \approx V_p \Lambda_p,$$

so that the columns of V_p approximate the eigenvectors of $P_0 A$.

3 Implementation

The approximation of a number of the leftmost eigenpairs is a costly task which can not be performed at each linear system solution. To reduce the cost of this operation we devise different strategies depending on how we obtain the spectral information.

3.1 Eigenpairs of A obtained by DACG

The computation of a number of the leftmost eigenpairs by DACG is a preprocessing stage that in principle should be executed before every system solving. However, in view of the fact that the system matrices A_i do not change much during the simulation we propose to evaluate selectively the eigenpairs, whenever the PCG solution of a generic linear system $A_j \boldsymbol{x}_j = \boldsymbol{b}_j$ takes more than a fixed number of iterations ($k_i \geq \mathtt{it}_{switch}$). In this case, except for the very first linear system, we use as the initial DACG eigenvector guess, the previously computed eigenvectors.

Spectral PCG Algorithm: DACG variant

  1. Compute the p leftmost eigenpairs by the DACG procedure with preconditioner P_0 and accuracy τ_{DACG}.
  2. Form matrices V_p, Λ_p.
  3. Solve the $i-$th linear system by PCG preconditioned by $P_0 + V_p \Lambda_p^{-1} V_p^T$.
  4. switch= FALSE.
- IF $k_i > it_{prec}$ switch = TRUE
- IF $k_i > it_{chol}$ chol_switch = TRUE

END FOR

3.2 Eigenpairs of $P_0 A$ obtained by Lanczos-PCG

Computation of matrices T_m and W_m is carried out during the PCG process and hence it needs no additional cost. The main computational burden due to this strategy is given by the matrix-matrix product $V_m = W_m Q_p$ which is implemented via BLAS-3 subroutines, with a consequent optimal use of memory accesses. Due to the slow convergence of the Lanczos process to the smallest eigenvalues, and also for memory reasons, it is convenient to recover a relatively small number of eigenpairs (independently of the size m of V_m which should be taken sufficiently large). In the Lanczos process we use only the $p = \{10, 20\}$ smallest eigenvalues and corresponding eigenvectors thus obtaining a $n \times p$ matrix V_p and a $p \times p$ diagonal matrix Λ_p.

END FOR

4 Numerical results

In this section we illustrate the behaviour of the spectral preconditioner on a sequence of linear systems arising in the discretization of the PDE modeling the optimal transport (OT) problem. Starting from the PDE-version of the L^1 Monge-Kantorovich OT problem formulated by [7], Facca et al. in [8] have proposed a general formulation of a dynamical system whose infinite-time solution is conjecture to be related to the OT and BT problems. The model reads as: find (μ, u) such that:

$$-\nabla \cdot (\mu(t,x)\nabla u(t,x)) = f(x) = f^+(x) - f^-(x) \tag{6}$$

$$\mu'(t,x) = |\mu(t,x)\nabla u(t,x)|^\beta - \mu(t,x) \tag{7}$$

$$\mu(0,x) = \mu_0(x) > 0 \tag{8}$$

where μ is the transport density, u is the transport potential, f is the zero-average forcing function (f^+ and f^- being the initial and final mass configurations), and $\beta > 0$ is related to the branching exponent. The model is completed by imposing homogeneous Neumann boundary conditions to 6). Here, the gradient and divergence operators are computed with respect to the spatial coordinate x, while μ' indicates time differentiation.

Experimental evidence shows that for $\beta > 1$ the proposed formulation reaches and equilibrium state that resembles solutions of the branched transport problem. In this case, in fact, the transport density concentrates on sets that have a fractal nature, thus providing a naturally network-forming model of optimal transportation.

Numerically, the problem is solved by a combination of Galerkin FEM and Euler time stepping. Spatial discretization is obtained by employing two different triangulations $\mathcal{T}_h$ and $\mathcal{T}_{h/2}$, the second one obtained from the first by uniform refinement, we adopt a piecewise constant ($\mathcal{P}_0(\mathcal{T}_h)$) representation of μ_h on $\mathcal{T}_h$ and a linear ($\mathcal{P}_1(\mathcal{T}_{h/2})$) representation of u_h on $\mathcal{T}_{h/2}$. Forward Euler time-stepping completes the numerical approach, which reads:

$$A[\mu^k]u^k = b \tag{9}$$

$$\mu^{k+1} = (I + \Delta t^k B[u^k])\mu^k \tag{10}$$

$$\mu^0 = \Pi_h \mu_0 \tag{11}$$

 ISBN: 978-84-617-8694-7

where A is the classical Galerkin $\mathcal{P}_1$ stiffness matrix, vector μ collects the elemental values of μ_h, u is the vector of nodal values of u_h, B is the matrix defining the norm of the gradient of u_h, and Π_h denotes the L^2 projector on $\mathcal{T}_h$. Equilibrium is achieved by repeating the above algorithm until $(\|\mu_h^{k+1} - \mu_h^k\|_{L^2(\Omega)})/\Delta t^k \|\mu_h^k\|_{L^2(\Omega)} < \tau$. We generally impose $\tau = 10^{-8}$.

At each time step of the method, a linear system involving the sparse symmetric and positive definite system matrix $A[\mu^k]$ needs to be solved. PCG convergence becomes increasingly difficult as time progresses as the condition number of the system matrix grows indefinitely with β. In fact, the dynamics of the model is such that μ_h tends to zero in large portions of Ω.

The test case addressed in this work is shown in Figure 1. The simulation considers a mesh $\mathcal{T}_h$ of 412417 nodes and $n_{nz} = 1647617$ nonzero elements. The timestep Δt^k is increased by a factor 1.05 at each time step starting from $\Delta t^0 = 10^{-3}$ up to a maximum value of $\Delta t^k = 10^{-1}$. This leads to a sequence of 800 linear systems of type (1) to reach equilibrium at the chosen tolerance τ.

As the boundary conditions imposed to the PDE (1)-(3) are only Neumann, the resulting discretized system is singular, with $\ker A_i = \text{span}\{c\} = \text{span}\{\big(1, \ldots, 1\big)^T\}$. However following [11] we guarantee the consistency (and the PCG solution) of our linear systems by also modifying the right hand side: $\tilde{b} = b - \dfrac{c^T b}{\|c\|^2} c$. Moreover, all the linear systems has been symmetrically scaled with the diagonal of A_i in order to reduce the condition number. . .

The code is written in Fortran 90. All the experiments were run on a 2 x Intel Xeon CPU E5645 at 2.40GHz (six core) and with 4GB RAM for each core. Times are expressed in seconds. The stopping criterion for the linear solver is independent of the preconditioner used and it is based on the relative residual. The iterative procedure stops whenever

$$\frac{\left\| A_i \boldsymbol{x}_i^{(k)} - \boldsymbol{b}_i \right\|}{\|\boldsymbol{b}_i\|} < \varepsilon = 10^{-11}. \tag{12}$$

The initial preconditioner P_0 is computed by setting the maximum number of nonzero per row LFIL= 30 and the drop tolerance $\tau_{IC} = 10^{-4}$. Using lower LFIL and/or larger τ_{IC} values prevented the existence of the IC factorization for all systems in the simulations. This choice of parameters produced a rather dense L factor with a number of nonzero roughly 8 times that of the lower triangular part of A. Therefore computation of this preconditioner for each linear system of the sequence was not effective. We decided to compute the IC preconditioner for a given matrix A_i if $i = 1$ or the number of PCG iterations in the previous linear system was above a fixed value, it_{chol}. We used the previously computed IC preconditioner, otherwise.

In the sequel we will report the number of eigenvectors p used to build the low rank correction to the initial preconditioner, the way these eigenvectors have been approximated,

 ISBN: 978-84-617-8694-7

by using the Lanczos method to recover them from the Krylov space built by the linear solver (LAN) or explicitly approximated by the DACG eigensolver, the overall iteration count of the PCG solver for the total number of linear systems to be solved, and timings accounting for computation of the preconditioner (T_{prec}), of the approximated eigenvectors (T_{eig}), of the PCG solver (T_{PCG}) and the total CPU time (T_{tot}).

We first perform a preliminary study on the sensitivity of the preconditioner efficiency versus the accuracy of the eigencomputation. To this end we considered the first 200 linear systems and use three different tolerances for the relative eigenresidual test: $\tau_{DACG} \in \{0.1, 0.3, 0.5\}$. Other parameters were: $it_{prec} = 60, it_{chol} = 60, p = 20$. As a benchmark, we also solved the first 200 systems by the PCG method preconditioned by an IC factorization computed selectively (with $it_{chol} = 100$).

τ_{DACG}	ITER	T_{eig}	T_{prec}	T_{PCG}	T_{tot}
–	20646	0.00	187.9	1687.8	1875.7
0.1	9907	326.9	117.9	1002.1	1446.2
0.3	10006	198.5	117.2	1011.5	1327.8
0.5	10055	150.0	117.2	1017.7	1284.9

These results show that there is no need for high accuracy in the computation of the eigenvectors. With a very low accuracy ($\tau_{DACG} = 0.5$) the number of PCG iterations is halved and the CPU time reduced of a factor 1.5 with respect to the fixed IC preconditioner (first row in the previous Table).

We report in Table 1 the results of a complete simulation i.e. the cumulative number of PCG iterations and CPU times in solving the 800 linear systems. In addition to the previously described parameters we used as the maximum size of the Lanczos subspace $m_{\max} = 80$, which experimentally revealed the optimal value. We set $\tau_{DACG} = 0.5$.

We notice from Table 1 that the proposed low-rank updated spectral preconditioner is effective in both variants, providing an important reduction of the number of iterations as well of the CPU time. On the average, our spectral preconditioners provide a halving of the total CPU time and a $30\% - 40\%$ reduction of the number of iterations. Using $p = 10$ or $p = 20$ eigenvectors produces only slight variations in the number of iterations/CPU time. Hence, the choice $p = 10$ seems to be preferred in terms of memory storage.

Surprisingly, the DACG variant, though the eigenvector approximation is done outside the PCG and hence is expected to be more costly, reveals as effective as the Lanczos variant. This is mainly due to the fact that after an initial and costly assessing of the leftmost eigenvectors, the subsequent computations are very cheap since the previously computed eigenvectors are very good initial guesses for the next systems. However, we may expect a different behavior of the two techniques in cases of higher variations of the matrices involved. In this case, the DACG preprocessing time will increase as opposite to the Lanczos

technique. Moreover, the Lanczos approach can be accelerated by employing a method similar to that described in [14]. This aspect will be investigated in a future work.

5 Conclusions

We have proposed a class of spectral preconditioners to accelerate the PCG solution of a sequence of linear systems arising from the discretization of a continuous branched transport model, where Galerkin FEM discretization combined with explicit Euler time stepping yield a linear system to be solved at each time step, characterized by a large sparse very ill conditioned symmetric matrix A. Using the fact that the matrices involved display mild variations at close simulation times, we have used eigeninformation obtained at a given timestep, to accelerate the subsequent linear systems solution. Numerical results reveal that the proposed spectral preconditioner are able to consistently reduce the number of iterations and halve the CPU time with respect to keeping fixed the IC preconditioner. Moreover, the CPU time required by the eigenanalysis is almost negligible as shown in our experiments where it represents less than 5% of the overall CPU time when $p = 10$ approximated eigenvectors are computed.

emails: cmartinez@maths.nuim.ie

Abstract

We study cyclic codes which include generalized Reed-Solomon codes as function field codes. This geometric approach allows to construct longer codes and to get more information on the parameters defining the codes.

Key words: Algebraic code, function field, cyclic code

1 Introduction

Function fields are used ubiquitously in algebraic coding theory for their flexibility in constructions and have produced excellent linear codes. Suitable families of function fields, for example good towers of function fields, have been used to construct families of codes with parameters bound better than the asymptotic bound.

Let q a power of a prime number p. It is well known, that there exists exactly one finite field with q elements which is isomorphic to the splitting field of the polynomial $x^q - x$ over the prime field $\mathbb{F}_p$. Any other field F of characteristic p contains a copy of $\mathbb{F}_p$. We denote respectively by $\mathbb{A}^n(\mathbb{F}_q)$ and $\mathbb{P}^n(\mathbb{F}_q)$ the affine space and the projective space over $\mathbb{F}_q$. Let $\mathbb{F}_q[x_1, x_2, \ldots, x_n]$ be the algebra of polynomials in n variables over $\mathbb{F}_q$.

The encoding of an information word into a $k-$dimensional subspace is usually known as coding for errors and erasures in random network coding, [KK]. Namely, let V be an $N-$dimensional vector space over $\mathbb{F}_q$, a code for an operator channel with ambient space V is simply a nonempty collection of subspaces of V. The collection of subspaces is a code for error correcting errors that happen to data sent through an operator channel. The matrix coding the information is parametrized by random variables $a_1, a_2, \ldots, a_n$ which constitute the letters of an alphabet. Here the operator channel is an abstraction of the operator encountered in random linear network coding, when neither transmitter nor receiver has

 ISBN: 978-84-617-8694-7

knowledge of the channel transfer characteristics. The input and output alphabet for an operator channel is the projective geometry. A good code is capable of correcting error and erasures at the output of the operator channel. Thus in order to construct good codes one need to choose a metric consistent with channel errors and search of a set of vectors with given metric properties as a correcting code. The codes considered here are codes for channels whose errors are consistent with the weighted Hamming metric (WHM).

Let $\mathcal{C}$ be a non-singular, projective, irreducible curve defined over $\mathbb{F}_q$, as the vanishing locus of a polynomial $F \in \mathbb{F}_q[x_0, x_1, x_2]$. We define the number $N(q)$ of $\mathbb{F}_q-$rational points on the curve to be

$$N(q) = |\{(x_0, x_1, x_2) \in \mathbb{P}^2(\mathbb{F}_q) | F(x_0, x_1, x_2) = 0\}|.$$

It is a polynomial in q with integer coefficients, whenever q is a prime power.

The number of points $\overline{\mathcal{C}}(\mathbb{F}_{q^r})$ on $\mathcal{C}$ over the extensions $\mathbb{F}_{q^r}$ of $\mathbb{F}_q$ is encoded in an exponential generating series, called the zeta function of $\overline{\mathcal{C}}$:

$$Z(\mathcal{C}, t) = exp\left(\sum_{r=1}^{\infty} \sharp\overline{\mathcal{C}}(\mathbb{F}_{q^r}) \frac{t^r}{r}\right).$$

Garcia and Stichtenoth analyzed the asymptotic behavior of the number of rational places and the genus in towers of function fields, [GS]. From Garcia-Stichtenoth's second tower one obtains codes over any field $\mathbb{F}_q$ where q is an even power of a prime, [GMMR].

One of the main problems in coding theory is to obtain non-trivial lower bounds of the number $N(F_i)$ of rational places of towers of function fields $\{F_i/\mathbb{F}_q\}_{i=1}^{\infty}$ such that $F_i \subsetneq F_{i+1}$. Suitable families of function fields, for example good towers of function fields, have been used to construct families of codes that beat the Gilbert-Varshamov bound. This paper aims to explore this link for the study and construction of cyclic codes. For example good codes are obtained for curves of genus 0, they are in fact extended generalised Reed-Solomon codes.

2 Algebraic geometric codes

Let $\mathbb{F}_q$ be a finite field of q elements, where q is a power of a prime. We consider as an alphabet a set $\mathcal{P} = \{P_1, \ldots, P_N\}$ of $N - \mathbb{F}_q$ rational points lying on a smooth projective curve $\mathcal{C}$ of genus g and degree d defined over the field $\mathbb{F}_q$. Goppa in [Go], constructed algebraic geometric linear codes from algebraic curves over finite fields with many rational places.

Definition 2.1 *AGC codes are constructed by evaluation of the global sections of a line bundle or a vector bundle on the curve $\mathcal{C}$. Namely, let $F|\mathbb{F}_q$ be the function field of the*

 ISBN: 978-84-617-8694-7

curve and $\mathcal{D}$ a divisor of $F|\mathbb{F}_q$ such that $\operatorname{Supp} \mathrm{G} \cap \operatorname{Supp} \mathrm{D} = \emptyset$*, then the geometric Goppa code associated with the divisors D and G is defined by*

$$\mathbf{C}(D,G) = \{(x(P_1), \ldots, x(P_n)) |\, x \in \mathcal{L}(G)\} \subseteq \mathbb{F}_{q^n}.$$

Recall that $\mathbb{F}_{q^n}|\mathbb{F}_q$ is a cyclic Galois extension and by the Theorem of the primitive element is finitely generated by unique element $\alpha \in \mathbb{F}_q$. In particular, each element in $\mathbb{F}_{q^n}$ can be written as a quotient of two polynomials in α with coefficients in $\mathbb{F}_q$. In the sequel, an $[n,k]_q-$code C is a $k-$dimensional subspace of $(\mathbb{F}_q)^n$.

2.1 Generalized Reed-Solomon codes as cyclic codes

Another important family of Goppa codes is obtained considering the rational normal curve $\mathcal{C}^n$ defined over $\mathbf{F}_q$:

$$\mathcal{C}^n := \{\mathbb{F}_q(1, \alpha, \ldots, \alpha^n) :\ \alpha \in \mathbb{F}_q \cup \{\infty\}\}.$$

The Goppa codes of dimension n defined over $\mathcal{C}^n$ are constructed by evaluating non-zero polynomials of degree less than n over a sequence $\alpha_1, \ldots, \alpha_n$ of n distinct elements in $\mathbb{F}_q$, if $k \leq n$, then the map

$$\epsilon : \mathbb{F}_q[x] \to \mathbb{F}_q^n, \quad f \mapsto (f(\alpha_1, \ldots, \alpha_n)) \tag{1}$$

is injective, since the existence of a non-zero polynomial of degree less than k vanishing on all α_i implies $n < k$ by the fundamental theorem of algebra (a non-zero polynomial of degree r with coefficients in a field can have at most r roots). These are just Reed-Solomon codes of parameters $[n,k,d]$ over a finite field $\mathbb{F}_q$, with parity check polynomial $h(x) = \prod_{i=1}^{q}(x-\alpha^i)$, where α is a primitive root of $\mathbb{F}_q$ such that $\alpha^{k+1} = \alpha + 1$. Any codeword $(c_0, c_1, \ldots, c_{n-1})$ can be expanded into a q-ary k vector with respect to the basis $\{1, \alpha, \ldots, \alpha^{k-1}\}$.

Construction of generalized Reed-Solomon codes over $\mathbb{F}_q$ only employ elements of $\mathbb{F}_q$, hence their lengths are at most $q+1$. In order to get longer codes, one can make use of elements of an extension of $\mathbb{F}_q$, for instance considering subfield subcodes of Reed-Solomon codes. In this way, one gets cyclic codes. Recall that a linear cyclic code is an ideal in the ring $\mathbb{F}_q[x]/(x^n-1)$ generated by a polynomial $g(x)$ with roots in the splitting field $\mathbb{F}_q^l$ of $x^n - 1$, where $n|\, q^l - 1$. We shall identify the code with the set of its codewords.

Theorem 2.2 *Given a set of integers $\{0, 1, \ldots, n-1\}$ module n, there is a set J of k integers which is a set of roots, that is, there is a polynomial $h(x) = \prod_{j \in J}(x - \alpha^j)$, where α is a generator of $(\mathbb{F}_p)^m$ for some prime number p and m is the least integer such that $n|p^m - 1$. The ideal $h(x)$ generates in $\mathbb{F}_{p^m}[x]/(x^n-1)$ is a cyclic linear code of parameters $(n, k, n-k+1)$.*

Another important family of cyclic codes is obtained considering the roots of the polynomial $x^n - 1$ over its splitting field. These codes are of great importance in ADN-computing and as they are linear codes, they can be described as function fields.

 ISBN: 978-84-617-8694-7

Theorem 2.3 *Cyclic codes are function field codes constructed over the curve $\mathcal{C}_{n,m}$ with affine equation $y^m + x^n = 1$ defined over a finite field $\mathbb{F}_q$ of q elements, where q is a power of a prime p and n, m are integer numbers greater or equal than 2.*

Proof. Let us assume n is an integer even number, thus $n = 2^k \cdot s$, with s an integer odd number. We recall that a linear cyclic code is an ideal in the ring $\mathbb{F}_q[x]/(x^n-1)$ generated by a polynomial $g(x)$ with roots in the splitting field $\mathbb{F}_q^l$ of x^n-1, where $n|\, q^l-1$. If we consider the factorisation of the polynomial x^n-1 over $\mathbb{F}_p[x]$, we get $(x^{n/2}-1)\,(x^{n/2}+1) = (x^{n/4}-1)\,(x^{n/4}+1)\,(x^{n/2}+1) = (x^{n/2^k}-1)\,(x^{n/2^k}+1)\,(x^{n/2^{(k-1)}}-1)\,(x^{n/2^{(k-1)}}+1)\ldots\,(x^{n/2}+1)$. We see that the point $P_0 = (\alpha, 0) \in \mathbb{P}(\mathbb{F}_q^2)$ with $\alpha^{n/2} = p-1$ is an $\mathbb{F}_{q^2}-$rational place of the affine curve $y^m = (x^{n/2}+1)$. The other rational places are $P_k = (\beta, 0)$ with $\beta^{n/2^k} = p-1$,..., $P_2 = (\beta^2, 0)$, $P_1 = (1, 0)$, $P_0 = (-1, 0)$ and the place $P_\infty = (0, \alpha)$ at ∞.The cyclic code is realized as the algebraic geometric code associated to the divisors $D = P_0 + P_1 + \ldots + P_k$, $G = \mu\, P_\infty$ and the parameter μ satisfies the bound $\mu > 2g-2$, where g is the genus of the curve $\mathcal{C}_{n,m}$. Note that m is the least integer such that $n|\, p^m - 1$. In particular α is a generator of $(\mathbb{F}_p)^m$.

If n is an integer odd number, by Theorem 2.2, we know there is a set of roots $\{\alpha^j\}_{j\in J}$, such that α is a generator of $(\mathbb{F}_p)^m$. Now we consider the points $P_j = (\alpha^j, 0)$ with $j \in J$ and the point P at $P_\infty = (0, \alpha) = \infty$, and the cyclic code is realised as the function field code associated to the divisors $D = \sum_{j\in J} P_j$ and μP_∞.

Abstract

In a time series context the nearest neighbour algorithm looks for the historical observations most similar to the latest observations of the time series. However, some nearest neighbours can be misleading. In this paper we propose that, if prior information about the structure of the time series is known, the search space of possible neighbours can be narrowed so that some possibly misleading neighbours are avoided. This way a more effective forecasting method can be obtained.

Key words: time series forecasting, lazy learners

1 Introduction

Time series forecasting has been traditionally done using statistical models, such as ARIMA [1] or exponential smoothing [2]. However, the last decades have seen the widespread use of computational intelligence techniques, such as artificial neural networks [3], to forecast univariate time series.

Lazy learners [4], such as nearest neighbours, are one of the computational intelligence techniques applied in time series forecasting. As the next section will explain in more detail, a nearest neighbours algorithm tries to forecast the next future values of a time series looking for past realizations that are similar to the last observations in the time series. The subsequent observations of the past similar realizations are used to forecast the time series.

 ISBN: 978-84-617-8694-7

However, we think that in certain time series, some similar past realizations can be misleading and, therefore, produce bad forecasts. To solve this problem, we propose to narrow the search space of possible neighbours, excluding possibly misleading instances.

The remainder of this paper is structured as follows. Section 2 describes how the nearest neighbour algorithm can be applied to predict the future values of a time series. Section 3 explains why to narrow the search space of neighbours could be effective. Section 4 describes the experimental setup and how the meta parameters of the nearest neighbour algorithm have been chosen. Section 5 shows the results of our experimentation and Section 6 draws some conclusions.

2 Using nearest neighbours in time series forecasting

The nearest neighbour is a classical supervised algorithm in machine learning. Originally, it was applied in classification tasks. Given an unlabeled example, we look for the most similar labeled example, according to some features of the examples and using a distance function to express similarity. The label of the most similar example is used to classify the unlabeled example. The labeled examples can contain outliers and errors that can distort the prediction, so instead of looking for the nearest neighbour normally the k nearest neighbours are found and their majority class is used as prediction.

The nearest neighbours algorithm can be easily extended to a regression task. Instead of having labeled examples, the examples contain a numeric target value and the target value of the k nearest neighbours is combined—for example, it is averaged—to produce the predicted value. In a time series forecasting scenario, the target value of an example is a time series observation and the features describing the example are lagged values of the observation. This way, the next value of a time series is predicted looking for examples in the time series similar to the last observations—see Figure 1. Figure 1 shows an example of one-step ahead forecasting using lags 1 to 4 as features and two nearest neighbours. The last four values of the time series are the features of the example to be regressed on and the two sets of consecutive white squares the 2 nearest neighbours, whose targets are the black triangles. The mean of the two targets is the forecast—the asterisk.

The underlying reason to using nearest neighbours in a time series scenario is that a time series contains repetitive patterns. Hence, given the last behaviour of a time series we try to look for similar past behaviours in the hope that their subsequent values can be similar to the future values of the time series.

3 Why to narrow the search space of neighbours

When we do not know too much about the structure of a time series, we simply select the features—lagged values—of the future observation to be forecast and look for the most

 ISBN: 978-84-617-8694-7

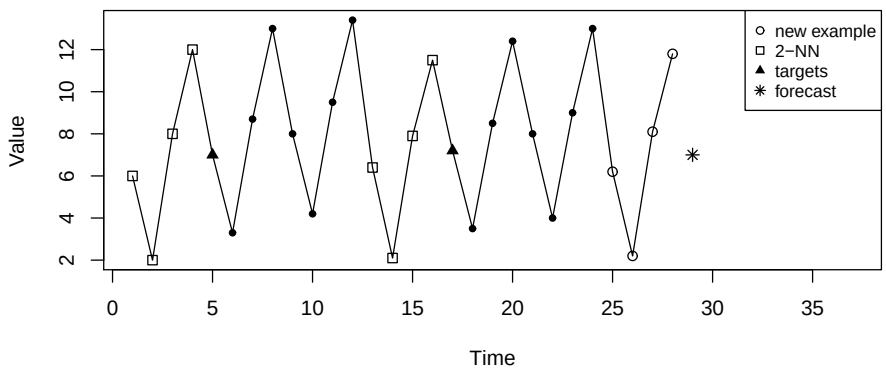

Figure 1: Example of 2 nearest neighbours for one-step-ahead forecasting.

similar examples in the time series. However, frequently we *do* know about the structure. For example, in the data explained in more detail in the next section, we are going to work with daily time series of cash money withdrawals at cash-machines. Apart from other patterns, these series have a strong weekly seasonality. Concretely, the withdrawals on weekends are very different from the withdrawals on workdays. Suppose now that we have information until a certain Friday and we want to predict the withdrawals on the following day, i.e., a Saturday. Let us also suppose that we are using the nearest neighbour algorithm and we use as feature the first lagged value. That is, to predict a Saturday we will find the day more similar to its previous day—a Friday. The most similar day found could be any day, let us suppose that it is a Tuesday. So we are going to predict the next Saturday withdrawals using the withdrawals on a Wednesday. This is not a desirable situation, because the withdrawals on Saturdays have nothing to do with the withdrawals on Wednesdays.

In our proposal, for this case we propose to narrow the search space looking only on previous Fridays to produce a more sensible forecast. That is, the prediction on a Saturday will be the average of several Saturdays whose previous Fridays are similar to the last Friday in the time series.

 ISBN: 978-84-617-8694-7

4 Experimental setup

In order to assess the effectiveness of our proposal we have used data from the NN5 time series competition[1]. In this competition 111 time series of 2 years of daily cash money withdrawals at various automatic teller machines (ATMs, or cash machines) at different locations in England were used. The goal was to forecast the cash money demand for the next 56 days ahead of every one of the 111 time series.

To assess forecast accuracy the symmetric mean absolute percentage error—SMAPE—was used. Given a vector forecast f for the next 56 days of a time series and the vector y of actual future values, the SMAPE is computed as follows:

$$SMAPE = \frac{1}{56}\sum_{t=1}^{56}\frac{|y_t - f_t|}{(|y_t| + |f_t|)/2}100$$

The SMAPE obtained for every one of the 111 time series by a given method is averaged to obtain a final SMAPE, which is used as the main forecast accuracy measure to compare the different methods.

Figure 2 includes a time series from the NN5 competition. Although these series contain multiple overlying seasonalities, in this work we are interested in experimenting with their strong weekly seasonality pattern.

4.1 The lazy learner meta parameters

In order to apply the nearest neighbours algorithm several meta parameters have to be chosen. Next, we describe our choices:

- As similarity function, i.e. to select how similar two examples are given their features, the Euclidian distance has been used.
- As combination function, i.e. to combine the target values of the k nearest neighbours, the arithmetic mean has been used.
- For k—the number of nearest neighbours—several values have been used to assess how robust the proposed method is.
- The final parameter is the lagged observations that are used as feature vector to compare the similarity among examples. We have used consecutive lags starting from lag 1. Concretely, we have experimented with lags 1, 1 to 7 and 1 to 14. We have chosen multiples of seven, because we are interested in the weekly seasonality.

[1] http://www.neural-forecasting-competition.com/NN5/

 ISBN: 978-84-617-8694-7

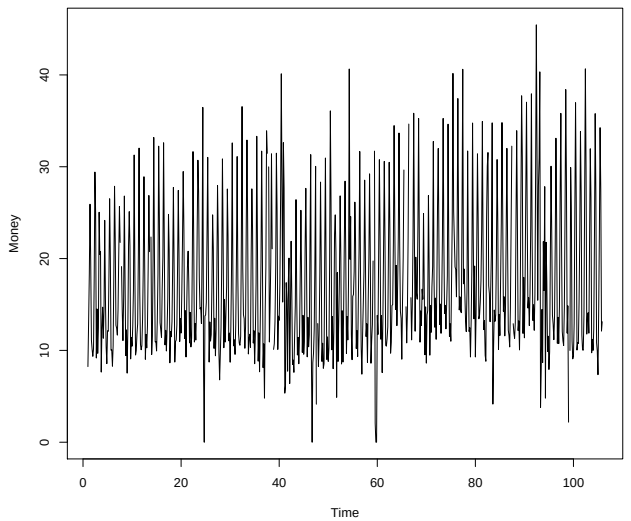

Figure 2: Example of time series from the NN5 competition.

Finally, we have to explain how the multiple—in this case 56—step-ahead forecasts are generated. When the forecast horizon is higher than 1 you have to chose among different strategies to generate the multiple forecasts, being the most used ones the direct, recursive and MIMO [5]. To date, there is no clear evidence that any strategy is superior than the others. Given this situation, we have chosen the recursive or iterative strategy because is quite straightforward. This strategy is used in the ARIMA and exponential smoothing methodologies. The recursive strategy uses a one-step-ahead model iteratively to get all the forecasts. That is, for forecasting horizon 1, the lagged observations of the time series are used as autoregressive variables for the model. For forecasting horizon 2, lacking a historical lagged one value to be used as autoregressive variable, the forecast for horizon 1 is used instead.

5 Experimentation

The goal of our experimentation is to assess whether, knowing information about the structure of a time series, the use of a selected space of possible neighbours can improve the forecast accuracy of the nearest neighbours algorithm. To that end, we have experimented with forecasting the 111 time series of the NN5 competition. We try to take advantage of our prior knowledge of the weekly seasonality pattern in the time series of this competition.

 ISBN: 978-84-617-8694-7

The way in which we are going to use this knowledge is as follows: in order to forecast the money withdrawals on one day, we take into account the day of the week to be forecast and only use as possible nearest neighbours examples, those examples whose targets have the same day of the week as the day being forecast.

In order to assess whether this strategy is effective we are going to execute the following nearest neighbours instances to predict 56 days ahead of the 111 time series of the NN5 competition:

- Classical nearest neighbours algorithm with k ranging from 1 to 10 and autoregressive lagged values at consecutive lags: 1, 1 to 7 and 1 to 14.
- Nearest neighbours algorithm with the same meta parameters, but using a selected space of possible neighbours, so that only examples whose targets have the same day of the week as the day of the value being forecasted are included.

Table 1: Global SMAPE of different algorithms over the 111 NN5 time series.

	1	2	3	4	5	6	7	8	9	10
C - 1	49.04	42.52	40.27	39.36	39.04	38.30	38.98	39.20	38.77	39.00
SS - 1	32.87	27.66	26.32	25.27	24.60	24.51	24.18	24.09	24.14	24.13
C - 1:7	31.55	28.21	25.33	23.95	23.61	23.43	23.36	23.51	23.60	23.48
SS - 1:7	30.16	25.42	23.56	23.08	22.56	22.37	22.32	22.44	22.51	22.58
C - 1:14	32.19	26.63	24.77	23.97	23.39	23.06	22.99	22.81	22.71	22.76
SS - 1:14	31.28	25.33	24.02	23.04	22.93	22.46	22.35	22.15	22.12	22.15

The results of our experiment are shown in Table 1. The first row of this table indicates the numbers of neighbours—i.e., the k meta parameter. The first column indicates whether the algorithm uses the classical approach (C) or our proposal of a selected search space (SS). After the hyphen the number of lags used as autoregressive variables is shown—for example, C - 1:7 means the classical algorithm with lags from 1 to 7. For every combination of type of algorithm, lags and k the table shows its forecast accuracy using the SMAPE measure over the 111 time series from the NN5 competition. The computation of SMAPE was described in the previous section. The most outstanding result is that for every combination of k and lags, the new approach outperform the results of the classical algorithm. The improvement in forecast accuracy is especially evident when only one lag is considered. This is a expected result, as with only a lagged value is easier to find misleading neighbours.

6 Conclusions

In this paper we have proposed to reduce the search space of possible neighbours in a nearest neighbours algorithm applied to time series forecasting when prior information about the

 ISBN: 978-84-617-8694-7

structure of the time series is known. The goal is to look for only significant neighbours. Our preliminary experimentation on the time series of the NN5 competition seems to indicate that the proposal is quite effective.

Abstract

This paper considers the problem of estimating a poverty measure, the Head Count Index, using the auxiliary information available, which is incorporated into the estimation procedure by calibration techniques. The proposed method does not directly use the auxiliary information provided by auxiliary variables related to the variable of interest in the calibration process, but the auxiliary information, after a transformation, is incorporated by calibration techniques applied to the distribution function of the study variable. Monte Carlo experiments were carried out for simulated data and for real data taken from the Spanish living conditions survey to explore the performance of the new estimation methods of the Head Count Index.

Key words: Auxiliary information, calibration estimator, poverty index, survey sampling

1 Introduction

The estimation of a proportion in finite populations is a interesting topic in many areas such as medical and pharmaceutical statistics, marketing research, sociological studies and has important applications in the field of economics. Indeed, the analysis of poverty and social exclusion measures is a topic of increased interest to society. For governments is of high interest the estimation of poverty, inequality and life condition indicators and many social indicators related to the measurement of poverty are based upon binary variables or require the use of proportions to obtain such indicators. Among these poverty measures, we

 ISBN: 978-84-617-8694-7

can find the Head Count Index that is widely used by institutions to elaborate their reports on poverty. The Head Count Index (HCI) can be calculated as the proportion of persons (or households) with an equivalised disposable income below the 60% of the national median equivalised income. In the literature, numerous references discuss about the HCI and related poverty indicators. For instance, some references are [11], [1], [14], [13] and [12]. The real HCI is unknown in practice, but it is estimated by using survey data, therefore estimation methods for proportions are required, since the HCI can be expressed as a proportion. Usually the method for estimating the HCI is by using direct estimators without using auxiliary information, but official surveys on income and living conditions generally contain additional variables related to the variable of interest and the efficient insertion of the auxiliary information available would improve the precision of the estimations for the proportion of a categorical variable of interest. These additional variables includes numeric and binary attributes and the HCI can have stronger relationship with auxiliary quantitative variables. In the presence of auxiliary information, there exist several procedures to obtain more efficient estimators for the proportion of a categorical variable of interest, maybe some of them ([17] and [8]) assume that the auxiliary information is given by binary variables and consequently the auxiliary quantitative variables can not include at the estimation stage. In the case that the auxiliary information available includes both categorical and numerical attributes, we can use the logistic generalised regression estimator, proposed by [5] but has the problem of estimating the parameter associated to the logistic model.
In this paper, we consider the problem of estimating the population proportion of a categorical variable using the calibration framework. Calibration techniques were first employed by [2] to estimate the total population, but this approach is also applicable to the estimation of parameters more complex than the total population. [4], [15] and [16] use different ways to implement the calibration approach in the estimation of the distribution function and the quantiles. The use of calibration techniques in the estimation of population proportion of a categorical variable is not new. In [8] the authors proposed estimation procedures for a proportion and based on calibration framework but as we discussed previously, the estimator obtained cannot be applied for the estimation of the HCI, since they assume that the auxiliary information is exclusively given by binary variables. Another calibration alternative when the auxiliary information includes both categorical and numerical attributes is given in [7] where it was proposed a calibration estimator based on probit regression. In this paper, we consider the incorporation of the auxiliary information with calibration techniques applied to the distribution function of the study variable under simple random sampling. The article is arranged as follows. In Section 2, the HCI and indirect estimation methods are introduced. Section 3 gives a alternative calibration estimator for HCI based on the estimation of the distribution function. In Section 4, we derive optimum estimators in the sense of minimum variance when the sample is selected under simple random sampling without replacement (SRSWR). Finally, in Section 5, simulation studies are carried

 ISBN: 978-84-617-8694-7

out to analyze the performance of estimator proposed in this paper. Simulation studies are based upon real survey data and simulated finite populations. The real data is obtained from the Spanish living conditions survey. Section 5 gives some concluding remarks.

2 The Headcount Index and Indirect Estimation of population proportion

Let $U = \{1, 2, \ldots, N\}$ be a finite population consisting of N different elements. Let $s = \{1, 2, \ldots, n\}$ be the set of the units included in a sample, selected according to a specified sampling design with inclusion probabilities π_k and π_{kl} assumed to be strictly positive. We assume that y is the quantitative variable used to obtain the HCI and L is the poverty line used to classify the population into poor and nonpoor, that is, an individual (or households) is considered as poor if its income or expenditure y is less than the poverty line L. Thus, the real Head Count Index can be defined as the population proportion of the attribute A in the population U, $HCI = P_A = \sum_{k \in U} A_k/N$, where $A_k = 1$ if the unit k is classified as poor ($y_k \leq L$) and $A_k = 0$ otherwise. The value A_k is only available for the sample units. We assume that the poverty line L is established by the corresponding authority, i.e., L is fixed at some official quantity. For instance, Eurostat fixes the relative poverty line in the 60% of the median of the equivalised net income. To estimate P_A, the usual design-weighted Horvitz-Thompson estimator is $\widehat{P}_{AHT} = \sum_{k \in s} d_k A_k/N$, where $d_k = 1/\pi_k$. Now, we assume the existence of a vector $\mathbf{x} = (x_1, x_2, \ldots x_P)'$ of auxiliary information, such that for every population unit k the value $\mathbf{x}_k = (x_{1k}, x_{2k}, \ldots, x_{Pk})$ is known. We also assume that the variables included in the vector $\mathbf{x}$ can be either numeric or binary attributes of the same type as the study attribute A. Most official surveys on income and living conditions contain auxiliary variables related to the variable of interest, these auxiliary variables can be quantitative variables or qualitative attributes.

The Horvitz-Thompson estimator $\widehat{P}_{AH}$ is an unbiased estimator for P_A but does not use the auxiliary information provided by the vector $\mathbf{x}$. The incorporation of auxiliary information in estimating the population proportion P_A is not new and has been treated in many works. If the auxiliary vector $\mathbf{x}$ only includes binary attributes, we can use the estimation methods proposed by [17]. In the case that the vector $\mathbf{x}$ includes both categorical and numerical attributes, we can use the logistic generalised regression estimator, proposed by [5]. This estimator is given by:

$$\widehat{P}_{LGREG} = \frac{1}{N}\left(\sum_{k \in U} pl_k + \sum_{k \in s} \frac{A_k - pl_k}{\pi_k}\right) \tag{1}$$

 ISBN: 978-84-617-8694-7

where $pl_k = exp(x_k\widehat{\beta})/(1 + exp(x_k\widehat{\beta}))$ and $\widehat{\beta}$ is the BLUP estimator of the β parameter of the logistic regression. [3] provided some codes to compute the LGREG estimator and a Monte Carlo study to empirically investigate the accuracy of the confidence intervals when HT and LGREG estimators are used.

One way of incorporating auxiliary information provided by $\mathbf{x}$ in the estimation of P_A is via replacing the weights d_k of the estimators $\widehat{P}_{AH}$ by new weights ω_k, using calibration techniques. Following [2], to obtain a calibration estimator for the attribute A, we calculate the weights ω_k minimizing the chi-square distance

$$\Phi_s = \sum_{k\in s} \frac{(\omega_k - d_k)^2}{d_k q_k} \tag{2}$$

subject to a set of calibration constraints, where q_k are known positive constants unrelated to d_k. Thus, if $\mathbf{x}$ only includes binary attributes, we can estimate P_A through calibration techniques proposed by [8]. Calibration techniques have also recently been used in the estimation of P_A when the vector of auxiliary variables $\mathbf{x}$ contains both binary and numerical attributes. Thus, in [7], it was proposed a calibration estimator $\widehat{P}_{CP}$ based on probit regression, where the calibrated weights ω_k are obtained by minimizing (2) subject to the following conditions:

$$\frac{1}{N}\sum_{k\in s}\omega_k p_k = \bar{P} = \frac{1}{N}\sum_{k\in U} p_k; \text{ and } \frac{1}{N}\sum_{k\in s}\omega_k = 1 \tag{3}$$

with $p_k = \widehat{P}[A_k = 1] = F(\widehat{\beta}' \cdot \mathbf{x}_k)$, where F is the normal-standard distribution function and $\widehat{\beta}$ is the π-weighted likelihood estimator of the β parameter of the probit regression ([8]).

In the next section we consider the estimation of the population proportion by estimating the distribution function $F_A(t)$ of the attribute of study A.

3 Calibration Estimation of population proportion by estimating distribution function

In this section, we describe alternative calibration estimation methods for the problem of estimating P_A, based on auxiliary vector $\mathbf{x}$ that includes numeric and binary attributes. This calibration methods define a new indirect estimator for P_A through the estimation of the distribution function $F_A(t) = \sum_{k\in U} \Delta(t - A_k)/N$ of the attribute of study A, where $\Delta(t - A_k) = 1$ if $t \geq A_k$ and $\Delta(t - A_k) = 0$ otherwise. Since the aim is to estimate the population proportion P_A by estimating the distribution function, we will consider the

 ISBN: 978-84-617-8694-7

complementary attribute $\bar{A}$ of the attribute A, this is $\bar{A}_k = 1 - A_k$. Thus, if $F_{\bar{A}}(t)$ is the distribution function associated with the complementary attribute, it is clear that $P_A = F_{\bar{A}}(0)$ and the estimate of the population proportion P_A can be obtained by the methods of estimating the distribution function. The usual estimator of distribution function is the Horvitz-Thompson estimator given by

$$\widehat{F}_{\bar{A}HT}(t) = \frac{1}{N}\sum_{k\in s} d_k \Delta(t - \bar{A}_k) \tag{4}$$

From (4) it is easy to see that $\widehat{P}_{AH} = \widehat{F}_{\bar{A}HT}(0)$. Thus, we will obtain new indirect estimators of P_A through calibration techniques applied to $F_{\bar{A}}(t)$ at the point $t = 0$.
Recently, the calibration approach have been employed for the estimation of the distribution function and quantiles in different ways ([4], [15] and [16]). Following [15], we consider the definition of a pseudo-variable $g_k = \widehat{\beta}'\mathbf{x}_k$ for $k = 1, 2, \ldots, N$ with

$$\widehat{\beta}' = \left(\sum_{k\in s} d_k q_k \mathbf{x}_k \mathbf{x}_k'\right)^{-1} \sum_{k\in s} d_k q_k \mathbf{x}_k \bar{A}_k,$$

where q_k are known positive constants unrelated to d_k. With the pseudo-variable g, we consider the estimation of $P_A = F_{\bar{A}}(0)$ with the calibration estimator obtained with the minimization of (2) subject to the following conditions:

$$\frac{1}{N} = \sum_{k\in s} \omega_k \Delta(\mathbf{t_g} - g_k) = F_g(\mathbf{t_g}) \tag{5}$$

with $\mathbf{t_g} = (t_1, \ldots, t_P)'$ is a vector chosen arbitrarily, where $t_1 < t_2 < \ldots < t_P$. Assuming that the inverse of symmetric matrix $T = \sum_{k\in s} d_k q_k \Delta(\mathbf{t_g} - g_k)\Delta(\mathbf{t_g} - g_k)'$ exists, the resulting estimator ([15]) is given by

$$\widehat{P}_{AC} = \widehat{F}_{\bar{A}C}(0) = \widehat{P}_{AHT} + \left(F_g(\mathbf{t_g}) - \widehat{F}_{GHT}(\mathbf{t_g})\right)' \cdot \widehat{D} \tag{6}$$

where $\widehat{D} = T^{-1} \cdot \sum_{k\in s} d_k q_k \Delta(\mathbf{t_g} - g_k)\Delta(0 - \bar{A}_k)$ and $\widehat{F}_{GHT}(\mathbf{t_g})$ is the Horvitz-Thompson estimator of $F_g(\mathbf{t_g})$.

The asymptotic variance of $\widehat{F}_{\bar{A}C}(0)$ ([15]) is given by:

$$AV(\widehat{F}_{\bar{A}C}(0)) = \frac{1}{N^2}\sum_{k\in U}\sum_{l\in U} \Delta_{kl}(d_k E_k)(d_l E_l) \tag{7}$$

where $D = \left(\sum_{k\in U} q_k \Delta(\mathbf{t_g} - g_k)\Delta(\mathbf{t_g} - g_k)'\right)^{-1} \cdot \left(\sum_{k\in U} \Delta(\mathbf{t_g} - g_k)\Delta(0 - \bar{A}_k)\right)$ and $E_k = \Delta(0 - \bar{A}_k) - \Delta(\mathbf{t_g} - g_k) \cdot D$.

 ISBN: 978-84-617-8694-7

4 Determining optimal calibration estimators

The precision of $\widehat{F}_{\bar{A}C}(0)$ changes with the selection of $\mathbf{t_g}$. In [6] and [9], the authors studied, for a fixed P, the problem of selection the optimal vector $\mathbf{t_g}$ under simple random sampling and $q_k = 1$ for all $k \in U$, that gives the best estimation of $F_y(t)$ with the calibration estimator $\widehat{F}_{yc}(t)$ developed in [15], that is, the problem of determining an auxiliary vector $\mathbf{t_g} = (t_1, \ldots, t_P)'$, with $t_1 < t_2 < \ldots < t_P$ that minimizes the variance of the estimator $\widehat{F}_{yc}(t)$ given a point t for which we want to estimate $F_y(t)$. Moreover, in [10], the problem of the optimal dimension P of the auxiliary vector $\mathbf{t}_P$ and the optimal vector of this dimension is studied for the calibrated estimator of [15]. Following [9], the minimization of the asymptotic variance (7) under simple random sampling, is equivalent to minimizing the following function:

$$G(t_1, t_2, \ldots, t_P) = 2NP_A \cdot k_P - \sum_{j=1}^{P} \frac{(k_j - k_{j-1})^2}{(F_g(t_j) - F_g(t_{j-1}))} - k_P^2 \tag{8}$$

where $k_i = \sum_{k \in U} \Delta(0 - \bar{A}_k)\Delta(t_i - g_k)$ with $i = 1, 2 \ldots, P$; $k_0 = 0$ and t_0 is a value such that $F_g(t_0) = 0$.

If we consider the auxiliary vector $\mathbf{t}_P = t_1$ (dimension $P = 1$), the value of t_1 at which the calibration estimator $\widehat{P}_{AC}$ is optimum ([6]) is given by $t_{opt} = \arg\min_{a_k \in A_0} G(a_k)$, where $A_0 = \{g_k : k \in U, \bar{A}_k = 0\} = \{g_k : A_k = 1\} = \{a_1, a_2, \ldots, a_M\}$ with $a_1 < a_2 < \ldots < a_M$. The optimal value of t_1, (t_{opt}) depends on some unknown values, so we go to replace the optimal vector t_{opt} by sample-based estimates. For it, we consider the following set $A_{0_s} = \{g_k : k \in s, \bar{A}_k = 0\} = \{a_{1_s}, a_{2_s}, \ldots, a_{m_s}\}$, and the global minimum of the function $\widehat{G}(t_1)$ (the usual estimation of $G(t_1)$), is at one point of A_{0_s} ([6]). Thus, we can define a new calibration estimator $\widehat{P}_{AC1}$ based on the auxiliary point $\widehat{t}_{opt}$ that minimizes the function $\widehat{G}(t_1)$. The asymptotic behaviour of the estimator $\widehat{P}_{AC1}$ is the same as the estimator based on optimum point t_{opt} ([6]). Thus the asymptotic variance of $\widehat{P}_{AC1}$ is given by (7) with $\mathbf{t_g} = t_{opt}$.

On the other hand, if the dimension of the auxiliary vector is $P > 1$, the global minimum of the function $G(\mathbf{t}_g)$ ([9]) is a vector $\mathbf{t_{GP}} = (t_1, t_2, \ldots, t_P)$, with $t_1 < t_2 < \ldots < t_P$ and $t_i \in A_0$ or $t_i \in B_0$ for $i = 1, 2, \ldots, P$, where $B_0 = \{b_1, b_2, \ldots, b_M\}$ with $b_h = \max_{l \in U_h}\{g_l\}$ for $h = 1, \ldots, M$; $U_1 = \{l \in U : g_l < a_1\}$ and $U_h = \{l \in U : a_{h-1} \leq g_l < a_h\}$, $h = 2, 3, \ldots, M$. It is clear that $b_1 < b_2 < \ldots < b_M$. Since the sets A_0 and B_0 are finite, finding the global minimum is computationally simple. For some h in $1, 2, \ldots, M$ the corresponding point b_h may not exist, but in this case, the minimization problem is simpler than the current case

 ISBN: 978-84-617-8694-7

([9]). Again, the optimal auxiliary vector $\mathbf{t_{GP}}$ depends on some unknown values, therefore we will replace the optimal vector with sample-based estimates. For it, we consider the usual estimation of the function G denoted by $\widehat{G}(\mathbf{t}_g)$, the sample-based set A_{0_s} and the set $B_{0_s} = \{b_{1_s}, b_{2_s}, \ldots, b_{m_s}\}$ with $b_{h_s} = \max_{l \in U_{h_s}}\{g_l\}$ for $h = 1, \ldots, m$; $U_{1_s} = \{l \in s : g_l < a_{1_s}\}$ and $U_{h_s} = \{l \in s : a_{(h-1)_s} \leq g_l < a_{h_s}\}$, $h = 2, 3, \ldots, m$.
The potential points for the global minimum of $\widehat{G}(\mathbf{t}_g)$ are $\widehat{\mathbf{t}}_{\mathbf{GP}} = (\widehat{t}_1, \widehat{t}_2, \ldots, \widehat{t}_P)$ with $\widehat{t}_i \in A_{0_s}$ or $\widehat{t}_i \in B_{0_s}$ ([9]). The calibration estimator $\widehat{P}_{ACP}$ based on $\widehat{\mathbf{t}}_{\mathbf{GP}}$ has the same asymptotic behaviour that the estimator based on $\mathbf{t_{GP}}$ and the asymptotic variance is given by (7) with $\mathbf{t_g} = \mathbf{t_{GP}}$.

Following [10], the optimal dimension P of the auxiliary vector $\mathbf{t}_g$ is $2M$ if b_1 exists and for all $i = 1, \ldots, M-1$, $b_{i+1} \neq a_i$. The optimal vector in this case is $\mathbf{t_{OPT}} = (b_1, a_1, \ldots, b_M, a_M)$. If for some $i_1, i_2, \ldots i_R \in \{0, 1, \ldots, M-1\}$; $a_{i_1} = b_{i_1+1}$ with $R \leq M$ and $i_h \neq i_j$ if $h \neq j$ the optimal dimension is $P = 2M - R$ and the optimal auxiliary vector $\mathbf{t_{OP}} = (t_{O1}, \ldots, t_{O(2M-R)})$ is given by:

$$\mathbf{t_{OP}} = (b_1, a_1, b_2, a_2, \ldots, b_{i_1}, a_{i_1}, a_{i_1+1}, b_{i_1+2}, \ldots, b_{i_h}, a_{i_h}, a_{i_h+1}, b_{i_h+2}, \ldots b_M, a_M) \quad (9)$$

The optimal auxiliary vector $\mathbf{t_{OP}}$ depends on some unknown values, furthermore, although the vector $\mathbf{t_{OP}}$ be known, we could have incompatible restrictions in (5) when a sample s is selected. Thus, similarly to the previous cases, we can define a new calibration estimator $\widehat{P}_{ACOPT}$ based on $\widehat{\mathbf{t}}_{\mathbf{OP}}$, a sample-based estimation.

The Horvitz-Thompson estimator $\widehat{P}_{AHT}$, under SRSWOR, has the following shift invariance property $\widehat{P}_{AHT} = 1 - \widehat{Q}_{AHT}$, where $\widehat{Q}_{AHT}$ is the Horvitz-Thompson estimator for $Q_A = 1 - P_A$. Thus, $\widehat{P}_{AHT}$ has the same performance in the estimation of P_A as the performance of $\widehat{Q}_{AHT}$ in the estimation of Q_A. In general, this property is not satisfied by the calibration estimators considered $\widehat{P}_{AC1}$, $\widehat{P}_{ACP}$ and $\widehat{P}_{ACOPT}$. It is easy to see that this property is fulfilled by a calibration estimator if $N = \sum_{k \in U} \omega_k$. A way to obtain this condition consists in the incorporation of the value $g_{max} = \max_{k \in U} g_k$ in the auxiliary optimum vectors. Thus, we can define a calibration estimator $\widehat{P}_{AQ1}$ based on the auxiliary vector $(\widehat{t}_{opt}, g_{max})$, a calibration estimator $\widehat{P}_{AQP}$ based on $(\widehat{\mathbf{t}}_{GP}, g_{max})$ and a calibration estimator $\widehat{P}_{AQOPT}$ based on $(\widehat{\mathbf{t}}_{OP}, g_{max})$. Nothing guarantees that we can use this vector in the calibration constraints given by (5), when selecting a sample s, since we could have incompatible restrictions. In this case, we consider the calibration constraints given by (5) without $g_{max} = \max_{k \in U} g_k$.
It is easy to see that the incorporation of the value g_{max} in the calibration conditions (5) does not produces a negative effect in the asymptotic variance. For it, from equation (8) we have

$$G(\widehat{\mathbf{t}}_{\mathbf{GP}}) - G((\widehat{\mathbf{t}}_{GP}, g_{max}) = (NP_A - k_P)^2 - \frac{(NP_A - k_P)^2}{(1 - F_g(t_P))} \leq 0$$

 ISBN: 978-84-617-8694-7

Another way to incorporate shift in-variance property, consists in the minimization of the function (8) when the auxiliary vector considered is $(\mathbf{t_1}, g_{max})$. Following [6] the optimal auxiliary vector is $\mathbf{t_{GMAX}} = (t_1, g_{max})$ where $t_1 \in A_0$ or $t_1 \in B_0$. Similarly to the previous cases, we can define a new calibration estimator $\widehat{P}_{ACMAX}$ based on $\widehat{\mathbf{t}}_{\mathbf{GMAX}}$, a sample-based estimation.

5 Numerical Comparison

In this sections, we present the results of a Monte Carlo simulation study where we compare the precision of the proposed calibration estimators: $\widehat{P}_{AC1}$, $\widehat{P}_{ACP}$, $\widehat{P}_{ACOPT}$, $\widehat{P}_{AQ1}$, $\widehat{P}_{AQP}$, $\widehat{P}_{AQOPT}$ and $\widehat{P}_{ACMAX}$ with the Horvitz-Thompson estimator $\widehat{P}_{AHT}$; the multivariated ratio estimator $\widehat{P}_{AMratio}$ (see [17]); calibration estimators P_{AR} and the multivariate calibration estimator $\widehat{P}_{AWM}$ (see [8]); the logistic generalised regression estimator $\widehat{P}_{LGREG}$ ([5] and calibration estimator $\widehat{P}_{CP}$ based on probit regression (see [7]). The estimators $\widehat{P}_{ACP}$ and $\widehat{P}_{AQP}$ are based on auxiliary vector with dimension $P = 2$. Our simulations are programmed in `R`, with some new code developed to compute the estimators to be compared. The performance of each proportion estimator was measured and compared in terms of relative bias (RB) and relative efficiency (RE). The simulated values of RB and RE for a particular proportion estimator T were computed as

$$\text{RB} = B^{-1}\sum_{b=1}^{B}(T^b - P)/P, \quad \text{RE} = MSE(\widehat{P}_{AHT})/MSE(T^b)$$

where $MSE(T^b) = B^{-1}\sum_{b=1}^{B}(T^b - P)^2$, $MSE(\widehat{P}_{AHT}) = B^{-1}\sum_{b=1}^{B}(\widehat{P}^b_{AHT} - P)^2$, and T^b and $\widehat{P}^b_{AHT}$ are the values of T and $\widehat{P}_{AHT}$ from the bth simulation, respectively.

To investigate the efficiency of the proposed estimators under a variety of situations, we conside different stages. First, we will consider the estimation of a population proportion in simulated populations and secondly we will use the proposed estimators in the estimation of the Head Cont Index. For the estimation of population proportion, we consider 5 populations generated as a random sample of 10000 units from a Bernoulli distribution with parameter $P = 0.9$, and the attributes of interest were thus achieved with the aforementioned population proportion. Auxiliary attributes were also generated using the same distribution, but a given proportion of values was randomly changed so that Cramers V coefficient between the attribute of interest and the auxiliary attribute would range from 0.5 to 0.9. For each of the 5 populations, $B = 10000$ samples of sizes n =150, 250, 350 and 450 were selected, under simple random sampling, to compare the considered estimators in terms of relative bias (RB) and relative efficiency (RE). Tables 1 give the values of RB and RE in percentages for the binomial populations.

The results derived from this simulation study gave values for RB within a reasonable range. All the estimators considered produced absolute relative bias values of less than 0.5%. The estimators $\widehat{P}_{AHT}$, $\widehat{P}_{AMratio}$, $\widehat{P}_{AC1}$ and $\widehat{P}_{AQ1}$ has the same variance and have a larger variance than the other estimators considered. With large Cramer's V coefficient (ρ) values, the proposed estimators $\widehat{P}_{ACP}$, $\widehat{P}_{AQP}$, $\widehat{P}_{ACMAX}$, $\widehat{P}_{ACOPT}$ and $\widehat{P}_{AQOPT}$ produce good results. It can also be seen that as ρ increases, all the estimators achieve greater precision, which is particularly marked for very high correlations.
Of all the estimates that use auxiliary information, the calibration estimators $\widehat{P}_{ACOPT}$ and $\widehat{P}_{AQOPT}$ has the highest degree of efficiency for small values of ρ while for the large values, the estimators $\widehat{P}_{ACP}$, $\widehat{P}_{AQP}$ and $\widehat{P}_{ACMAX}$ present a greater efficiency. In all cases, the calibration estimators $\widehat{P}_{ACP}$, $\widehat{P}_{AQP}$, $\widehat{P}_{ACMAX}$, $\widehat{P}_{ACOPT}$ and $\widehat{P}_{AQOPT}$ perform better than

the estimators P_{AR}, $\widehat{P}_{AWM}$, $\widehat{P}_{LGREG}$ and $\widehat{P}_{CP}$.
The sample size produces a clear effect on the behaviour of the estimators: as the sample size increases, so does the efficiency of the estimators.

For the estimation of Head Count Index, we consider real data taken from the 2008 Spanish living conditions survey carried out by the Instituto Nacional de Estadística (INE) of Spain. For our simulation study, we considered the survey data collected as a population, from which samples are selected.The poverty threshold is calculated each year, using the distribution of the equivalised net income for the previous year. Following the criteria recommended by Eurostat, this threshold is set at 60% of the median of the equivalised net income. We considered the variable "Returns and additional revenue from adjustments in taxes" and the attribute "Home with own car" (1 for home with own car, 0 otherwise) as the auxiliary variables. Again, $B = 10000$ samples of sizes n =500, 600, 700 and 800 were selected, under simple random sampling, to compare the relative bias (RB) and relative efficiency (RE) of the considered estimators. Table 2 give the values of RB and RE in percentages for the real population.

Table 2: RB % and RE % for several sample sizes of the estimators compared under SRSWOR from the 2008 Spanish living conditions survey population.

	RB%	RE%	RB%	RE%	RB%	RE%	RB%	RE%
Estimator	$n = 500$		$n = 600$		$n = 700$		$n = 800$	
$\widehat{P}_{AHT}$	-0.066	100.00	-0.333	100.00	-0.256	100.00	0.044	100.00
$\widehat{P}_{AMratio}$	-0.066	100.00	-0.333	100.00	-0.258	100.00	0.044	100.00

$\widehat{P}_{AWM}$	-0.184	104.88	-0.227	102.49	-0.306	102.10	0.017	102.03
$\widehat{P}_{LGREG}$	-0.151	105.04	-0.190	102.50	-0.276	103.01	0.037	102.73
$\widehat{P}_{CP}$	-0.155	104.96	-0.221	102.47	-0.274	102.71	0.042	102.57
$\widehat{P}_{AC1}$	-0.199	99.08	-0.288	100.23	-0.342	99.53	-0.041	99.66
$\widehat{P}_{AQ1}$	-0.107	99.199	-0.287	100.85	-0.273	99.68	0.027	99.68
$\widehat{P}_{ACP}$	-0.648	104.31	-0.337	112.15	-0.532	103.16	-0.053	102.95
$\widehat{P}_{AQP}$	-0.638	104.39	-0.380	112.90	-0.522	103.22	-0.053	103.04
$\widehat{P}_{ACOPT}$	-0.167	105.05	0.388	102.45	-0.157	103.06	0.057	102.55
$\widehat{P}_{AQOPT}$	0.169	105.04	0.788	102.23	0.156	103.23	0.058	102.77
$\widehat{P}_{ACMAX}$	-0.238	105.70	-0.443	103.63	-0.238	104.32	0.050	103.60

In this population, the results are slightly different. The relative biases usually remain negligible (less than 0.5 %) but the efficiency is different:

- The calibration estimator P_{AR}, $\widehat{P}_{AC1}$ and $\widehat{P}_{AQ1}$ performs poorly and has worse efficiency than the estimator $\widehat{P}_{AHT}$.
- The remaining estimates are more efficient than the estimator $\widehat{P}_{AHT}$ but the gain in

 ISBN: 978-84-617-8694-7

efficiency is not as great as in the previous example.

- The proposed calibration estimator $\widehat{P}_{ACP}$, $\widehat{P}_{AQP}$, $\widehat{P}_{ACMAX}$, $\widehat{P}_{ACOPT}$ and $\widehat{P}_{AQOPT}$ often work better than the other estimators. The estimator $\widehat{P}_{ACMAX}$ is the most efficient for all sample sizes, except for the sample size $n = 600$ where the estimators $\widehat{P}_{ACP}$ and $\widehat{P}_{AQP}$ present the best results.

Abstract

The concept of geometric-arithmetic index was introduced in the chemical graph theory recently, but it has shown to be useful. The aim of this paper is to obtain new inequalities involving the geometric-arithmetic index GA_1 and characterize graphs extremal with respect to them. Our main results provide lower bounds on $GA_1(G)$ involving just the minimum and the maximum degree of the graph G.

Key words: Geometric-arithmetic index, Graph invariant, Vertex-degree-based graph invariant, Topological index.
MSC 2000: 05C07, 92E10

1 Introduction

A single number, representing a chemical structure in graph-theoretical terms via the molecular graph, is called a topological descriptor and if it in addition correlates with a molecular property it is called topological index, which is used to understand physicochemical properties of chemical compounds. Topological indices are interesting since they capture some of the properties of a molecule in a single number.

The first geometric-arithmetic index GA_1 was defined in [3] as

$$GA_1 = GA_1(G) = \sum_{uv \in E(G)} \frac{\sqrt{d_u d_v}}{\frac{1}{2}(d_u + d_v)}$$

where uv denotes the edge of the graph G connecting the vertices u and v, and d_u is the degree of the vertex u.

 ISBN: 978-84-617-8694-7

Herein, $G = (V(G), E(G))$ denotes a (nonoriented) finite simple (without multiple edges and loops) nontrivial ($E(G) \neq \emptyset$) graph. The aim of this paper is to obtain lower bounds on $GA_1(G)$ involving just the minimum and the maximum degree of the graph G and characterize graphs extremal with respect to them.

2 Main results

Let us recall Lemma 2.2 and Corollary 2.3 in [2].

Lemma 2.1. *Let f be the function $f(t) = \frac{2t}{1+t^2}$ on the interval $[0, \infty)$. Then f strictly increases in $[0, 1]$, strictly decreases in $[1, \infty)$, $f(t) = 1$ if and only if $t = 1$ and $f(t) = f(t_0)$ if and only if either $t = t_0$ or $t = t_0^{-1}$.*

Corollary 2.2. *Let g be the function $g(x, y) = \frac{2\sqrt{xy}}{x+y}$ with $0 < a \leq x, y \leq b$. Then $\frac{2\sqrt{ab}}{a+b} \leq g(x, y) \leq 1$. The equality in the lower bound is attained if and only if either $x = a$ and $y = b$, or $x = b$ and $y = a$, and the equality in the upper bound is attained if and only if $x = y$.*

Let us denote by $K_{\delta,\Delta}$ the complete bipartite graph with a partition K_1, K_2 with δ and Δ vertices respectively.

Given integers $0 < \delta \leq \Delta$, let us define $\mathcal{G}_{\delta,\Delta}$ as the set of graphs G with minimum degree δ, maximum degree Δ and such that:

(1) G is isomorphic to the complete graph with $\Delta + 1$ vertices $K_{\Delta+1}$, if $\delta = \Delta$,

(2) $|V(G)| = \Delta + 1$, there are Δ vertices with degree δ, if $\delta < \Delta$ and $\Delta(\delta + 1)$ is even,

(3) $|V(G)| = \Delta + 1$, there are $\Delta - 1$ vertices with degree δ and a vertex with degree $\delta + 1$, if $\delta < \Delta - 1$ and $\Delta(\delta + 1)$ is odd,

(4) $|V(G)| = \Delta + 1$, there are $\Delta - 1$ vertices with degree δ and two vertices with degree Δ, if $\delta = \Delta - 1$ and Δ is odd (and thus $\Delta(\delta + 1)$ is odd).

Proposition 2.3. *For any integers $1 < \delta \leq \Delta$, we have*

(1) *if $\frac{\Delta}{\delta} > \left(2 + \sqrt{3}\right)^2$, then $GA_1(H_{\delta,\Delta}) > GA_1(K_{\delta,\Delta})$,*

(2) *if $\frac{\Delta}{\delta} < \left(2 + \sqrt{3}\right)^2$ and $\Delta(\delta + 1)$ is even, then $GA_1(H_{\delta,\Delta}) < GA_1(K_{\delta,\Delta})$.*

It may be wondered if for any graph G with minimum degree δ and maximum degree Δ

$$GA_1(G) \geq \min\left\{GA_1(H_{\delta,\Delta}), GA_1(K_{\delta,\Delta})\right\}. \tag{1}$$

The following example shows that the answer is negative.

Example 2.4. *Let us suppose $\delta = 4$ and $\Delta = 56$. Consider a graph G with 57 vertices, two of them, a_1, a_2 with degree 56 and the rest, $b_1, \ldots, b_{55}$ with degree 4. Let us assume*

 ISBN: 978-84-617-8694-7

the edges are as follows. There is an edge a_ib_j for every i, j, an edge a_1a_2 and the vertices $b_1, \ldots, b_{55}$ induce a cycle of length 55.

Then, $GA_1(G) = \frac{2\cdot 110\sqrt{4\cdot 56}}{4+56} + 56 \approx 110.8776$.

However, $GA_1(H_{4,56}) = \frac{112\sqrt{224}}{60}+84 \approx 111.9377$, and $GA_1(K_{4,56}) = \frac{448\sqrt{224}}{60} \approx 111.7508$.

Nevertheless, we are able to find the critical lower bound in some cases:

Theorem 2.5. *Let G be a graph with minimum degree $\delta > 0$ and maximum degree $\Delta \geq 2$. If*

$$\frac{2\sqrt{\delta\Delta}}{\delta+\Delta} \geq \frac{\Delta(\delta-1)}{\Delta(\delta-1)+2}, \tag{2}$$

then

$$GA_1(G) \geq \frac{2\Delta\sqrt{\delta\Delta}}{\delta+\Delta} + \frac{\Delta(\delta-1)}{2}. \tag{3}$$

Furthermore, if $\Delta(\delta+1)$ is odd,

$$\frac{2\sqrt{\delta\Delta}}{\delta+\Delta} \geq \frac{\Delta(\delta-1)}{\Delta(\delta-1)+2} \quad \text{and} \quad \frac{3\sqrt{\delta\Delta}}{\delta+\Delta} + \delta - \frac{1}{2} \geq \frac{2\sqrt{(\delta+1)\Delta}}{\delta+1+\Delta} + \frac{2\delta\sqrt{\delta(\delta+1)}}{2\delta+1}, \tag{4}$$

then

$$GA_1(G) \geq \frac{2(\Delta-1)\sqrt{\delta\Delta}}{\delta+\Delta} + \frac{2\sqrt{(\delta+1)\Delta}}{\delta+1+\Delta} + \frac{2\delta\sqrt{\delta(\delta+1)}}{2\delta+1} + \frac{(\Delta-2)(\delta-1)-1}{2}. \tag{5}$$

If Δ and δ verify (2), then the equality in (3) is attained if and only if $\Delta(\delta+1)$ is even and $G \in \mathcal{G}_{\delta,\Delta}$. If Δ and δ verify (4) and $\Delta(\delta+1)$ is odd, then the equality in (5) is attained if and only if $G \in \mathcal{G}_{\delta,\Delta}$.

Corollary 2.6. *Let G be a graph with minimum degree $\delta > 0$ and maximum degree $\Delta = \delta + h \geq 2$. If we have*

(1) *$h = 0$ or $h = 1$, for every $\Delta \geq 2$,*
(2) *$h = 2$, for every $\Delta \geq 3$,*
(3) *$h = 3$, for every $\Delta \geq 4$,*
(4) *$h = 4$, for every $\Delta \geq 5$,*
(5) *$h = 5$, for every $\Delta \in \{6, 7, 8\}$,*
(6) *$h = 6$, for every $\Delta \in \{7, 8\}$,*
(7) *$h \geq 7$ and $\Delta = h + 1$,*

then

$$GA_1(G) \geq \frac{2\Delta\sqrt{\Delta(\Delta-h)}}{2\Delta-h} + \frac{\Delta(\Delta-h-1)}{2}.$$

Theorem 2.7. *Let G be a graph with minimum degree 2 and maximum degree $\Delta \geq 28$. Then,*

$$GA_1(G) \geq 2\Delta\frac{2\sqrt{2\Delta}}{\Delta+2},$$

and the equality is attained if and only if $G = K_{2,\Delta}$.

Low memory computation algorithm of recurrence plot of recurrence plots for long time series

Tomáš Martinovič[1]

[1] *IT4Innovations, VŠB - Technical University of Ostrava, Ostrava, Czech Republic*

emails: tomas.martinovic@vsb.cz

Abstract

Recurrence plot analysis is well established method to analyse time series in numerous areas of research. As the main result, the technique for computation of recurrence plot of recurrence plots(RPoRPs) is outlined. RPoRPs is extension of RP. This method significantly reduces spatial complexity of computation by computing RPoRPs directly from the time series. Additionally, a way to store RPoRPs in optimal format for diagonal recurrence quantitative analysis is proposed.

Key words: RPoRPs, recurrence plot, algorithms, time series
MSC 2000: 37M10,

1 Introduction

Recurrence quantitaive analysis (RQA) is a well established method for nonlinear time series analysis [5] [1]. RQA is the extension of a recurrence plot (RP), which is a visualisation tool for the recurrences in the state-space. Recurrence plots are used in number of disciplines such as medicine, engineering, economics and more, see e.g. [4], [8], [7] respectively.

Main advantages of RQA is its robustness to noise, possibility to study nonstationary time series and numerous extensions of RP, which allow study of stochastic and linear systems [2]. This paper is focused on computation of recurrence plot of recurrence plots (RPoRPs) [3], which is approximation of RP for very long time series. Main advantage of this technique is, that it computes RPoRPs directly from the time series and saves a lot of space.

 ISBN: 978-84-617-8694-7

2 Recurrence plot

Generally, recurrence plot is computed from the embedded time series. Embedding time series to the phase space is common practice in the nonlinear dynamical systems analysis. In case of observing one feature of multi dimensional dynamical system, embedding of this observed time series should re-create phase space with same dynamics as the original system see e.g. [9].

Let $\{x(t) \in \mathbb{R} | \, t = 1, 2, \ldots, n\}$ be observed time series of length n. Then embedded vector $X(t)$ at time t, is defined as $X(t) = [x(t), x(t+l), x(t+2l), \ldots, x(t+(m-1)l)]$, where t is observed time, l is delay time and m is embedding dimension.

First is computed the distance matrix of all the vectors $X(t)$. The euclidean distance matrix is computed as

$$D(t_1, t_2) = d(X(t_1), X(t_2)) = \sqrt{\sum_{k=0}^{m-1} (x(t_1 + kl) + x(t_2 + kl))^2}, \tag{1}$$

for all the pairs $X(t_1), X(t_2)$, where $t_1, t_2 \in \{1, 2, \ldots, n-(m-1)l\}$. Recurrence plot is then computed as

$$RP^{\varepsilon}(i,j) = \begin{cases} 1, & D(i,j) < \varepsilon \\ 0, & \text{otherwise,} \end{cases} \tag{2}$$

for $i, j \in \{1, 2, \ldots, n-(m-1)l\}$. This may be alternatively written as $RP^{\varepsilon}(i,j) = \Theta(D(i,j))$, where $\Theta(\cdot)$ is the Heaviside function.

3 Recurrence plot of recurrence plots

Recurrence plot of recurrence plots is a method to analyse long time series, for which it is normally impossible to compute recurrence plots since the number of elements in recurrence plot is exponential to the time series length. It was firstly proposed in Fukino[3]. RPoRPs is based on the windowed RP analysis as can be found in [6].

First the windowed RPs are computed. The elements of windowed RP are given by

$$RP_t^{\varepsilon}(i,j) = \Theta(d(S(ts+i), (S(ts+j)))), \tag{3}$$

where $t \in \{1, 2, \ldots, (t-(m-1)l-w)/s\}$ and $i, j \in \{1, 2, \ldots, w\}$. Analysis of windowed RPs is used to study local characteristics of the time series and to discover transitions in a dynamical system.

RPoRPs is defined as the thresholded distance matrix of all the windowed RPs.

$$RPoRP(i,j) = \Theta\left(\sqrt{\sum_{k,l=1}^{w} \left(RP_i(k,l) - RP_j(k,l)\right)^2}\right), \tag{4}$$

 ISBN: 978-84-617-8694-7

where i and j are RPoRPs element's indices. While windowed RPs are reflection of local characteristics. RPoRPs describes global characteristics of the time series.

RP and RPoRPs were tested on the Tent map T defined by

$$T(x) = 1 - |2x - 1|, \quad x \in [0, 1]. \tag{5}$$

The elements of time series are given by $x_t = T(x_{t-1})$, with the initial value $x_0 = \sqrt{(}2)/2$. Example of RP and RPoRPs of width 798 is shown in Figure 3 and Figure 3. 800 iterations of tent map were used to compute RP and 80050 iterations were used to compute the RPoRPs. The windowed RP used for the computation of RPoRPs had width of 400 and shift width was 100.

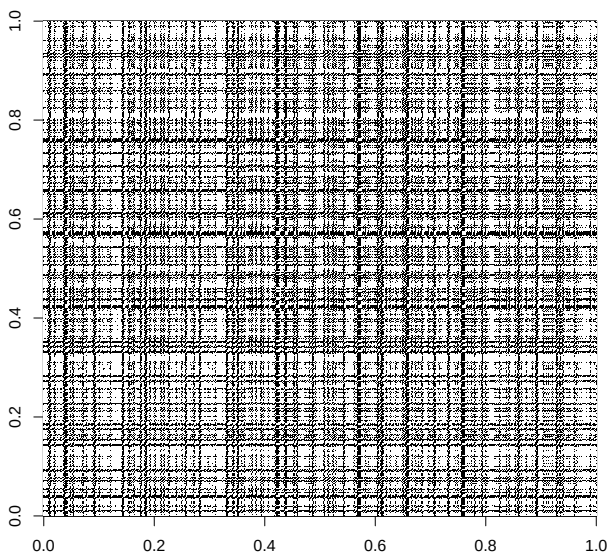

Figure 1: RP of tent map iterations

 ISBN: 978-84-617-8694-7

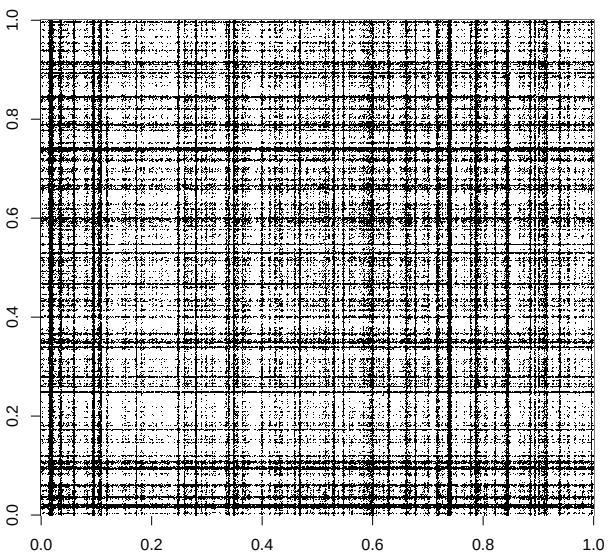

Figure 2: RPoRP of tent map iterations

4 Recurrence quantitative analysis

Although recurrence plots are powerful tool for time series analysis. Depending solely on the visual examination is often difficult. For long time series the visualisation of RPs is not exact, because the resolution of RP is higher than the screen resolution. Another thing is that, visual examination of RPs is not possible in automatic systems and therefore it is not suitable for practical use in automated tools.

Because of this, the RQA was created. It is quantification of main informations in the RPs. These can be divided into three categories: recurrence rate based, diagonal line based and vertical line based. Diagonal line based measures are generally connected with predictability of the system, while vertical line based measures are describing how long the system is trapped in the same state.

For RQA, measures of main interest are determinism, diagonal line length and entropy. Determinism is computed from the histogram of diagonal lines and is defined as

$$DET = \frac{\sum_{l=l_{min}}^{N} lP(l)}{\sum_{i,j=1}^{N} RP(i,j)}, \tag{6}$$

where l is the length of diagonal lines and $P(\cdot)$ is the histogram of diagonal lines. Deter-

 ISBN: 978-84-617-8694-7

minism is related to the predictability of the system, because deterministic process should contain many long diagonal lines in the RP and few single recurrence points. On the other hand, RP of noise, or random process should contain many single recurrence points with a few short diagonals.

5 Computation

Simple calculation of distance matrix requires computing n^2 distances for all pairs of n vectors. Naturally this may be reduced to computing only the lower/upper triangle, $n(n-1)/2$ pairs, since the distance matrix is symmetric and the main diagonal is always zero. Despite this reduction, the computational complexity grows exponentially. Equally grows memory requirements for storage of such distance matrix. For example to store the lower triangle of distance matrix for the time series of 100,000 observations would take approximately 372 GB. This means, it would be impossible to store it in RAM of most modern computers. This would make computation excessively difficult and computationally and spatially complex.

This issue is partially solved by windowed RPs, since their length is much smaller and therefore their memory requirements are acceptable. However to compute RPoRPs it is necessary to compute a large number of distance matrices, which are later used to compute RPoRPs.

However this is unnecessary, since the RPoRPs can be effectively computed from the original time series. The formula for computing RPoRPs directly from the time series is simple expansion of the equation (4)

$$d_{RPoRP}(i,j) = \sqrt{2\sum_{a=0}^{w-1}\sum_{b=a+1}^{w}\left(\sqrt{\sum_{n=0}^{m-1}\alpha_n^2}-\sqrt{\sum_{n=0}^{m-1}\beta_n^2}\right)}, \tag{7}$$

$$\alpha_n = x(t_{i+a}+nl) - x(t_{i+b}+nl), \tag{8}$$

$$\beta_n = x(t_{j+a}+nl) - x(t_{j+b}+nl), \tag{9}$$

where $x(t)$ is observation of time series x at time t, m is embedding dimension, l is time delay and w is distance matrix window width.

To reduce cache misses it is important to compute elements of RPoRPs in diagonal order. This allows to compute diagonal RQA measures by cycling through consecutive elements of array containing RPoRPs, so the prefetching mechanism may easily predict which elements will be used.

6 Conclusion

It was outlined how to compute RPoRPs directly from the time series by exploiting the definition of RPoRPs. This method introduces much lower spatial complexity of computa-

 ISBN: 978-84-617-8694-7

tion, significantly increasing performance and reducing cache misses when computing RQA. This should open up new possibilities in RP analysis, allowing study of much longer time series with multiple resolutions. Moreover, simulations of RP and RPoRPs were done on experimental example based on the Tent map.

Abstract

In this work we investigate convex Gaussian mixtures, namely an usually considered statistical hypothesis in data analysis, the variance equality. Under variance equality hypothesis it is possible to avoid a large number of parameters and to rewrite the mixture. Moreover, approximations to simpler distributions can sometimes be achieved. These approximations, namely to the Beta distribution, can be used to perform a variance equality test.

Key words: Gaussian mixtures, variance equality.

1 Introduction

Let us define a convex Gaussian mixture of N subpopulations as a random variable with density function

$$f_X(x) = \sum_{j=1}^{N} w_j \frac{1}{\sqrt{2\pi}\sigma_j} \exp\left\{-\frac{1}{2}\left(\frac{x-\mu_j}{\sigma_j}\right)^2\right\}, \quad \sigma_j > 0, w_j > 0, \sum_{j=1}^{N} w_j = 1, \tag{1}$$

where μ_i, σ_i and ω_i denote the mean, the variance and the weight of subpopulation i.

This type of mixtures is often used in statistical data analysis, because convex gaussian mixtures are very flexible. They can deal with multimodality, different shapes and always have finite moments, which is a plus. In a remarkable work of 1894 [6], Pearson used a two component Gaussian to fit biological data. This was, as far as we now, the first use of

 ISBN: 978-84-617-8694-7

Gaussian mixtures in a real data situation, together with the presentation of several theoretical aspects. [1] and its followers used these mixtures when dealing with financial data, usually with a small number of components. A recent application to image processing can be found in [4]. Image deconvolution is also a prolific field of Gaussian mixture's applications. A reference book for finite Gaussian (and non Gaussian) mixtures is [5], containing many applications to several fields of knowledge together with theoretical background.

2 Cumulants, Moments and Simplifications

For a random variable (r.v.) X with density as stated in (1), moments can be retrieved from the cumulant generation function,

$$\ln[\varphi_X(-it)] = \kappa_{1,X}t + \kappa_{2,X}\frac{t^2}{2!} + \kappa_{3,X}\frac{t^3}{3!} + \kappa_{4,X}\frac{t^4}{4!} + O\left(t^5\right) \tag{2}$$

with

$$\kappa_{1,X} = \mu'_{1,X} \quad \kappa_{2,X} = \mu_{(2,X)} \quad \kappa_{3,X} = \mu_{(3,X)} \quad \kappa_{4,X} = \mu_{(4,X)} - 3\mu^2_{(2,X)}, \tag{3}$$

where $\mu_{(k,X)}$ is the centred k-moment, $\mu'_{k,X}$ represents the raw k-moment and $\kappa_{k,X}$ denotes the k-cumulant of r.v. X.

One common assumption is to consider the same variance for all the components, that is to consider $\sigma_j = \sigma$ for $j = 1, ..., N$. When all the subpopulations have the same variance, [2] showed that

$$X \overset{d}{=} V + Y \tag{4}$$

where V and Y are independent random variables, $V \sim N(0, \sigma)$ and Y is a discrete random variable where $P(Y = \mu_j) = w_j$, for $j = 1, ..., N$.

Thus, using equations (3) and (4) when $\sigma_j = \sigma$ for $j = 1, \ldots, N$, the mixture cumulants can be rewritten as a sum. Using cumulants properties,

$$\kappa_{1,X} = \kappa_{1,Y} \quad \kappa_{2,X} = \kappa_{2,Y} + \sigma^2 \quad \kappa_{3,X} = \kappa_{3,Y} \quad \kappa_{4,X} = \kappa_{4,Y}. \tag{5}$$

The equality $\kappa_{2,X} = \kappa_{2,Y} + \sigma^2$ is important, because the knowledge of $\kappa_{2,Y} = \mu_{(2,Y)}$ or σ^2 is enough to estimate all the other parameters by the moments method, and even to fit (in some situations) an Y distribution.

3 Pearson System Approximation

Let $\beta_{1,X}$ (skewness) and $\beta_{2,X}$ (kurtosis) coefficients be defined as

$$\beta_{1,X} = \frac{\mu_{(3,X)}}{\mu^{3/2}_{(2,X)}} \qquad \beta_{2,X} = \frac{\mu_{(4,X)}}{\mu^2_{(2,X)}}. \tag{6}$$

 ISBN: 978-84-617-8694-7

Any unimodal mixture can be approximated by a Pearson system distribution [3]. The selected distribution depends on $\beta_{1,X}$ and $\beta_{2,X}$.

For unimodal gaussian mixtures where $\sigma_j = \sigma$ for $j = 1, ..., N$, the Pearson type I (four parameters beta) approach arises in multiple situations, namely when

$$\mu_{(2,Y)}\sqrt{\frac{1.5\beta_{1,Y}^2 - \beta_{2,Y} + 3}{3}} - \mu_{(2,Y)} < \sigma^2 < \frac{1.5\beta_{1,Y}^2\mu_{(2,Y)}}{\beta_{2,Y} - 3} - \mu_{(2,Y)}. \quad (7)$$

However, in most situations it is impossible to decompose the mixture into a random variable sum, since both $\mu_{(2,Y)}$ and σ^2 are unknown. Therefore, the use of the above equation in estimation issues or when testing variance equality is limited.

4 Gaussian Mixtures with Two Components

Since the general result stated in the previous section has limited usefulness, we will present an approximation that works well for unimodal Gaussian mixtures with two components. This approximation allows us to develop a variance equality test based on Beta distribution fit. The test quality is ascertain using both simulation studies and real data applications.

Abstract

The reinfection SIRI model describes the spreading of an epidemics in a population of susceptible (S), infected (I), and recovered (R) individuals, where after an initial infection the recovered individuals only have partial immunity against a possible re-infection. Grassberger, Chaté and Rousseau considered similar models with partial immunization, and observed transitions between phases of no-growth, annular growth and compact growth (see [5]). The transition between no-growth and annular growth corresponds to the transition between the disease-free equilibrium and the endemic equilibrium and so it is well characterized. The characterization of the transition between annular growth and compact growth is much more dubious because it not corresponds to a sharp threshold. This is transition is known as the reinfection threshold. In this work, we propose a new approach to characterize the reinfection threshold based on the curvature of the infected individuals quantity.

Key words: Reinfection threshold, SIRI model

1 Introduction

In 2004, Gomes, White and Medley pointed out the attention to the epidemic models with partial immunity with the discovery of the reinfection threshold [3]. Besides the well known first infection threshold, between a disease free state and a non-trivial state with strictly positive endemic equilibrium, they found a second threshold characterized by the

 ISBN: 978-84-617-8694-7

ratio between the infection and reinfection rates. They called to this second threshold the "reinfection threshold". The existence of the reinfection threshold is an extremely important discovery because partial immunity is a frequent feature of many pathogens, like Neisseria meningitidis, Streptococcus pneumoniae, Mycobacterium tuberculosis (see [3, 8]). But the concept of the reinfection threshold was not consensual and was under debate in the following years (see [1, 4]) The main concern with this new concept was that the so called reinfection threshold does not exhibit a sharp threshold behaviour and therefore it is dubious that corresponds to a phase transition.

Some years before, Grassberger, Chaté and Rousseau considered a model for the spreading of an agent in a medium whose susceptibility changes irreversibly at the first infection, that shows transitions between phases of no growth below the direct percolation or dynamical percolation critical points which are joined by a phase transition line, and another transition between annular growth and compact growth in two and higher spatial dimensions (see [5, 6]). The model considered in their work has the possibility to model epidemics with partial immunization, where after a first infection the recovered host only have partial immunity against the pathogen or a genetically close mutant pathogen. Hence, the three phases of growth are expected to be observed in epidemic models with partial immunity and more than one phase transition should exist.

Here, we consider the basic reinfection SIRI epidemic model in a stochastic spatial setup, and we analyze dynamics of the mean total numbers of susceptibles, infected and recovered, in the mean field approximation. The deterministic models considered before by Gomes, White and Medley [3] where the reinfection threshold was found are automatically related with the mean field dynamics considered in this work. In the stochastic version of the SIRI model considered here, we introduce a transition from recovered to susceptibles as effect of temporary immunity with rate α. In the limit of vanishing α, we observe a sharp threshold behaviour characterized by the parameter values of the reinfection threshold of Gomes, White and Medley [3]. Indeed, for positive values of α the observed threshold is not a sharp threshold.

In this work, we propose a new approach to characterize analytically the reinfection threshold even for positive values of α. Our approach is based on the curvature of the infected individuals quantity at stationarity.

 ISBN: 978-84-617-8694-7

2 The reinfection SIRI model

For the basic reinfection SIRI epidemic model, we have the transitions identified by the following reaction schemes (see [7, 8]))

$$S + I \xrightarrow{\beta} I + I$$

$$I \xrightarrow{\gamma} R$$

$$R + I \xrightarrow{\tilde{\beta}} I + I$$

$$R \xrightarrow{\alpha} S$$

where the transition rates are: the infection rate β as a transition from susceptible S to infected I, the recovery rate γ from I into the recovered R class, the reinfection rate $\tilde{\beta}$ as effect of only partial immunization of the recovered, and a transition rate α from recovered R to susceptibles S as effect of temporary immunization. Since we consider the SIRI model in a spatial setup , we have for the variables S_i, I_i and $R_i \in \{0, 1\}$ the constraint that an individual i belongs to one of the three classes

$$S_i + I_i + R_i = 1 \quad .$$

Let J be the $N \times N$ adjacency matrix that describes the neighbouring structure of the N individuals of the population. The matrix J is symmetric, with zero diagonal elements, and with the elements $J_{i,j} \in \{0, 1\}$ defined such that: $J_{i,j} = 1$ if the individual i is a neighbour of j, and $J_{i,j} = 0$ if the individual i is not a neighbour of j. The time evolution of the probability of the state $S_1, I_1, R_1, S_2, I_2, R_2, ..., R_N$ occur at time t is stated by the master equation, and can be used to obtain the dynamic equation for the expected values of the state variables (see [8]).

Let $\langle I \rangle(t)$ denotes the mean value of the total number of infected hosts at a given time t

$$\langle I \rangle(t) \;=\; \sum_{S_1=0}^{1} \sum_{I_1=0}^{1} \sum_{R_1=0}^{1} ... \sum_{R_N=0}^{1} \left(\sum_{i=1}^{N} I_i \right) p(S_1, I_1, R_1, ..., R_N, t) \, .$$

Taking the time derivative of $\langle I \rangle(t)$ and applying the master equation, that defines $\frac{d}{dt} p(S_1, I_1, R_1, S_2, ..., R_N, t)$, we obtain after some calculations, the time evolution of $\langle I \rangle(t)$.

 ISBN: 978-84-617-8694-7

In terms of all variables S, I and R, we obtain the ODE system

$$\begin{aligned}
\frac{d}{dt}\langle S\rangle &= \alpha\langle R\rangle - \beta\,\langle SI\rangle_1 \\
\frac{d}{dt}\langle I\rangle &= \beta\,\langle SI\rangle_1 - \gamma\langle I\rangle + \tilde{\beta}\,\langle RI\rangle_1 \\
\frac{d}{dt}\langle R\rangle &= \gamma\langle I\rangle - \alpha\langle R\rangle - \tilde{\beta}\,\langle RI\rangle_1
\end{aligned}$$

where e.g.

$$\langle RI\rangle_1(t) = \sum_{S_1=0}^{1} ... \sum_{R_N=0}^{1} \left(\sum_{i=1}^{N}\sum_{j=1}^{N} (J^1)_{ij} R_i I_j \right) \cdot p(S_1, ..., R_N, t)$$

is the mean number of pairs of recovered next to infected. In the equation for the dynamics of $\langle RI\rangle_1$ also an expression $\langle RI\rangle_2$ could show up. These are longer range correlations, formally given by a power of two of the adjacency matrix J^2 and then its elements $(J^2)_{ij} = \sum_{k=1}^{N} J_{ik} \cdot J_{kj}$.

2.1 The mean field approximation

From now on we will only consider regular lattices where all sites has the same number of neighbours, hence, for all i,

$$\sum_{j=1}^{N} J_{ij} = Q_i = Q\,.$$

In mean field approximation we assume that the exact number of inhabited infected neighbors is replaced by the average number of infected individuals in the full system, acting like a mean field on the actually considered site

$$\sum_{j=1}^{N} J_{ij} I_j \approx \sum_{j=1}^{N} J_{ij} \frac{\langle I\rangle}{N} = \frac{Q}{N}\langle I\rangle$$

Hence, we obtain

$$\langle RI\rangle_1(t) \approx \frac{Q}{N}\langle R\rangle\langle I\rangle\,.$$

With similar approximations for the other pairs, we obtain closed ODE system for the

 ISBN: 978-84-617-8694-7

expectation values of S, I and R:

$$\begin{aligned}
\frac{d}{dt}\langle S\rangle &= \alpha\langle R\rangle - \beta\frac{Q}{N}\,\langle S\rangle\langle I\rangle \\
\frac{d}{dt}\langle I\rangle &= \beta\frac{Q}{N}\,\langle S\rangle\langle I\rangle - \gamma\langle I\rangle + \tilde{\beta}\frac{Q}{N}\,\langle R\rangle\langle I\rangle \\
\frac{d}{dt}\langle R\rangle &= \gamma\langle I\rangle - \alpha\langle R\rangle - \tilde{\beta}\frac{Q}{N}\,\langle R\rangle\langle I\rangle \quad .
\end{aligned}$$

2.2 Stationarity analysis

The previous ODE system can be studied in the scaled quantities, time changed to $\tau = t/\gamma$ and consequently

$$\rho = \beta Q/\gamma\,, \qquad \varepsilon = \alpha/\gamma$$

and the ratio of infectivities given by

$$\sigma = \tilde{\beta}/\beta \quad .$$

Further, we consider densities of susceptibles, infected, and recovered $s = \langle S\rangle/N$, $\quad i = \langle I\rangle/N$, $\quad r = \langle R\rangle/N = 1 - s - i$, and we obtain the two-dimensional ODE system:

$$\begin{aligned}
\frac{d}{d\tau}s &= \varepsilon(1 - s - i) - \rho s i \\
\frac{d}{d\tau}i &= \rho i(s + \sigma(1 - s - i)) - i
\end{aligned}$$

The stationary solution is either the disease-free state

$$i_1^* = 0$$

or the endemic state

$$i_2^* = -\frac{r}{2} + \sqrt{\frac{r^2}{4} - q}$$

with

$$r = \frac{1}{\rho\sigma}\,(1 - \rho\sigma + \varepsilon) \qquad \textit{and} \qquad q = \frac{\varepsilon}{\rho^2\sigma}\,(1 - \rho)\,.$$

The first infection threshold occurs when the stationary solutions i_1^* and i_2^* meet each other, i.e. $i_1^* = i_2^* = 0$, at

$$\rho = 1\,.$$

 ISBN: 978-84-617-8694-7

When $\varepsilon = 0$, we obtain another change of regime at

$$\rho = \frac{1}{\sigma}\,.$$

This second change of regime was called the reinfection threshold by Gomes *et al.* [3], and appears as a sharp threshold in the limit of ε decreasing to zero.

We observe that for large values of ε the behaviour of i^* is dominated by the first threshold behaviour around $\rho = 1$. In contrast, for small values of ε there is only the qualitative behaviour left from the behaviour around the second threshold $\rho = 1/\sigma$. The change between these two extremes is quite continuous, however, close to the reinfection threshold $\rho = 1/\sigma$, the solutions for i^* for small ε are a smoothened out version of that threshold. It is in this smoothened transition that we propose a new definition for the reinfection threshold. For positive values of $\epsilon = \alpha/\gamma$ we propose a new approach to the reinfection threshold based on the parameter values that maximize the curvature of the stationary value of infecteds

$$arg\max_{\rho} K\left(i(\rho)\right),$$

where K defines the curvature of the endemic state. The curvature of a smooth curve measures how fast the curve is changing direction at a given point. For the endemic stationary value of infecteds this maximum change is the closest behavior to a sharp threshold and therefore is the best possible approach to the reinfection threshold.

3 Conclusions and future work

We considered the spatial stochastic reinfection SIRI model and we made a stationary analysis in the mean field approximation. Taking the limit of vanishing the endemic equilibrium, we found the first infection threshold. In analogy with other spreading models, this first threshold corresponds to the transition between no-growth and annular growth (see [5, 2]). The second transition between annular growth and compact growth, called in an epidemic context "the reinfection threshold", was also found for the mean field dynamics. Since this second transition was under discussion for a while, we propose in this work a new approach to characterize the reinfection threshold. This approach will be used to make an analytical characterization of the reinfection threshold for some parameters values where the reinfection threshold was questionable. The characterization of the phase transition lines can also be made considering the pair approximation dynamics instead of the mean field dynamics [7].

Abstract

Several commercial enzyme immunoassays are available for screening glutumate dehydrogenase. In this work, a meta-analysis is performed using the results provided in 22 papers published since 2009. The sensitivity and specificity of the index tests is assessed jointly using hierarchical summary receiver operatoring characteristic (HSROC) models estimated under a Bayesian setting. Results show a specificity of the index tests lower than what has been published in previous meta-analysis.

Key words: C. difficile, meta-analysis, HSROC
MSC 2000: 62F15, 62P10

1 Introduction

To the best of our knowledge, there are three meta-analysis published concerning the accuracy of the commercial EIA tests for GDH screening. The first one was published in 2011. It was performed by Shetty *et al.* [22] based on 13 full papers. In 2016, two meta-analysis were published almost simultaneously. Arimoto *et al.* [1] undertook a meta-analysis using a large number of studies (42), some of them obtained from conference abstracts or posters. However, despite being a recent review it uses tests no longer available in the market and that perform worse than those that are actually available (according to their results). This may have led to under estimate the sensitivity of the EIA tests. Crobach *et al.* work [5] aimed to update the guidelines for *C. difficile* diagnostic published in 2009. They updated their previous sample (and excluded tests that are not commercially available) resulting in the use of 16 full papers. Our meta-analysis is based on 22 papers [2-4;6-21;23-25].

Effective fluid flow trough corrugated pipe and the Darcy-Weisbach law

Eduard Marušić-Paloka[1] **and Maja Starčević**[1]

[1] *Department of mathematics, University of Zagreb*

emails: emarusic@math.hr, mstarcev@math.hr

Abstract

We study an incompressible viscous fluid flow through a pipe with rough wall. Starting from the Stokes system, prescribing the pressure drop on pipe's ends and assuming the periodicity of the asperities, we find an effective boundary condition of the Navier type on the rough wall and the corrector for the Darcy-Weisbach friction coefficient. The results are justified by an error estimate. Asymptotic expansions, homogenization and boundary layer techniques are used in the analysis.

Key words: pipe flow, rough boundary, Navier law, Darcy-Weisbach law
MSC 2000: 35B27, 35B25, 76D05, 76M50, 76M45

1 Introduction

Fluid flows in pipes are of interest in applications. They can be found in natural circumstances, for instance in circulation systems of humans, animals and plants, but also in water supplies, irrigation and sewer water systems, etc. In engineering applications the pressure drop caused by the friction of the viscous fluid against the pipe's wall is computed from the Darcy-Weisbach law, saying that it is proportional with the square of the velocity. In case of smooth pipe and laminar flow the friction coefficient can be computed as $f_D = 32/Re$. Frequently for pipe flows we need to take into account the effects of rough boundaries. Pipe's walls are never perfectly smooth and some boundary roughness appears either due to its fabrication or because of the demage or the sedimentation of material during it's use. Flows in rough domains in general represent a challenge for numerical simulations. The subject of this article is the flow in a pipe that is corrugated (i.e. periodically wrinkled in the longitudinal direction) . We use the Stokes model of the incompressible fluid flow ([1]).

 ISBN: 978-84-617-8694-7

Important feature is the geometry of the pipe, in particular it's roughness. In applications, the pipe roughness amplitude could vary from 0.0015 mm for glass, drawn brass and copper pipe material, 0.26 mm for cast iron, 0.18-0.6 mm for concrete, 0.12 mm for PVC, and 45 mm for corrugated metal.
We derive here the corrector to the usual friction coefficient, due to the rugosities of the pipe. For derivation of the approximation and of the effective boundary condition we use asymptotic analysis, homogenization and boundary layer techniques.

2 Geometry and equations

Let $F : \mathbf{R} \to \mathbf{R}$ be a smooth periodic function, with period 1. We define the fluid flow domain and it's wall as

$$\Omega_\varepsilon = \{(r,\varphi,z) \in \mathbf{R}^3 \; ; \; 0 \le \varphi < 2\pi \; , \; 0 < z < 1 \; , \; 0 \le r < 1 + \varepsilon \; F(z/\varepsilon) \; \}$$
$$\Gamma_\varepsilon = \{(r,\varphi,z) \in \mathbf{R}^3 \; ; \; 0 \le \varphi < 2\pi \; , \; 0 < z < 1 \; , \; r = 1 + \varepsilon \; F(z/\varepsilon) \; \} \; .$$

A stationary flow of an incompressible, viscous, Newtonian fluid with, small Reynolds number, can be fairly described by the Stokes system. Our system can thus be written as

$$-\mu \Delta u^\varepsilon + \nabla p^\varepsilon = 0 \;\; , \;\; \operatorname{div} u^\varepsilon = 0 \;\text{ in }\; \Omega_\varepsilon \;\; , u^\varepsilon = 0 \;\text{ on } \Gamma_\varepsilon \; , \;\; u^\varepsilon \times \mathbf{n} = 0 \;\; , \;\; p^\varepsilon = p_z \;\text{ for }\; z = 0, 1 \; .$$

Here u^ε denotes velocity, p^ε pressure and $\mathbf{n}$ stands for the outward normal.

3 Formal computation

After introducing the change of the variables $\rho = r - \varepsilon \; F\left(\frac{z}{\varepsilon}\right)$ we define $\mathcal{U}^\varepsilon(\rho,\varphi,z) = u^\varepsilon(r,\varphi,z)$. Assuming that the pressure is linear$p^\varepsilon = p_0 + z \; \delta P$, $\delta P = p_1 - p_0$ and that the velocity has only the component along the pipe, i.e. $u^\varepsilon = \mathcal{U}^\varepsilon_z \mathbf{e}_z$, we arrive at

$$\mu \left\{ \frac{1}{\rho + \varepsilon \, F} \frac{\partial}{\partial \rho} \left((\rho + \varepsilon F) \frac{\partial \mathcal{U}^\varepsilon_z}{\partial \rho} \right) + \frac{\partial^2 \mathcal{U}^\varepsilon_z}{\partial z^2} - 2F' \frac{\partial^2 \mathcal{U}^\varepsilon_z}{\partial \rho \partial z} + (F')^2 \frac{\partial^2 \mathcal{U}^\varepsilon_z}{\partial \rho^2} - \frac{F''}{\varepsilon} \frac{\partial \mathcal{U}^\varepsilon_z}{\partial \rho} \right\} = \delta P$$
$$\frac{\partial \mathcal{U}^\varepsilon_z}{\partial z} - F' \; \frac{\partial \mathcal{U}^\varepsilon_z}{\partial \rho} = 0 \; . \tag{1}$$

We look for an asymptotic expansion of the form $\mathcal{U}^\varepsilon_z = U_0(\rho, z, z/\varepsilon) + \varepsilon \; U_1(\rho, z, z/\varepsilon) + \cdots$. We get by direct computation that $U_0(\rho) = \frac{1}{4\mu}(\rho^2 - 1) \; \delta P$ and $U_1 = F(\xi) \frac{\partial U_0}{\partial \rho} + A$. The constant A is to be determined from the appropriate boundary condition, which will be discussed in the next section.

 ISBN: 978-84-617-8694-7

4 Boundary layer

In this section we construct an additional corrector, using the boundary layers techniques, to fix the boundary condition on the wall of the pipe. The approximation

$$\overline{\mathcal{U}}^{\varepsilon}(\rho,\xi) = (U_0(\rho) + \varepsilon\, F(\xi)\frac{\partial U_0}{\partial \rho}(\rho) + \varepsilon\, A)\mathbf{e}_z$$

cannot satisfy the boundary condition $\overline{\mathcal{U}}^{\varepsilon}(1,\xi) = 0$ due to the term $\varepsilon\, F(\xi)\frac{\partial U_0}{\partial \rho}$ and we need to add a boundary layer corrector. Thus we postulate an approximation of the form

$$\mathcal{V}^{\varepsilon} = U_0(\rho)\mathbf{e_z} + \varepsilon\, F(\xi)\frac{\partial U_0}{\partial \rho}(\rho)\mathbf{e_z} + \varepsilon\, B\, \frac{\partial U_0}{\partial \rho}(1) + \varepsilon\, A\mathbf{e_z}\ , \tag{2}$$

where $B = B\,(\tau,\xi) = B_\tau(\tau,\xi)\mathbf{e}_r + B_\xi(\tau,\xi)\mathbf{e}_z$, with $\xi = \frac{z}{\varepsilon}$, $\tau = \frac{1-r}{\varepsilon} + F(\xi)$. We also need to add an additional term to the pressure approximation

$$p^{\varepsilon} = p_0 + z\ \delta P + b(\tau,\xi)\ \frac{\partial U_0}{\partial \rho}(1)\ \ .$$

The couple (B,b) satisfies the following boundary layer problem

$$-\mu\left((1+(F')^2)\frac{\partial^2 B_\tau}{\partial \tau^2} + \frac{\partial^2 B_\tau}{\partial \xi^2} + F'\frac{\partial^2 B_\tau}{\partial \xi \partial \tau} + \frac{\partial}{\partial \xi}\left(F'\frac{\partial B_\tau}{\partial \tau}\right)\right) - \frac{\partial b}{\partial \tau} = 0\ , \tag{3}$$

$$-\mu\left((1+(F')^2)\frac{\partial^2 B_\xi}{\partial \tau^2} + \frac{\partial^2 B_\xi}{\partial \xi^2} + F'\frac{\partial^2 B_\xi}{\partial \xi \partial \tau} + \frac{\partial}{\partial \xi}\left(F'\frac{\partial B_\xi}{\partial \tau}\right)\right) + \frac{\partial b}{\partial \xi} + F'\frac{\partial b}{\partial \tau} = 0\ ,$$

$$-\frac{\partial B_\tau}{\partial \tau} + \frac{\partial B_\xi}{\partial \xi} + F'\frac{\partial B_\xi}{\partial \tau} = 0 \quad \text{for} \quad \tau > 0\ \ ,\ \ 0 < \xi < 1\ , \tag{4}$$

$$(B_\tau(0,\xi), B_\xi(0,\xi)) + (0, F(\xi)) = K = (K_\tau, K_\xi) \tag{5}$$

$$\nabla B(\tau,\xi) \to 0\ \ ,\ b(\tau,\xi) \to 0 \text{ for } \tau \to +\infty\ ,\ \ (B,b) \quad \text{is} \quad 1-\text{periodic} \quad \text{in } \xi\ \ . \tag{6}$$

The solution of the above boundary layer problem decays exponentially as $\tau \to +\infty$ to some constant. As b is determined up to a constant, it can be chosen in a way that it decays to 0. As for the velocity B, due to the linearity of the equation, we can choose K in a way that it decays to zero too. Indeed, denoting $\omega = \{(\tau,\xi) \in \mathbf{R}^2\ \ ,\ \tau > 0\ \ ,\ \ 0 < \xi < 1\ \}$, we have:

Theorem 1 *The problem (3)-(6) has a unique solution $B \in V = \{w \in L^2_{loc}(\omega)^2\ \ ,\ \nabla w \in L^2(\omega)^4\}$, $b \in L^2(\omega)/\mathbf{R}$. Furthermore, the constant vector K can be chosen such that*

$$|B(\tau,\xi)| \le Ce^{-\beta\tau} \quad , \quad |b(\tau,\xi)| \le Ce^{-\beta\tau}\ , \tag{7}$$

for some $C > 0$ and $\beta > 0$. Finally $K_\tau = 0$.

The approximation with the boundary layer corrector can be justified by an appropriate error estimate (see [2])

 ISBN: 978-84-617-8694-7

5 Darcy-Weisbach friction coefficient

In engineering applications the Darcy-Weisbach formula is used to compute the pressure drop in the pipe, due to the friction against the wall. It s usually written in the form

$$\delta P = f_D \ \rho \frac{\langle \mathcal{V}_z^\varepsilon \rangle^2}{4} \ ,$$

where δP is the pressure drop, ρ is the fluid density, $\langle \mathcal{V}_z^\varepsilon \rangle$ is the mean velocity, and f_D is the friction coefficient. For smooth pipe, the Poiseuille formula gives $f_D = \frac{32}{Re}$, which is the well-known expression for the friction coefficient in case of laminar flow. Here the Reynolds number is defined as $Re = \rho V/\mu$. In case of rough pipe, a corrector due to the roughness is needed. Since, up to the order ε, we have

$$\langle \mathcal{V}_z^\varepsilon \rangle = \frac{1}{|\Omega_\varepsilon|} \int_{\Omega_\varepsilon} \mathcal{V}_z^\varepsilon = \frac{\delta P}{\mu} \left[-\frac{1}{8} + \varepsilon \left(\frac{7}{12} \langle F \rangle - \frac{1}{2} K_\xi \right) \right] \ ,$$

where $\langle F \rangle = \int_0^1 F(t) \ dt$. Taking the Poiseuille velocity $V = \frac{\delta P}{8\mu}$ as the characteristic velocity we get the Reynolds number $Re = \rho \ \frac{V}{\mu}$ and then

$$\langle \mathcal{V}_z^\varepsilon \rangle = -V \ \left[1 + \varepsilon \ \left(\frac{14}{3} \ \langle F \rangle - 4 \, K_\xi \right) \right] \ .$$

Since $f_D = \frac{4 \, \delta P}{\rho \, \langle \mathcal{V}_z^\varepsilon \rangle^2}$ neglecting the terms of order ε^2 and smaller leads to

$$f_D = \frac{32}{Re} \ \left[1 \ - 4 \, \varepsilon \ \left(\frac{7}{3} \, \langle F \rangle - 2 \, K_\xi \right) \right] \ .$$

Abstract

We consider the problem of efficiently solving Lyapunov and Sylvester equations of medium and large scale, in the case where all the coefficients are quasiseparable, i.e., they have off-diagonal blocks of low-rank. This comprises the case with banded coefficients and right-hand side, recently studied in [6, 9].

We show that, under suitable assumptions, this structure is guaranteed to be numerically present in the solution, and we provide explicit estimates of the numerical rank of the off-diagonal blocks. Moreover, we describe an efficient method for approximating the solution, which relies on the technology of hierarchical matrices.

A theoretical characterization of the quasiseparable structure in the solution is presented, and numerically experiments confirm the applicability and efficiency of our approach. We provide a MATLAB toolbox that allows easy replication of the experiments and a ready-to-use interface for our solver.

1 Introduction

Lyapunov and Sylvester equations, i.e., linear matrix equations of the form

$$AX + XA^T = C, \qquad AX - XB = C,$$

respectively, appear in many different areas of mathematics, and are a recurrent problem in numerical analysis. In many practical cases, such as the problems arising from control theory

 ISBN: 978-84-617-8694-7

[1, 3], the right-handside (RHS) of the above equations is often low-rank, or numerically low-rank, i.e., $C \approx uv^T$, with u, v tall and thin matrices.

In this case it is well-known that, if the coefficient matrices A and B satisfy certain spectral properties, the solution X can be well-approximated by a low rank matrix [2]. This has enabled the study of projection methods, based on several variants of Krylov subspaces (such as classical, extended, and rational Krylov spaces).

However, recently there has been a growing interest in considering Sylvester and Lyapunov equations arising from discretization of $2D$ PDEs [9]. On of the easiest and most classical examples can be obtained by the discretization of the Laplacian operator, but this approach can handle heat and convection-diffusion PDEs as well. In general, one can consider problems arising from equations of the form $Lu = f$, where L is a linear differential operator and u is defined on a rectangular domain.

In this framework the matrix C is nothing else that the discretization of the RHS of the PDE on the chosen grid. When the function is well-approximated by a separable function, i.e., $f(x, y) \approx f_1(x)f_2(y)$, or a linear combination of functions of this form, then the matrix C has numerically low rank, and Krylov methods can be applied. However, this is not always the case, and often the matrix C can have a more complicated structure.

We consider the situation where the RHS C is quasiseparable. Many interesting cases fall under this framework, such as a diagonal or diagonal plus low rank matrix, as well as banded matrices. These matrices can be full-rank in general, but they have a low rank structure in their off-diagonal blocks. We investigate the preservation of this structure in the solution X, and we propose a new method for the approximation of this structured solution. For this approach to work, also the matrices A and B need to have the same structure. This is not restrictive, since they are often banded, which is a particular case of quasiseparable matrices.

Some previous attempts to exploit a similar structure (relying on the band of these matrices), can be found in [6]. We show that our approach yields faster computation times and better accuracy.

2 An approximation result

A key result in our analysis is that, under certain spectral conditions on the matrices A and B similar to the ones needed for the results in the classical low-rank case, one can prove that the solution X has a numerical quasiseparable structure, i.e., its off-diagonal blocks have numerically low rank.

We provide numerical evidence of this fact as well as propose an argument to prove that the structure must be present in the solution, relying on arguments from approximation theory inspired by the theory of Krylov and rational Krylov subspaces. These result provide an extension of the approximation results in [4, 5] that prove the preservation of

 ISBN: 978-84-617-8694-7

the quasiseparable structure in the solution of quadratic matrix equations, which can also be described by means of integral formulas.

This opens the door to the treatment of large scale problems, where the size of X would make its storage unfeasible otherwise. In fact, to store a quasiseparable matrix of order n with a quasiseparable rank of k only $\mathcal{O}(nk)$ or $\mathcal{O}(nk \log n)$ storage is needed, depending on the chosen representation. It is clear that if $k \ll n$ this enables the study of large scale problems.

As a motivating example, consider the partial differential equation

$$\begin{cases} \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \log\left(\epsilon + |x - y|\right), & (x, y) \in \Omega, \\ u(x, y) \equiv 0 & (x, y) \in \partial\Omega, \end{cases}$$

where Ω is some rectangular domain of the form $[a, b] \times [a, b]$ and ϵ is small. In this case the RHS $f(x, y)$ is large when $x \approx y$, and can be well approximated by a separable function elsewhere. In fact, the matrix C obtained sampling this function has full-rank, but a low quasiseparable order.

The coefficient matrix A obtained discretizing the Laplacian is tridiagonal, and every banded matrix is quasiseparable. Therefore, this problem is covered by our framework.

3 Approximating the solution

In order to approximate the solution X, which we have proved to be quasiseparable, we need to develop a method that exploits the quasiseparable structure of A, B, and C.

We propose to consider the integral representation of the solution X, that is

$$X = \int_0^\infty e^{-tA} C e^{-tA^T} dt,$$

and we discuss numerical strategies to approximate the above integral formula effectively using the available structure. This problem is linked with many different topics, such as the efficient approximation of matrix functions whose argument is quasiseparable [8], and the devise of efficient integration schemes for quasiseparable matrix valued functions.

We draw a connection with previous work of Hackbush et al. [7], and we discuss several improvements to the available tools in the literature, and the state of the art procedures.

Numerical experiments confirm that our approach is faster than all the other available (such as the one in [6]), and has a much higher accuracy. Moreover, our scheme does not suffer when the conditioning of the problem increases.

The algorithm presented has been implemented in a MATLAB toolbox, called `hm-toolobx`, that can be used to easily manipulate Hierarchical matrices. We provide some examples of its use, and on the solution of Lyapunov equations.

Abstract

Given matrices A and B such that $B = f(A)$, where $f(z)$ is a holomorphic function, we analyze the relation between the singular values of the off-diagonal submatrices of A and B. We provide a family of bounds which depend on the interplay between the spectrum of the argument A and the singularities of the function. In particular, these bounds guarantee the numerical preservation of quasiseparable structures under mild hypotheses. We extend the Dunford-Cauchy integral formula to the case in which some poles are contained inside the contour of integration. We use this tool together with the technology of hierarchical matrices ($\mathcal{H}$-matrices) for the effective computation of matrix functions with quasiseparable arguments.

Key words: Matrix functions, Quasiseparable matrices, Hierarchical matrices

1 Introduction

Matrix functions are an evergreen topic in matrix algebra due to their wide use in applications. It is not hard to imagine why the interaction of structures with matrix functions is an intriguing subject [11]. In fact, in many cases structured matrices arise and can be exploited for speeding up algorithms, reducing storage costs or allowing to execute otherwise not feasible computations [4, 5]. The property we are interested in is the *quasi-separability*. That is, we want to understand whether the submatrices of $f(A)$ contained in the strict upper triangular part or in the strict lower triangular part, called *off-diagonal submatrices*, have a "small" numerical rank.

Studies concerning the numerical preservation of data-sparsity patterns were carried out recently [1, 2, 3, 7]. Regarding the quasiseparable structure, in [8, 9, 10] Gavrilyuk,

 ISBN: 978-84-617-8694-7

Hackbusch and Khoromskij addressed the issue of approximating some matrix functions using the hierarchical format [6]. In these works the authors prove that, given a low rank quasiseparable matrix A and a holomorphic function $f(z)$, computing $f(A)$ via a quadrature formula applied to the contour integral definition, yields an approximation of the result with a low quasiseparable rank. Representing A with a $\mathcal{H}$-matrix and exploiting the structure in the arithmetic operations provides an algorithm with almost linear complexity. The feasibility of this approach is equivalent to the existence of a rational function $r(z) = \frac{p(z)}{q(z)}$ which well-approximates the holomorphic function $f(z)$ on the spectrum of the argument A. More precisely, since the quasiseparable rank is invariant under inversion and sub-additive with respect to matrix addition and multiplication, if $r(z)$ is a good approximation of $f(z)$ of low degree then the matrix $r(A)$ is an accurate approximation of $f(A)$ with low quasiseparable rank. This argument explains the preservation of the quasiseparable structure, but still needs a deeper analysis which involves the specific properties of the function $f(z)$ in order to provide effective bounds to the quasiseparable rank of the matrix $f(A)$.

In this work we deal with the analysis of the quasiseparable structure of matrix functions by studying the interplay between the off-diagonal singular values of the matrices A and B such that $B = f(A)$. Our intent is to understand which parameters of the model come into play in the numerical preservation of the structure and to extend the analysis to functions with singularities.

2 Theoretical analysis

Because of the sub-additivity with respect to the matrix sum and to the matrix product of the quasiseparable rank, it is straightforward that a polynomial of degree d evaluated in an argument A of quasiseparable rank k provides a matrix of quasiseparable rank at most $d \cdot k$. Using this observation it is possible to provide estimates on the numerical quasiseparable rank of $f(A)$ based on the polynomial approximation of the function f. More precisely, if f is well approximated by a polynomial of low degree on the spectrum of A then $f(A)$ has off-diagonal blocks with fast decay in their singular values. So it is possible to obtain bounds on the off-diagonal singular values exploiting classical results of polynomial approximation in the complex plane like Bernstein theorem. In the case in which f has singularities close to the spectrum of A these bounds do not provide useful information. We introduce new technical tools that enable us to overcome the problem, getting meaningful bounds.

3 Exploiting the structure

In order to take advantage of the quasiseparable structure we need a representation that enable us to perform the storage and the matrix operations cheaply. We rely on the frame-

Operation	Computational complexity
Matrix-vector multiplication	$O(km\log(m))$
Matrix-matrix addition	$O(k^2m\log(m))$
Matrix-matrix multiplication	$O(k^2m\log(m)^2)$
Matrix-inversion	$O(k^2m\log(m)^2)$
Solve linear system	$O(k^2m\log(m)^2)$

work of Hierarchical representations originally introduced by Hackbusch [10] in the context of integral and partial differential equations. It consists in a class of recursive block representations with structured sub-matrices that allows the treatment of a number of data-sparse patterns. Here, we consider a particular member of this family — sometimes called Hierarchical off-diagonal low-rank representation (HODLR) — which has a simple formulation and an effective impact in handling quasiseparable matrices.

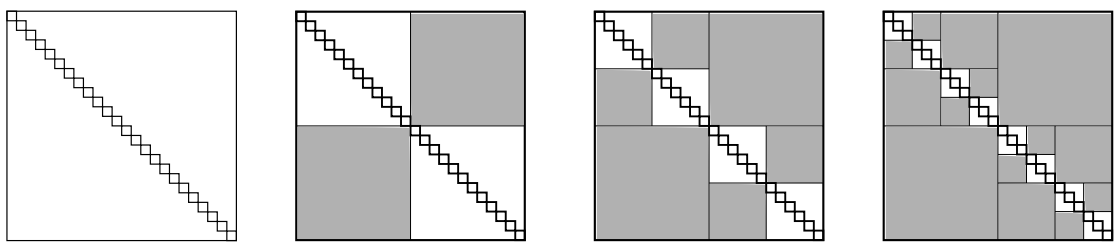

Figure 1: The behavior of the block partitioning in the HODLR-matrix representation. The blocks filled with grey are low rank matrices represented in a compressed form, and the diagonal blocks in the last step are stored as dense matrices.

The HODLR representation acts on a matrix by compressing many of its sub-blocks. Therefore, it is natural to perform the arithmetic operations in a block-recursive fashion. The basic steps of these procedures require arithmetic operations between low-rank matrices or small size matrices. If the rank of the off-diagonal blocks is small compared to m, then the algorithms performing the arithmetic operations have linear polylogarithmic complexities [6][Chapter 6]. The latter are summarized in the table where it is assumed that the constant k bounds the quasiseparable rank of all the matrices involved. Moreover, the operations are performed adaptively with respect to the rank of the blocks. This means that the result of an arithmetic operation will be an HODLR matrix with the same partitioning, where each low rank block is a truncated reduced SVD of the corresponding block of the exact result. This operation can be carried out with linear cost, assuming that the quasiseparable rank stays negligible with respect to m.

Kantorovich method to solve an integral equation arising from a problem in mathematical biology

Abdelaziz Mennouni[1]

[1] *Department of Mathematics, LTM, University of Batna 2, Algeria*

emails: aziz.mennouni@yahoo.fr

Abstract

Kantorovich method is formulated and justified for solving numerically an integral equation arising from a problem in mathematical biology, using a sequence of orthogonal finite rank projections. The convergence analysis and associated theorems are considered in this work. Numerical examples illustrate the theoretical results and show the effectiveness of the method.

Key words: Kantorovich method, integral equations, orthogonal finite rank projections.
MSC 2000: 45A05, 45B05

1 Introduction

Let us consider the following integral equation of the second kind

$$x(s)\int_0^1 k(s-t)dt = \int_0^1 x(\tau)k(\tau-s)d\tau + f(s), \quad 0 \le s \le 1, \tag{1}$$

where $k(\cdot,\cdot)$ is a Fredholm kernel, and where f is a known function.

Equation (1) reads as

$$x(s) - \int_0^1 \frac{x(\tau)k(\tau-s)d\tau}{\int_0^1 k(s-t)dt} = f(s), \quad 0 \le s \le 1. \tag{2}$$

Define the integral operator T:

$$Tx(s) := \int_0^1 \frac{x(\tau)k(\tau-s)d\tau}{\int_0^1 k(s-t)dt}, \quad 0 \le s \le 1.$$

 ISBN: 978-84-617-8694-7

Set $\mathcal{H} := L^2[0,1]$. Suppose $k \in \mathcal{L}^1[0,1]$, $k > 0$ almost everywhere. We recall that for each $f \in \mathcal{H}$, T is compact from $\mathcal{H}$ into itself, (see [6]). Hence, the integral equation (1) has a unique solution $x \in \mathcal{H}$.

Let I denote the the identity operator on $\mathcal{H}$. Eq. (2) can be rewritten in operator form as follows:

$$(I - T)\, x = f.$$

The purpose of this work is to approximate x through the exact solution x_n of the Kantorovich equation

$$(I - \pi_n T)\, x_n = f. \tag{3}$$

2 Projection approximations using general grids

Let $(s_{n,j})_{j=0}^{n}$ be a grid on $[0,1]$ such that

$$0 < s_{n,0} < s_{n,1} < \ldots < s_{n,n} < 1.$$

Set

$$h_{n,i} := s_{n,i} - s_{n,i-1}, \quad i \in [\![1, n]\!], \quad h_n := (h_{n,1}, h_{n,2}, \ldots, h_{n,n}).$$

Let us consider $(\pi_n)_{n\geq 1}$, a sequence of bounded projections each one of finite rank, such that

$$\pi_n x := \sum_{j=1}^{n} \langle x, e_{n,j} \rangle\, e_{n,j},$$

where

$$e_{n,j} := \frac{\phi_{n,j}}{\sqrt{h_{n,j}}}, \quad \phi_{n,j}(s) := \begin{cases} 1 \text{ for } s \in]s_{n,j-1}, s_{n,j}[, \\ 0 \text{ otherwise.} \end{cases}$$

Let

$$J_n := \{s_{n,j}, \quad j \in [\![0, n]\!]\}.$$

Define the modulus of continuity of the function $\psi \in H$ relative to h_n as follows:

$$\omega_2(\psi, J_n) := \sup_{0\leq\delta\leq h_n} \left(\int_0^1 |\psi(\tau + \delta) - \psi(\tau)|^2\, d\tau \right)^{\frac{1}{2}}.$$

All functions are extended by 0 outside $[0,1]$. We recall that

$$\omega_2(\psi, J_n) \to 0 \text{ as } n \to \infty \text{ for all } \psi \in H,$$

and that, for all $\psi \in H$ (cf. [4]),

$$\|(I - \pi_n)\psi\| \leq \omega_2(\psi, J_n). \tag{4}$$

 ISBN: 978-84-617-8694-7

3 Kantorovich method

We have

$$\pi_n Tx := \sum_{j=1}^{n} \langle Tx, e_{n,j}\rangle \, e_{n,j}.$$

Applying T to both sides of equation (3), and performing the inner product with $e_{n,i}$ to both sides of this equation, we get

$$\langle Tx_n, e_{n,i}\rangle - \sum_{j=0}^{n-1} \langle Tx_n, e_{n,j}\rangle \langle Te_{n,j}, e_{n,i}\rangle = \langle Tf, e_{n,i}\rangle ,$$

or, equivalently,

$$(I_n - A_n)X_n = b_n, \tag{5}$$

where

$$X_n(j) := \langle Tx_n, e_{n,i}\rangle ,$$

and

$$\begin{aligned} A_n(i,j) &:= \langle Te_{n,j}, e_{n,i}\rangle , \\ b_n(i) &:= \langle Tf, e_{n,i}\rangle . \end{aligned}$$

Hence

$$\begin{aligned} A_n(i,j) &:= \frac{1}{\sqrt{h_{n,j}h_{n,i}}} \int_{s_{j-1}}^{s_j} \int_{s_{i-1}}^{s_i} \frac{k(\tau - s)}{\int_0^1 k(s-t)dt} d\tau ds, \\ b_n(i) &:= \frac{1}{\sqrt{h_{n,i}}} \int_{s_{i-1}}^{s_i} \int_0^1 \frac{f(\tau)k(\tau - s)}{\int_0^1 k(s-t)dt} d\tau ds. \end{aligned}$$

4 Convergence analysis

For all $x \in \mathcal{H}$,

$$\lim_{n\to\infty} \|\pi_n Tx - Tx\| = 0,$$

and since T is compact,

$$\lim_{n\to\infty} \| (\pi_n T - T) T\| = 0, \quad \lim_{n\to\infty} \| (\pi_n T - T) \pi_n T\| = 0.$$

 ISBN: 978-84-617-8694-7

Theorem 1 *There exists a positive constant M, such that*

$$\|x_n - x\| \leq M \left[\omega_2(x, J_n) + \omega_2(f, J_n)\right].$$

Proof. In fact

$$\pi_n x = \pi_n T x + \pi_n f.$$

Since

$$\begin{aligned} x - \pi_n x &= x - x_n + x_n - \pi_n x \\ &= x - x_n + (\pi_n T x_n + f) - (\pi_n T x + \pi_n f) \\ &= x - x_n + \pi_n T (x_n - x) + (I - \pi_n) f \\ &= (I - \pi_n T)(x - x_n) + (I - \pi_n) f. \end{aligned}$$

Hence

$$x - x_n = (I - \pi_n T)^{-1} \left[(I - \pi_n) x - (I - \pi_n) f\right],$$

and since T is compact, the

$$M := \sup_{n \geq N} \|I - \pi_n T\|,$$

is finite. Using (4), we get the desired result. ■

Numerical Solution of a Cancer Invasion Model Using DRBEM and FDM

Gülnihal Meral[1]

[1] , *Department of Mathematics and Computer Science, Ankara Yıldırım Beyazıt University, 06010, Ankara, Turkey*

emails: gmeral@ybu.edu.tr

Abstract

In this study, the haptotaxis-only model for cancer cell invasion of tissue [1] is solved by using the combination of Dual Reciprocity Boundary Element Method (DRBEM) and the Finite Difference Method(FDM). The model consists of a system of reaction-diffusion-taxis equations, describing the interactions between the cancer cells, the normal cells and the matrix degrading enzyme (MDE) which is produced by the cancer cells.

The space derivatives coming from the Laplacian terms in the equations for MDE concentration and cancer cell density are discretized by DRBEM using the fundamental solution of Laplace equation and considering the rest of the terms as nonhomogenity. The nonhomogenity for the equation describing the change in the cancer cell density involves the first and second order space derivatives of the unknowns and their products and in order to handle this diffculty the finite difference method is made use of. The resulting time dependent ordinary differential equations(ODEs) obtained after the spatial discretization of the equations for the cancer cell density and for the concentration of the MDE and the ODE for the normal cell density are then solved by using a combination of the forward and backward Euler methods.

Because of the nonlinear terms in the model, the numerical solution in two-space dimensions has some difficulties and with the proposed method these diffculties are overcome mainly by using DRBEM in space discretization which only needs to discretize the boundary only and thus the method gives the solution with a lower computational cost. The haptotactic behaviour and the effect of the reestablishment of the cells are analysed by the numerical simulations and the results agree well with the expected behaviour of the invasion.

Key words: DRBEM, FDM, Mathematical Modelling, Cancer Invasion

 ISBN: 978-84-617-8694-7

1 Introduction

The crucial point of cancer is the metastasis, which is defined as the formation of a secondary tumour at a distant side of the body. Metastasis forms following the invasion of the tissue where the tumour arises. This is followed by the penetration of the cancer cells into adjacent tissues. Then the tumour cells migrate via blood or lymph system and form a secondary tumour, i.e. the metastasis. Thus the turning point is the invasion step. Chemotaxis and haptotaxis are two mechanisms effecting the movement of cancer cells through tissue network. Chemotaxis is the movement of the cancer cells in response to a chemoattractant in the solution [1]. On the other hand the cells have to adhere to the extracellular matrix (ECM) fibres in order to move and thus they start to migrate from a region of low concentration of the present adhesive molecule on ECM to an area with higher concentration, which is called haptotaxis. The contact with the tissue stimulates the production of the proteolytic enzyme called matrix degrading enzyme (MDE) which degrades the tissue fibres and this let the cancer cells to migrate towards neighbouring blood vessels.

In the last decades, several models are proposed on invasion considering different factors, such as the pH level of the environment [2, 3], role of heat shock proteins [4, 5] or matrix-degrading enzymes [1].

Generally, the analytical solutions for the cancer invasion models are not available and thus it is important to find accurate and efficient numerical solutions to these models. However, because of the nonlinearities arise in the most of the models it is not easy to solve these models numerically, either. The models are usually solved by using finite difference method [3, 6, 7, 8]. However, when one considers the two-dimensional regions more discretization points are needed and the numerical solution becomes computationally expensive and stability problems may occur. To handle these problems a combined application of DRBEM and FDM is applied recently for the acid mediated invasion model [9].

In this study, the combined application of DRBEM and FDM is applied to the haptotaxis-only model [1]. The method is applied by using the fundamental solution of Laplace equation considering the time derivative, the nonlinearities coming from the haptotaxis and proliferation terms; and the production, decay terms for the equation describing the temporal and spatial evolution of cancer cell density; and MDE concentration, respectively. The haptotaxis term includes the first and second order space derivatives of the unknowns and their products. For the discretization of these derivatives in the nonhomogenity the forward and central differences are made use of. For the time discretization of the ODEs obtained after the space discretization a combination of forward and backward Euler methods are used. The proposed method is tested to see the effect of haptotaxis and proliferation of the cells and the expected behaviour is obtained in each case with a small number of discretization points.

 ISBN: 978-84-617-8694-7

2 Model Problem

The nondimensionalized model problem [1] describing the interactions among the cancer cell density, normal cell density and the concentration of the MDE is given by a system of reaction diffusion equations

$$\frac{\partial c}{\partial t} = \nabla \cdot (D_c \nabla c) - \nabla \cdot (\xi_c c \nabla n) + \mu_1 c(1-c-n) \quad (1)$$

$$\frac{\partial n}{\partial t} = -\delta_n m n + \mu_2 n(1-c-n) \quad (2)$$

$$\frac{\partial m}{\partial t} = D_m \nabla^2 m + \mu_3 c - \delta_m m \quad (3)$$

where D_c, D_m denote the diffusion coefficients for the cancer cells and MDE, respectively; ξ_c is the haptotaxis coefficient, μ_1, μ_2 are the production rates for the cancer and normal cells, respectively. Moreover, δ_n denotes the normal cell degradation rate, μ_3 and δ_m denote the production and decay rates of the MDE, respectively. The first and the second terms seen on the right hand side of Equation (1) describe the random motion and the haptotaxis; respectively. The last terms in Equations (1) and (2) models proliferation of the cancer and normal cells, respectively; using the logistic growth. The MDE degradation of normal cells is modelled by the first term in Equation (2) where the last term in Equation (3) is for the decay for the proteolytic enzymes MDE. The first and second terms in Equation (3) are modelling the diffusion and the production of MDEs.

For the boundary conditions, it is assumed there is no flux of cancer cells and MDE across the boundary of the problem domain and thus the Neumann type boundary conditions are considered, i.e.,

$$\frac{\partial c}{\partial \nu} = \frac{\partial m}{\partial \nu} = 0 \quad (4)$$

on the boundary $\partial\Omega$ of the domain $\Omega \subset \mathbb{R}^2$, with ν denoting the outward unit normal to $\partial\Omega$.

Finally, the problem is completed with the initial condiitons,

$$c(\mathbf{x},0) = c_0, \quad n(\mathbf{x},0) = n_0, \quad m(\mathbf{x},0) = m_0 \quad (5)$$

where c_0, n_0, m_0 are strictly positive functions which are consistent with the boundary conditions.

3 Discretization of the Model

For the spatial discretization of the model, combined application of DRBEM and FDM is used. For the spatial discretization of Equation (3) the DRBEM is used [10]. To this end,

 ISBN: 978-84-617-8694-7

Equation (3) is weighted by the fundamental solution $u^* = \frac{1}{2\pi} \ln \frac{1}{r}$ of Laplace equation

$$D_m \int_\Omega \nabla^2 m u^* d\Omega = \int_\Omega b_1 u^* d\Omega \tag{6}$$

where the nonhomogenity b_1 can be approximated by using radial basis functions $f_j(x, y)$ as

$$b_1 \left(m, c, \frac{\partial m}{\partial t} \right) = \frac{\partial m}{\partial t} - \mu_3 c + \delta_m m \approx \sum_{j=1}^{N+L} \alpha_j(t) f_j(x, y) \tag{7}$$

resulting with a linear systems of equations

$$[F] \{\alpha\} = \{b_1\} \tag{8}$$

with N and L being the number of boundary and selected interior nodes, F is the $(N + L) \times (N + L)$ matrix of distance functions f_j related to other distance functions $\hat{u}_j(x, y)$ through $\nabla^2 \hat{u}_j = f_j$.

Application of Green's second identity to both sides of equation (6) yields to

$$[H] \{m\} - [G] \left\{ \frac{\partial m}{\partial \nu} \right\} = \left([H] \left[\hat{U} \right] - [G] \left[\hat{Q} \right] \right) \{\alpha\} \tag{9}$$

with the $(N + L) \times (N + L)$ matrices $[G]$ and $[H]$ containing the boundary integrals of the fundamental solution and its normal derivative, respectively. Because of the non-flux boundary conditions the second term on the left hand side of equation (9) vanishes and back substitution of $\{\alpha\}$ gives

$$D_m [H] \{m\} = [C] \left(\left\{ \frac{\partial m}{\partial t} \right\} - \mu_3 \{c\} + \delta_m \{m\} \right) \tag{10}$$

which is an ODE, that is going to be discretized by using a combination of backward and forward Euler methods,

$$\left[(1 + \Delta t \delta_m) I - \Delta t \bar{H}_m \right] m^{k+1} = m^k + \Delta t \mu_3 c^k \tag{11}$$

which calculates the decay term implicitly and the production term explicitly. In Equation (11) k is the time level, Δt is the length of the time interval, $i, j = 1, 2, \cdots N + L$.

The ordinary differential equation (2) describing the time evolution of the normal cell density is discretized by using a combination of backward and forward Euler Methods, which discretizes the degradation term implicitly and the proliferation term explicitly; i.e.,

 ISBN: 978-84-617-8694-7

$$n_{ij}^{k+1} = \frac{1}{1+\Delta t \delta_n m_{ij}^{k+1}} \left(n_{ij}^k + \Delta t \mu_2 n_{ij}^k \left(1 - c_{ij}^k - n_{ij}^k \right) \right) \tag{12}$$

For the discretization of equation (1) , DRBEM is once again made use of with the fundamental solution of Laplace equation:

$$D_c \int_\Omega \nabla^2 c u^* d\Omega = \int_\Omega b_2 u^* d\Omega \tag{13}$$

where the nonhomogenity b_2 can be approximated by using radial basis functions $f_j(x,y)$ as

$$\begin{aligned} b_2\left(m, c, \frac{\partial c}{\partial t}\right) &= \frac{\partial c}{\partial t} - \xi_c \left[\frac{\partial c}{\partial x}\frac{\partial n}{\partial x} + \frac{\partial c}{\partial y}\frac{\partial n}{\partial y} + c\nabla^2 n \right] - \mu_1 c(1-c-n) \\ &\approx \sum_{j=1}^{N+L} \beta_j(t) f_j(x,y) \end{aligned} \tag{14}$$

After the application of the Green's second identity and using the boundary condition (4), one has

$$[\bar{H}_c]c = [C]\left[\left\{ \tfrac{\partial c}{\partial t} \right\} - \mu_1 c(1-c-n) + \xi_c \left(\left[\tfrac{\partial F}{\partial x} \right] [F]^{-1} \{d_1\} + \left[\tfrac{\partial F}{\partial x} \right] [F]^{-1} \{d_2\} + c\{d_3\} \right) \right] \tag{15}$$

where $[\bar{H}_c] = D_c[H]$ and $\{d_1\}$, $\{d_2\}$ and $\{d_3\}$ contain the FDM discretizations of the vectors $\left\{ \frac{\partial n}{\partial x} c \right\}$, $\left\{ \frac{\partial n}{\partial y} c \right\}$ and $\left\{ \nabla^2 n \right\}$ vectors by using forward difference for the first order derivatives and central difference for the second order derivatives included in the Laplacian term. For the time discretization, as for the other equations in the model, a combination of the forward and backward Euler methods is used by making use of the updated values coming from Equations (11) and (12) are used. Finally the resulting discretized ODE can be written as

$$\left[(1 + \Delta t d_4) I - \Delta t \bar{H}_c \right] c^{k+1} = c^k + \Delta t \mu_1 c^k (1 - c^k - n^{k+1}) \tag{16}$$

The solution is thus obtained iteratively using discretized equations ((11), (12) and 16) starting from the initial condition (5).

4 Numerical Results

For the numerical simulations the domain is considered to be the unit square. The number of nodes are taken as 25 and 20 inside the region and on the boundary of the domain; respectively. The time step is taken to be $\Delta t = 0.1$. Initially it is assumed that the cancer

 ISBN: 978-84-617-8694-7

cells penetrate a short distance while the space is occupied mainly by the normal cells and since the MDEs are produced by the cancer cells its initial concentration is also assumed to be proportional to the initial cancer cell density (Figure 1) . The boundary conditions are the non-flux boundary conditions which are given by (4). The parameter ranges in [1] are used and the following parameters are fixed in calculations:

$$D_c = 10^{-4}, \quad D_m = 10^{-2}, \quad \delta = 10, \quad \mu_3 = 0.075 \quad \delta_m = 0.15$$

In the sets of Figures 2-4 the time evolution of cancer and normal cell densities and MDE concentration are shown. For the figures, except Figure 3, the haptotaxis coefficient is taken as $\xi_c = 0.002$ and $\xi_c = 0.01$ is taken in Figure 3. The production rates for the cancer and normal cells are taken as $\mu_1 = 0.3$ and $\mu_2 = 0.5$ in Figures 2, 3. In Figure 4 in order to see the effect of bigger proliferation rate for cancer cells, the proliferation rate is doubled, i.e. $\mu_1 = 0.6$ is taken.

In Figure 2 the general behaviour of the haptotaxis-only model (1)-(3) can be observed that as time evolves the cancer cells use the MDEs they produce to migrate through the region and invade more than 80 % of the region by $t = 50$. Moreover, the corresponding decay is visible in the normal cell density in Figures 2(d)-2(f).

In the next set of figures (Figure 3), the effect of haptotaxis coefficient is tested. The coefficient is increased by a factor of 5 in order to see the effect of haptotaxis on the invasion.In these figures the haptotactic hills are observed showing that the cells construct larger clusters at the leading edge of the tumour by the effect of increased haptotaxis.

In the last set of figures the effect of proliferation is analysed. One can observe that with a higher proliferation rate, the cancer cells invade more, with a larger cluster.

5 Conclusion

In this study, a numerical method is proposed for the haptotaxis-only model (1)-(3).In order to discretize the space derivatives in the model system, DRBEM is used with the fundamental solution of Laplace equation. However, the nonhomogenity for the cancer cell density contains the first and second order space derivatives and their products and to overcome this difficulty FDM is used in combination with DRBEM. The method is tested in a two dimensional region, which is not easy to handle numerically due to the nonlinearities. By using the boundary-only nature of DRBEM the proposed method gives consistent results with the expected behaviour of the model with a small number of discretization points.

Abstract

In this work a multi-step technique based on the Power method for accelerating the parallel computation of PageRank is proposed. This new iterative scheme reduces the computation of the PageRank vector by eliminating synchronization points at which a process must wait for information from other processes. A hybrid MPI/OpenMP parallel implementation of this technique has been developed. The performance of the parallel model has been analyzed with realistic test data, showing that the multi-step algorithms can significantly speed up the convergence time with respect to the parallel Power algorithm.

Key words: PageRank, multi-step method, parallel algorithms, shared memory, distributed memory

1 Introduction

The PageRank algorithm, used by the Google search engine, is one of the most known and influential algorithms for determining the relevance of Web pages [12]. The core of this algorithm involves using the Power method to compute successive iterates that converge to the principal eigenvector of the Markov chain representing the Web link graph. The algorithm makes use of two key ideas: first, that links between Web pages provide information about their importance, and second, that the relationship between importance and linking is recursive. Given an ordered set of n Web pages, we can summarize the links between

 ISBN: 978-84-617-8694-7

them by means of the adjacency matrix of the Web graph $G = [g_{ij}]_{i,j=1}^{n}$, with elements $g_{ij} = 1$ when there is a link from page j to page i, with $i \neq j$, and zero otherwise. From this matrix we can construct a transition matrix $P = [p_{ij}]_{i,j=1}^{n}$ as follows: $p_{ij} = \frac{g_{ij}}{c_j}$ if $c_j \neq 0$ and 0 otherwise, where $c_j = \sum_{i=1}^{n} g_{ij}$, $1 \leq j \leq n$, represents the number of out-links from a page j. For pages with a nonzero number of out-links, i.e., $c_j \neq 0$ for all j, $1 \leq j \leq n$, the matrix P is column stochastic. Thus each element of this matrix has values between 0 and 1, and the sum of the components of each column is 1. In this case, the PageRank vector can be obtained by solving $Px = x$. Since we are interested in a probability distribution, the sum of the components of x is assumed to be one. Algorithm 1 shows the original Power method [14] for the PageRank computation where $e = (1, 1, \ldots, 1)^T$. Note that we use the L_1 norm $\|x\|_1 = \sum_{i=1}^{n} |x_i|$.

Algorithm 1: Power method.

Initialization $x^{(0)} = \frac{e}{n}$, $l = 0$;
repeat
  $x^{(l+1)} = Px^{(l)}$;
  $\delta = \|x^{(l+1)} - x^{(l)}\|_1$;
  $l = l + 1$;
until $\delta < \epsilon$;

When the matrix $P \geq 0$ is irreducible (i.e., its graph is strongly connected) and stochastic, its largest eigenvalue in magnitude is $\lambda_{max} = 1$. Thus, Algorithm 1 converges to the eigenvector corresponding to $\lambda_{max} = 1$, and when normalized, it is the stationary probability distribution over pages under a random walk on the Web.

However, the Web contains many pages without out-links, called dangling nodes. Dangling pages present a problem for the mathematical PageRank formulation because in this case the matrix P is non-stochastic and therefore Algorithm 1 can not be used. Moreover, the matrix irreducibility is not satisfied for a Web graph. In order to overcome these difficulties, Page and Brin [12] change the transition matrix P to a column stochastic matrix $\bar{P} = \alpha(P + vd^T) + (1-\alpha)ve^T$, where $d \in \Re^n$ is the dangling page indicator defined by $d_i = 1$ if and only if $c_i = 0$ and the vector $v \in \Re^n$ is some probability distribution over pages. This model means that the random surfer jumps from a dangling page according to a teleportation distribution v. Originally uniform teleportation $v = \frac{e}{n}$ was used. Then, setting α such that $0 < \alpha < 1$, Algorithm 1 can be reformulated using the matrix $\bar{P}$, obtaining Algorithm 2.

A key parameter in this model is the damping factor α that determines the weight given to the Web link graph in the model. In the original formulation of PageRank [12], the Power method was applied using $\alpha = 0.85$. Notice that, a higher value of α (close to 1) yields to a model that is mathematically closer to the actual link structure of the

 ISBN: 978-84-617-8694-7

Algorithm 2: Power method for solving $\bar{P}x = x$.

Initialization $x^{(0)} = \frac{e}{n},\ l = 0$;
repeat
  $x^{(l+1)} = \alpha P x^{(l)}$;
  $\gamma = \|x^{(l)}\|_1 - \|x^{(l+1)}\|_1$;
  $x^{(l+1)} = x^{(l+1)} + \gamma v$;
  $\delta = \|x^{(l+1)} - x^{(l)}\|_1$;
  $l = l + 1$;
until $\delta < \epsilon$;

Web but makes the computation more difficult [8] being that this parameter α controls the asymptotic rate of convergence and as $\alpha \to 1$, the expected number of iterations required for convergence increases dramatically [10]. Therefore, new approaches for accelerating the PageRank computation are required.

In the last years, several techniques to accelerate the Power method have been developed such as extrapolation methods [7], adaptive methods [6] or Arnoldi-type algorithms [5, 15, 16] and approaches based on linear system formulations [3, 4, 13]. Due to the large size of the Web link graph, to deal with realistic problems, a promising way of accelerating PageRank is the parallel processing, see e.g., [1, 3, 4] and the references cited therein.

In this paper a multi-step technique based on the Power method for accelerating the parallel computation of PageRank is proposed. This technique aims to reduce the number of power iterations by eliminating synchronization points at which a process must wait for information from other processes. Section 2 describes this new iterative technique and its formulation in order to assure the convergence. Section 3 reports the experimental results showing the behavior of the designed algorithms for realistic test data on a current Symmetric Multi-Processing (SMP) supercomputer. Finally, in Section 4 we give some conclusions.

2 Multi-step Power Algorithm

Consider that P is partitioned into p row blocks of the form $P = \left[P_1^t\ P_2^t\ \cdots\ P_p^t\right]^t$, where each P_i, $1 \le i \le p$, is a matrix of order $n_i \times n$, with $\sum_{i=1}^{p} n_i = n$. Analogously, we consider the iterate vectors $x^{(l)}$ and v partitioned according to the block structure of P. Obviously, the Power method for solving $\bar{P}x = x$ can be executed in parallel. In this case each process actualizes a block of the vector $x^{(l+1)}$ and a synchronization of all processes is performed at each iteration in order to construct the global iterate vector $x^{(l+1)}$. Due to this synchronization, we can use the formulation of Algorithm 2 because the property of

preserving the L_1 norm remains valid.

In order to reduce the work involved in this iterative algorithm we propose a parallel multi-step Power (MSTEP) algorithm (Algorithm 3). In this algorithm each part of $x^{(l+1)}$ is updated more than once ($q > 1$ times) without waiting for the other parts of $x^{(l+1)}$ to be updated and therefore eliminating some synchronization points. In this case the condition of preserving the L_1 norm is not assured and therefore, Algorithm 2, in its current formulation, can not be used for our purpose. For this reason, Algorithm 3 has been formulated such that the condition on the L_1 norm is not needed.

Algorithm 3: Parallel multi-step method for solving PageRank (MSTEP).

Initialization $x^{(0)} = \frac{e}{n}, v = \frac{e}{n},\ q,\ l = 0;$
for $i = 1, 2, \ldots, p$, **do in parallel**
  repeat
    $y^{(0)} = x^{(l)};$
    for $k = 1, 2, \ldots, q$, **do**
      $y_i^{(k)} = \alpha P_i y^{(k-1)};$
      $\gamma = \alpha d^T y^{(k-1)} + (1-\alpha)\|y^{(k-1)}\|_1;$
      $y_i^{(k)} = y_i^{(k)} + \gamma v_i;$ **(1)**
      $y_j^{(k)} = y_j^{(k-1)},\ j \neq i\ ;$
    end
    $x_i^{(l+1)} = y_i^{(q)};$
    Perform an all-gather operation to obtain $x^{(l+1)} = [x_1^{(l+1)}, \ldots, x_p^{(l+1)}];$
    Compute $\|x_i^{(l+1)} - x_i^{(l)}\|_1;$
    Perform a sum all-to-all reduction over $\|x_i^{(l+1)} - x_i^{(l)}\|_1$ to obtain
    $\delta = \|x^{(l+1)} - x^{(l)}\|_1;$
    $l = l + 1;$
  until $\delta < \epsilon;$
  Compute $\|x_i^{(l)}\|_1;$
  Perform a sum all-to-all reduction over $\|x_i^{(l)}\|_1$ to obtain $\|x^{(l)}\|_1;$
  Compute $\pi_i = \frac{x_i^{(l)}}{\|x^{(l)}\|_1};$
  Perform a gather operation over π_i to obtain $\pi = \frac{x^{(l)}}{\|x^{(l)}\|_1}$ in a root process;
end

Note that a relaxation parameter $\beta > 0$ can be introduced in the MSTEP Algorithm (that is, in Algorithm 3) and replace the computation of $y_i^{(k)}$ in (1) with the equation

 ISBN: 978-84-617-8694-7

$y_i^{(k)} = \beta(y_i^{(k)} + \gamma v_i) + (1-\beta)y_i^{(k-1)}$. In this case we obtain a parallel relaxed multi-step algorithm, that we have called RMST Algorithm. Clearly, with $\beta = 1$ equation (1) is recovered.

3 Numerical experiments

In order to investigate and analyze the MSTEP and RMST algorithms described here, we have used several datasets of different sizes, available from the Laboratory for Web Algorithmics [9]; see Table 1. These transition matrices have been generated from a web-crawl [2].

Graph	n	nnz	Dgn (%)	Dens	M (GB)

Table 1: Graphs collection. n =number of nodes, nnz =number of arcs, Dgn=percentage of dangling nodes, Dens=density (arcs/nodes), M=memory requirements using CSR' format.

To compute PageRank for large domains there is no possible way to work with the matrix in its full format because the memory requirements would be too high. Therefore, to take advantage of the large number of zero elements, special schemes are required to store sparse matrices. The main goal is to represent only the nonzero elements, and to be able to perform the common matrix operations. The modified Compressed Sparse Row (CSR') format used for storing the sparse matrices [11] has involved a reduction of memory requirements of about $63-73\%$ with respect to the original CSR format.

The algorithms described here have been implemented on an HPC cluster of 26 nodes HP Proliant SL390s G7 connected through a network of low-latency QDR Infiniband-based. Each node consists of two Intel XEON X5660 hexacore at up to 2.8 GHz and 12MB cache per processor, with 48 GB of RAM. The operating system is CentOS Linux 5.6 for x86 64 bit. The parallel environment has been managed using a hybrid MPI/OpenMP model: each process is assigned to a core as follows: let p be the number of physical cores used, $p = s \times c$ indicates that s nodes of the parallel platform have been used and for each one of these nodes, c cores have been considered. Therefore, we use a philosophy of distributed shared memory (DSM) using $p = s \times c$ processes or threads. Particularly, if $s = 1$, the algorithms are executed in shared memory (SM) using $p = c$ cores on a single node. Conversely, if $c = 1$, we are working on distributed memory (DM) using $p = s$ nodes.

Figure 1: Performance of parallel MSTEP and RMST algorithms, shared versus distributed memory, $\epsilon = 10^{-6},\ \beta = 0.99,\ \alpha = 0.99$.

The most expensive operation of these algorithms is the matrix-vector product. This is a perfectly parallel operation with several possible methods for partitioning both the matrix and the vector. In the link matrices used to calculate PageRank, the number of nonzero elements per row can differ immensely. In order to balance the calculations, a nonzero elements partitioning is used, where each node has to handle approximately the same amount of nonzero elements. Generally, for the PageRank calculations, this distribution strategy behaves better than row-wise distributions; see e.g. [1].

In the experiments reported here, we have used for the stopping criterion $\epsilon = 10^{-6}$, and we have run our algorithms for several values of α and β. The notation MSTEP(q) indicates that q steps are used in Algorithm 3. Similar notation is used for the RMST method. The synchronization points in the MSTEP methods are reduced in relation to the Power method as the number of steps q, in Algorithm 3, increases. However, applying a certain number of q steps in this algorithm without waiting for the update of other parts of the global iterate vector, is more computationally intense than applying one iteration of the Power method. As long as this overhead is minimal, the proposed acceleration is beneficial. Therefore, we must keep q small in Algorithm 3. Good choices of q, for this algorithm and its relaxed counterpart, are between 2 and 4. Tables 2 and 3 illustrate the gain obtained by these methods in relation to the parallel Power method varying the number of processes on both distributed and distributed shared memory, and using several values of α. Good choices of the relaxation parameter β, in the proposed RMST algorithms, are between 0.98 and 0.99. In these tables we have chosen $\beta = 0.98$. As it can be seen, the proposed algorithms can significantly speed up the convergence time relative to the parallel Power method, more specially for values of α close to 1. In fact, for $\alpha = 0.99$, the RMST algorithms achieve a gain in relation to the parallel Power method between 15.89% and 38.55% using 2 processes, while using 32 processes, the achieved gain by means of these algorithms was between 43.91% and 68.71%.

Table 4: Multistep versus In/Out methods, uk-2007-05, SM $p = 8$ (1×8), $\alpha = 0.99$.

Figures 1 and 2 compare the parallel algorithms treated herein in floating-point operations per second (Flops) for several configurations. We obtain an acceptable performance using the 12 available cores of one node but not comparable with the performance obtained using distributed memory.

However, to deal with larger problems, the strategies of parallelization require to use at the same time the benefits of shared and distributed memory. Generally, the best parallel results have been obtained for the RMST algorithms using from 1 to 4 cores in each node. Table 4 compares, using several values of ϵ for the stopping criterion, the multi-step algorithms treated here with the inner-outer methods proposed in [3]. As it can be seen, the parallel RMST algorithms accelerate the PageRank computation more significantly than these parallel inner-outer algorithms.

4 Conclusions

In this paper a multi-step technique based on the Power method for accelerating the parallel computation of PageRank is proposed. This technique aims to reduce the number of power iterations by eliminating synchronization points at which a process must wait for information from other processes. The parallel implementation has been developed using a mixed MPI/OpenMP model to exploit parallelism beyond a single level. In order to investigate and analyze the parallel MSTEP and RMST algorithms described here, we have used several realistic large datasets. Taking into account the characteristics of the transition matrices, a modified Compressed Sparse Row format has been used to store these sparse matrices that has involved a reduction of memory requirements of about $63 - 73\%$ with respect to the popular CSR format. In order to balance the calculations among nodes, a nonzero elements partitioning is used, where each node has to handle the same amount of nonzero elements. The numerical experiments show that these new parallel algorithms can considerably improve the convergence rate relative to the Power method.

Abstract

This paper extends some results on the existence, uniqueness, and stability of a Nash equilibrium in a distributed, negotiated decision process with a class of quadratic convex functions. Based on these results, it is derived the optimal decision of any given player when all the others act as its opponents. Furthermore, the paper conjectures the properties of the Nash equilibrium for the case with constrained decisions, provided the existence of a unique, stable Nash equilibrium for the equivalent unconstrained problem.

1 Introduction

Nowadays, it is becoming more and more frequent the shift from centralized to distributed or agent-based decision making, which finds important applications such as energy management in electrical grids, robotic systems, or cloud computing. Typically, each of these agents (also called players) has its local cost function and, therefore, the very definition of *optimal decisions* gets blurred and is replaced by concepts like Pareto efficiency and Nash equilibrium. On the one hand, a set of decisions is Pareto optimal when it is not possible to make any player better off without making at least another one worse off. On the other hand, a Nash equilibrium is a set of decisions that every player maintains if the decision of the others do not change. It is known that in general Nash equilibriums are not-Pareto efficient, but in negotiated competitive situations, Pareto optimals are commonly unstable, see [1].

 ISBN: 978-84-617-8694-7

This paper studies some interesting properties of a the distributed negotiation process in the work [2], which introduced conditions for the existence, uniqueness, and stability of a Nash equilibrium in a distributed, negotiated decision process with a class of quadratic convex functions. First, it is derived the optimal decision of any player when the goal of the rest of them consist of trying to harm it by maximizing its cost function. After that, the paper conjectures, based on simulation results, the existence and location of a unique Nash equilibrium for the case with constrained decisions, provided the existence of a unique, stable Nash equilibrium for the equivalent unconstrained problem.

2 Problem description

Consider a game-theoretical scenario defined over a set of p players, $i = 1, 2, \ldots, p$, connected through a network described by an undirected graph $G = (V, E)$, with vertexes $V = \{1, 2, \ldots, p\}$ and edges $E \subseteq V \times V$.

At each negotiation step k, each player makes its decision by minimizing an associated quadratic cost function $J_i(k) \triangleq \mathbf{x_i}(k)^\top A_i \mathbf{x_i}(k) - 2\mathbf{x_i}(k)^\top \Big(\mathbf{b_i} + \sum_{j \in N_i} C_{ij}\mathbf{x_j}(k-1)\Big)$, where $\forall i \in V$, $A_i \in \mathbb{R}^{q_i \times q_i}$ is a diagonal positive definite matrix, $\mathbf{b_i} \in \mathbb{R}^{q_i}$ is a vector and $C_{ij} \in \mathbb{R}^{q_i \times q_j}$ are matrices of appropriate dimensions, N_i is the set comprised by those players connected with player i, and $\mathbf{x_j}(k-1)$ are the decisions made and communicated by other players at the previous negotiation step.

Definition 1. A Nash equilibrium is a situation in which no player changes its decisions as long as the rest of the players keep the same decisions as well. It is defined by a set of decisions $x^* \triangleq \left[\mathbf{x_1^*}^\top \; \mathbf{x_2^*}^\top \; \cdots \; \mathbf{x_p^*}^\top\right]^\top$ such that $\mathbf{x_i^*} = arg\min_{\mathbf{x_i}} \; \mathbf{x_i}^\top A_i \mathbf{x_i} - 2\mathbf{x_i}^\top \left(\mathbf{b_i} + \sum_{j \in N_i} C_{ij}\mathbf{x_j^*}\right), \forall i.$

Throughout this paper, if A is a matrix and $\mathbf{b}$ is a vector, then $[A]_{ij}$ is the element at the i-th row and j-th column of matrix A, and $[\mathbf{b}]_i$ is the i-th element of vector $\mathbf{b}$.

3 The unconstrained case

This section studies the case with unconstrained decision variables. In this case, at every negotiation step k, the decisions that minimize the cost $J_i(k)$ can be found by determining $\mathbf{x_i}(k)$ such that $\frac{\partial J_i(k)}{\partial \mathbf{x_i}(k)} = 0$, since functions $J_i(k)$ are convex with respect to $\mathbf{x_i}(k)$.

Let us define $\mathcal{A} \triangleq diag\{A_1, A_2, \ldots, A_p\}$, $\mathcal{C} \triangleq [c_{ij}]$, where $C_{ij} \equiv 0$ if edge $(i, j) \notin E$. It was stated in [2] that the game admits a unique Nash equilibrium x^*, given by $x^* = (I - \mathcal{A}^{-1}\mathcal{C})^{-1}\mathcal{A}^{-1}\mathcal{b}$ iff $\det(I - \mathcal{A}^{-1}\mathcal{C}) \neq 0$ holds. The equilibrium x^* is globally asymptotically stable iff the eigenvalues of matrix $\mathcal{A}^{-1}\mathcal{C}$ belong to the unit circle.

 ISBN: 978-84-617-8694-7

Let us move now to the particular situation in which agent i takes a decision assuming that the rest of the players' objective is $J_j(k) = -J_i(k), \forall j$. This represents a competitive situation in which agent i decides its options taking into account that the other players are opponents pursuing to damage agent i. We study the max-min optimization problem, since agent i takes a decision before the rest of the players.

Theorem 1 *Consider the max-min problem in which agent i minimizes J_i and, later on, the rest of agents maximize the same cost function. Then, if $rank\,[C_{i1}\dots C_{ip}] \leq q_i$ holds, the optimal decision for player i taking into account every possible decision of the other players can be obtained as $\mathbf{x_i^*} = arg\min \mathbf{x_i}^\top A_i \mathbf{x_i} - 2\mathbf{x_i}^\top \mathbf{b_i}$ subject to $[C_{i1}\dots C_{ip}]^\top \mathbf{x_i}$. Otherwise, the optimal decision is the trivial one, that is, $\mathbf{x_i^*} = \mathbf{0}$.*

When $rank\,[C_{i1}\dots C_{ip}] \leq q_i$ holds, agent i can choose its decision in such a way that J_i is minimized for any decision of the other players.

Example 1 *Consider a two-player game with* $A_1 = \begin{pmatrix} 3 & 0 \\ 0 & 5 \end{pmatrix}, b_1 = \begin{pmatrix} 1 \\ 3 \end{pmatrix}, C_{12} = \begin{pmatrix} -5 \\ 2 \end{pmatrix}$. *Figure 1 illustrates the paraboloids for agent* 1 *at instant k for three decisions made by player 2 at $k-1$. Since this example satisfies the condition in Theorem 1 ($rank\,[C_{12}] = 1$,$q_1 = 2$), we see that there exists a region of the state-space (the intersection between the paraloboloids) different to the origin that is a solution for the max-min problem. The minimum of the cost is marked with a red dot. The reader can check that this minimum is lower that that obtained with the trivial decision, in a green dot.*

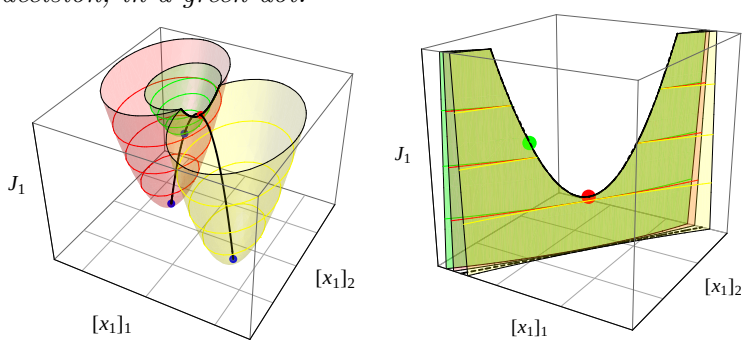

Figure 1: Paraboloids of J_1 for different $x_2(k-1)$ and its intersection.

4 The constrained case

Let us consider now the situation in which the decision variables are subjected to some restrictions. In this case, each player must find its decision vector $\mathbf{x_i}(k)$ by solving the optimization problem $\min_{\mathbf{x_i}(k)} J_i$, subject to $[\underline{\mathbf{x}}_\mathbf{i}]_l \leq [\mathbf{x_i}(k)]_l \leq [\overline{\mathbf{x}}_\mathbf{i}]_l$, $\forall l \in \{1, 2\dots, q_i\}$, where

 ISBN: 978-84-617-8694-7

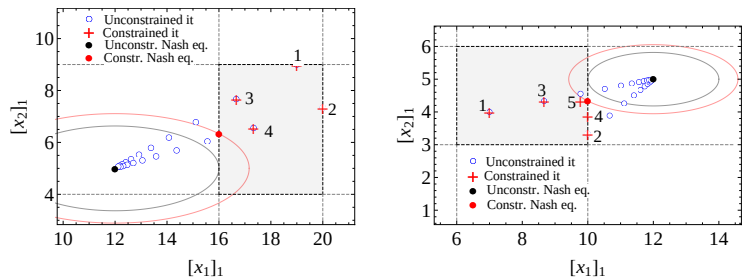

Figure 2: Decisions of both players for the constrained and unconstrained cases.

$\underline{\mathbf{x}}_\mathbf{i}$,$\overline{\mathbf{x}}_\mathbf{i}$ are two vectors containing the minimum and maximum bounds, respectively, for each decision variable.

It was proved in [2] that the constrained negotiation will converge to the Nash equilibrium for the unconstrained game provided that i) this Nash equilibrium belongs to the feasible set, and ii) the system $\tilde{y}(k+1) = \mathcal{A}^{-1}\mathcal{C}\tilde{y}(k)$ admits a quadratic Lyapunov fuction (QLF) with associated matrix P. The next example studies, nonetheless, the situation in which condition i) is not satisfied.

Example 2 *Consider a two-player game with one variable to optimize. The cost functions are described by* $A_1 = 1,\ b_1 = 2,\ C_{12} = 2;\ A_2 = 3,\ b_2 = 3,\ C_{21} = 1$. *Figure 2 shows two negotiation for different feasible sets. Note that the negotiation converges to an equilibrium although the Nash equilibrium for the unconstrained game is outside the feasible set.*

Conjecture 1 *There exists a unique Nash equilibrium for the constrained negotiation when the equivalent unconstrained problem has a unique Nash equilibrium outside of the feasible region. The Nash equilibrium belongs to the border of the feasible set, but it is not the point with minimum* P*-norm, being* P *the associated Lyapunov matrix for the unconstrained game.*

Abstract

This work concerns to third order impulsive problems with the fully nonlinear equation

$$u'''(x) = f(x, u(x), u'(x), u''(x))$$

for a.e. $x \in [0,1] \setminus \{x_1, ..., x_m\}$ where $f : [0,1] \times \mathbb{R}^4 \to \mathbb{R}$ is a L^1-Carathéodory function, the periodic boundary conditions

$$u^{(i)}(0) = u^{(i)}(1), \ i = 0, 1, 2,$$

and the impulsive effects given by the generalized functions

$$u^{(i)}\left(x_j^+\right) = I_{ij}\left(u(x_j), u'(x_j), u''(x_j)\right),$$

with $i = 0, 1, 2$, $x_j \in (0,1)$, for $j = 1, ..., m$, such that $0 = x_0 < x_1 < ... < x_m < x_{m+1} = 1$, and $I_{ij} : \mathbb{R}^3 \to \mathbb{R}$ are continuous and nondecreasing functions in all variables.

1 Introduction

This paper presents a nonlinear periodic third order impulsive problem composed by the fully differential equation

$$u'''(x) = f\left(x, u(x), u'(x), u''(x)\right) \tag{1}$$

for a.e. $x \in J \backslash \{x_1, ..., x_m\}$ with $J := [0,1]$, where $f : J \times \mathbb{R}^3 \to \mathbb{R}$ is a L^1-Carathéodory function, the periodic boundary conditions

$$u^{(i)}(0) = u^{(i)}(1), \ i = 0, 1, 2, \tag{2}$$

and the impulsive effects given by some generalized function in the form

$$u^{(i)}\left(x_j^+\right) = I_{ij}\left(u(x_j), u'(x_j), u''(x_j)\right), \tag{3}$$

where $i = 0, 1, 2$, $x_j \in (0,1)$, for $j = 1, ..., m$, such that $0 = x_0 < x_1 < ... < x_m < x_{m+1} = 1$ and $I_{ij} : \mathbb{R}^3 \to \mathbb{R}$ are continuous and nondecreasing functions in all variables.

Different types of third order boundary value problems (separated, periodic, multipoint, with delays, integro-differential, functional,...) have been studied by many authors and several methods, such as fixed point theory, topological and coincidence degree, lower and upper solutions, cone theory,..., and can describe real phenomena in medicine, physics, agriculture, biology, economics,...(see, for example, [2, 3, 4] and the references therein).

Impulsive problems are particularly well adapted to models where there are sudden changes at some moments, and they have been the subject of growing interest (see, for instance, [5, 6]). These jump situations may happen in many fields, such as, population dynamics, control theory, chemistry, ...

To our best knowledge, it is the first time where third order periodic impulsive problems are considered with the instantaneous changes, depending on the unknown function and its first and second derivatives, given by generalized functions. In this way, problem (1)-(3) covers cases where the jumps in each moment depend not only on the value of the function on this instant, but also on the velocity and the convexity of the solution in the referred moment.

The main tools rely on a perturbed and truncated auxiliary problem, on an iterative technique, not necessarily monotone, as in [1], and lower and upper solutions method. We

 ISBN: 978-84-617-8694-7

point out that, the nonlinear part must verify only a local monotone condition (see (11)) and no assumption on its periodicity or asymptotic growth is needed.

In Section 2 we describe the class of functions to be considered and an explicit expression for the solution of the associated linear problem. Section 3 contains the main result: an existence and localization theorem, that is, with some qualitative information on the solution. In Section 4 we present an example to illustrate the potentialities of the main theorem.

2 Definitions and auxiliary results

In this section we present some notations, definitions and auxiliary results, to be used forward.

For $m \in \mathbb{N}$, let $0 = x_0 < x_1 < ... < x_m < x_{m+1} = 1$, $D = \{x_1, ..., x_m\}$ and

$$u(x_j^{\pm}) := \lim_{x \to x_j^{\pm}} u(x).$$

Definition 1 *Denote by $PC(J)$ the set of functions $u : J \to \mathbb{R}$ continuous on $J \setminus D$ where $u\left(x_j^+\right)$ and $u\left(x_j^-\right)$ exist with $u\left(x_j^-\right) = u(x_j)$, for $k = 1, 2, ..., m$.*

For $u \in PC(J)$, we define the norm by

$$\|u\| = \sup_{x \in J} |u(x)|.$$

Consider $PC^l(J)$, $l = 1, 2$, as the space of the real-valued functions u, such that $u^{(l)} \in PC(J)$, $u^{(l)}\left(x_j^+\right)$ and $u^{(l)}\left(x_j^-\right)$ exist with $u^{(l)}\left(x_j^-\right) = u^{(l)}(x_j)$, for $l = 0, 1, 2$ and $j = 1, 2, ..., m$.

Therefore $u \in PC^2(J)$ can be written as

$$u(x) = \begin{cases} u_0(x) & \text{if } x \in [0, x_1], \\ u_1(x) & \text{if } x \in (x_1, x_2], \\ \vdots & \\ u_m(x) & \text{if } x \in (x_m, 1], \end{cases} \tag{4}$$

 ISBN: 978-84-617-8694-7

where $u_i := u_i|_{(x_i,x_{i+1}]}$ with $u_i \in C^2(x_i, x_{i+1}]$ for $i = 0, 1, ..., m$.

Denote, for $n \in \mathbb{N}$,

$$PC_D^n(J) = \left\{ u \in PC^n(J) : u^{(n)} \in AC(x_i, x_{i+1}],\ i = 0, 1, ..., m \right\}$$

and for each $u \in PC_D^n(J)$ we set the norm

$$\|u\|_D = \|u\| + \left\|u'\right\| + \cdots + \left\|u^{(n)}\right\|$$

Moreover for $p \in L^1(J)$ we consider the usual norm

$$\|p\|_1 := \int_J |p(t)|\, dt.$$

Throughout this paper the following hypothesis will be assumed :

(H1) $f : [0,1] \times \mathbb{R}^3 \to \mathbb{R}$ is a L^1-Carathéodory function, that is, $f(x, \cdot, \cdot, \cdot)$ is a continuous function for a. e. $x \in J$;

$f(\cdot, y_0, y_1, y_2)$ is measurable for $(y_0, y_1, y_2) \in \mathbb{R}^3$; and for every $M > 0$ there is a real-valued function $\psi_M \in L^1([0,1])$ such that

$$|f(x, y_0, y_1, y_2)| \leq \psi_M(x), \text{ for a. e. } x \in [0,1]$$

and for every $(y_0, y_1, y_2) \in \mathbb{R}^3$ with $|y_i| \leq M$, for $i = 0, 1, 2$;

(H2) the real valued functions I_{ij}, for $i = 0, 1, 2$ and $j = 1, ..., m$ are nondecreasing in all variables.

Definition 2 *A function $u \in PC_D^2(J)$ is a solution of (1)-(3) if it satisfies (1) almost everywhere in $J \setminus D$, the periodic conditions (2) and the impulse conditions (3).*

Next Lemma will give the unique solution for a linear Cauchy problem..

Lemma 3 *et $p : [0,1] \times \mathbb{R} \to \mathbb{R}$ be a L^1-Carathéodory function. Then for each interval $(x_j, x_{j+1}]$, $j = 0, 1, ..., m$, and a_j, b_j, $c_j \in \mathbb{R}$, the initial value problem composed by the equation*

$$u'''(x) = p(x), \text{ for } x \in (x_j, x_{j+1}] \tag{5}$$

 ISBN: 978-84-617-8694-7

and the conditions

$$u\left(x_j^+\right) = a_j, \quad u'\left(x_j^+\right) = b_j, \quad u''\left(x_j^+\right) = c_j, \tag{6}$$

has a unique solution $u_j \in C^2(x_j, x_{j+1}]$, *given by*

$$u_j(x) = a_j + b_j\,(x - x_j) + c_j \frac{(x - x_j)^2}{2} + \int_{x_j}^{x} \frac{(x - r)^2}{2} p\,(r)\,dr. \tag{7}$$

Therefore, $u \in PC_D^2\,(J)$, *given by (4), is the unique solution of*

$$u'''\,(x) = p\,(x)\,, \text{ for a.e. } x \in [0, 1], \tag{8}$$

verifying (6), for each $j = 0, 1, ..., m$.

The solution $u(x)$ given by (7) can be obtained by iterate integrations of (5).
Strict lower and upper solutions are defined by the following inequalities:

Definition 4 *A function* $\alpha \in PC_D^3\,(J)$ *is said to be a strict lower solution of the problem (1)-(3) if:*

(i) $\alpha'''\,(x) < f\,(x, \alpha\,(x)\,, \alpha'\,(x)\,, \alpha''\,(x))$, *for a.e.* $x \in (0, 1)\,.$

(ii) $\alpha\,(0) \leq \alpha\,(1)\,, \quad \alpha'\,(0) \leq \alpha'\,(1)\,, \quad \alpha''\,(0) \leq \alpha''\,(1)\,,$

(iii) $\alpha\left(x_j^+\right) \leq I_{0j}\,(\alpha(x_j), \alpha'(x_j), \alpha''(x_j))\,,$
$\alpha'\left(x_j^+\right) \leq I_{1j}\,(\alpha\,(x_j)\,, \alpha'\,(x_j)\,, \alpha''\,(x_j))\,,$
$\alpha''\left(x_j^+\right) \leq I_{2j}\,(\alpha(x_j), \alpha'(x_j), \alpha''(x_j))$

A function $\beta \in PC_D^3\,(J)$ *is a strict upper solution of problem (1)-(3) if the reversed inequalities hold.*

 ISBN: 978-84-617-8694-7

3 Existence and localization result

The main theorem provides not only the existence of a solution, but also gives some qualitative data about its behavior:

Theorem 5 *Let $\alpha, \beta \in PC_D^2(J)$ be, respectively, lower and upper solutions of (1)-(3) such that*

$$\alpha''(x) \leq \beta''(x) \text{ on } J \setminus D \tag{9}$$

and

$$\alpha^{(i)}(0) \leq \beta^{(i)}(0), \ i = 0, 1. \tag{10}$$

Assume that

$$f\left(x, \alpha, \alpha', y_2\right) \leq f(x, y_0, y_1, y_2) \leq f\left(x, \beta, \beta', y_2\right), \tag{11}$$

for fixed $(x, y_2) \in J \times \mathbb{R}$, $\alpha^{(i)} \leq y_i \leq \beta^{(i)}$, for $i = 0, 1$.

If conditions (H1) and (H2) hold, then the problem (1)-(3) has a solution $u(x) \in PC_D^2(J)$, such that

$$\alpha^{(i)}(x) \leq u^{(i)}(x) \leq \beta^{(i)}(x), \text{ on } J, \text{ for } i = 0, 1, 2.$$

Remark 6 *As one can notice by (10), the inequalities $\alpha^{(i)}(x) \leq \beta^{(i)}(x)$ hold for $i = 0, 1, 2$, and every $x \in J$.*

Consider the following modified problem composed by the equation

$$u'''(x) = f\left(x, \delta_0(x, u(x)), \delta_1\left(x, u'(x)\right), \delta_2\left(x, u''(x)\right)\right), \tag{12}$$

for $x \in (0, 1)$ and $x \neq x_j$ where the continuous functions $\delta_i : \mathbb{R}^2 \to \mathbb{R}$, for $i = 0, 1, 2$ are given by

$$\delta_i(x, y_i) = \begin{cases} \beta^{(i)}(x) & , \quad y_i > \beta^{(i)}(x) \\ y_i & , \quad \alpha^{(i)}(x) \leq y_i \leq \beta^{(i)}(x) \\ \alpha^{(i)}(x) & , \quad y_i < \alpha^{(i)}(x) \end{cases} \tag{13}$$

with the boundary conditions (2) and the impulse conditions (3).

 ISBN: 978-84-617-8694-7

To prove the existence of solution for the problem (12),(2),(3) we apply an iterative technique, not necessarily monotone. Let $(u_n)_{n\in\mathbb{N}}$ be the sequence in $PC^2_D(J)$ defined as follows

$$u_0(x) = \alpha(x), \tag{14}$$

and for $n = 1, 2, ...$ the problem composed by the equation

$$u'''_n(x) = f\left(x, \delta_0\left(x, u_{n-1}(x)\right), \delta_1\left(x, u'_{n-1}(x)\right), \delta_2\left(x, u''_n(x)\right)\right), \tag{15}$$

for a.e. $x \in [0,1]$, with the boundary conditions

$$u_n(0) = u_{n-1}(1), \quad u'_n(0) = u'_{n-1}(1), \quad u''_n(0) = u''_{n-1}(1), \tag{16}$$

and the impulsive conditions, for $j = 1, ..., m$,

$$\begin{aligned} u_n\left(x_j^+\right) &= I_{0j}\left(u_{n-1}(x_j), u'_{n-1}(x_j), u''_{n-1}(x_j)\right), \\ u'_n\left(x_j^+\right) &= I_{1j}\left(\delta_0(x_j, u_{n-1}(x_j)), u'_{n-1}(x_j), u''_{n-1}(x_j)\right), \\ u''_n\left(x_j^+\right) &= I_{2j}\left(\delta_0(x_j, u_{n-1}(x_j)), \delta_1\left(x_j, u'_{n-1}(x_j)\right), u''_{n-1}(x_j)\right), \end{aligned} \tag{17}$$

Remark that the initial conditions (16) are a particular case of the initial conditions (6). In fact

$$\begin{aligned} u_n(0) &= u_n(x_0) = u_{n-1}(1) := a_0, \\ u'_n(0) &= u'_n(x_0) = u'_{n-1}(1) := b_0, \\ u''_n(0) &= u''_n(x_0) = u''_{n-1}(1) := c_0. \end{aligned}$$

Therefore, by Lemma 3, the sequence $(u_n)_{n\in\mathbb{N}}$, is well defined.

Remark that the initial value problem (15)-(17) will become the periodic impulsive problem (1)-(3), if the two following claims hold:

- *Every solution $u_n(x)$ of the problem (15)-(17) verifies*

$$\alpha^{(i)}(x) \le u_n^{(i)}(x) \le \beta^{(i)}(x), \text{ for } i = 0, 1, 2,$$

 ISBN: 978-84-617-8694-7

for all $n \in \mathbb{N}$ *and every* $x \in J$, *which implies that*

$$\delta_i\left(x, u_n^{(i)}(x)\right) = u_n^{(i)}(x), \text{ for } i = 0, 1, 2, \ n \in \mathbb{N} \text{ and every } x \in J,$$

and, consequently, (15) become

$$u_n'''(x) = f\left(x, u_{n-1}(x), u_{n-1}'(x), u_n''(x)\right), \text{ for a.e. } x \in [0,1].$$

- *There is a subsequence of* $(u_n)_{n\in\mathbb{N}}$, *denoted by simplicity as* (u_n), *uniformly convergent to* $u \in PC_D^2$, *solution of problem (1)-(3).*

4 Example

Consider the third order fully differential equation

$$u'''(x) = e^{u(x)} + \left(u'(x)\right)^3 - 280\sqrt[5]{u''(x)}, \tag{18}$$

with the periodic boundary conditions (2) and the impulsive functions

$$\begin{aligned} u\left(\frac{1}{2}^+\right) &= \frac{1}{10}u\left(\frac{1}{2}\right) + \frac{1}{100}\left[u'\left(\frac{1}{2}\right) + u''\left(\frac{1}{2}\right)\right], \\ u'\left(\frac{1}{2}^+\right) &= \frac{1}{10}\left[u\left(\frac{1}{2}\right) + u'\left(\frac{1}{2}\right) + u''\left(\frac{1}{2}\right)\right], \\ u''\left(\frac{1}{2}^+\right) &= \frac{1}{5}\left[u\left(\frac{1}{2}\right) + u'\left(\frac{1}{2}\right)\right] + \frac{1}{10}u''\left(\frac{1}{2}\right). \end{aligned} \tag{19}$$

This problem is a particular case of (1)-(3) with

$$f(x, y_0, y_1, y_2) = e^{y_0} + (y_1)^3 - 280\sqrt[5]{y_2},$$

for all $x \in [0,1] \setminus \left\{\frac{1}{2}\right\}$, $m = 1$, $x_1 = \frac{1}{2}$ and the nondecreasing functions I_{i1}, $i = 0, 1, 2$, are given by

$$\begin{aligned} I_{01}(a,b,c) &= \frac{1}{10}a + \frac{1}{100}(b+c), \\ I_{11}(a,b,c) &= \frac{1}{10}(a+b+c), \\ I_{21}(a,b,c) &= \frac{1}{5}(a+b) + \frac{1}{10}c. \end{aligned} \tag{20}$$

 ISBN: 978-84-617-8694-7

The piecewise continuous $\alpha, \beta \in PC_D^2(J)$, with $D = \left\{\frac{1}{2}\right\}$, defined as

$$\alpha(x) = \begin{cases} -x^2 - 2x - 2 & , \ x \in \left[0, \frac{1}{2}\right] \\ -x^2 - \frac{1}{4} & , \ x \in \left(\frac{1}{2}, 1\right] \end{cases}$$

and

$$\beta(x) = \begin{cases} x^2 + 4x + 3 & , \ x \in \left[0, \frac{1}{2}\right] \\ x^2 + \frac{x}{2} + \frac{1}{4} & , \ x \in \left(\frac{1}{2}, 1\right] \end{cases},$$

are lower and upper solutions, respectively, for problem (18), (2), (19), assuming

$$\alpha'(x) = \begin{cases} -2x - 2 & , \ x \in \left[0, \frac{1}{2}\right] \\ -2x & , \ x \in \left(\frac{1}{2}, 1\right] \end{cases}, \quad \beta'(x) = \begin{cases} 2x + 4 & , \ x \in \left[0, \frac{1}{2}\right] \\ 2x & , \ x \in \left(\frac{1}{2}, 1\right] \end{cases},$$

and $\alpha''(x) = -2$, $\beta''(x) = 2$, for $x \in [0, 1]$.

As f satisfies assumption (H_1) and (11), the jump functions (20) verify (H_2), then, by Theorem 5 there is a periodic solution $u(x) \in PC_D^2(J)$ of problem (18), (2), (19), such that

$$\alpha^{(i)}(x) \leq u^{(i)}(x) \leq \beta^{(i)}(x), \text{ for } i = 0, 1, 2. \tag{21}$$

Remark that this solution can not be a trivial periodic one, as constants do not verify (18).

Abstract

Synthetic jet actuators (SJA) consist of a cavity with a mechanically moving diaphragm, whose actuation causes external fluid to enter and leave through a small orifice resulting in a net jet able to transfer of kinetic energy and momentum to a fluid medium without the addition of external flow. They are are expected to play a key role in active flow control (the application that motivates the present study), cooling and mixing.

This paper is focused on the interaction between the flow inside the actuator cavity and the external flow. Solving the coupling between the internal and external flows adds considerable complication and cost. It would be of interest to characterize the SJA outlet velocity and implement it as a boundary condition. To investigate the accuracy of this approach, an impinging jet configuration has been implemented with three different models: cavity and moving surface, cavity and imposed velocity and imposed velocity at the outlet. Time and phase averages of the external flows obtained with the different implementations are compared, and the effect of three different models is discussed.

Key words: AFC, synthetic jets, computational fluid dynamics, impingement

1 Introduction

Synthetic Jet (or Zero Net Mass Flow) actuators [1–6] consist of a cavity with a mechanically moving diaphragm (or piston). Its actuation changes the cavity volume periodically, causing external fluid to enter and leave through a small slot.

The expelled fluid creates a shear layer that rolls up forming vortices. Under certain conditions [7,8], when the cavity volume increases again they are too far to be ingested back, and therefore a train of vortices is created without the addition of mass flux. This property allows the transfer of kinetic energy and momentum to a fluid medium without the need of piping systems. This finds important applications in different areas such as active flow control (AFC) [9, 10], heat transfer enhancement [11, 12] and mixing enhancement [13, 14].

The flow patterns resulting from the interaction of the currents entering and leaving the cavity is very complex and have been the subject of many numerical and experimental studies. To mention just a few: [2] studied an incompressible laminar and turbulent Synthetic Jet using a URANS model (Spalart-Allmaras), assuming it to be two-dimensional. [17] performed a DNS three-dimensional periodic simulations of a synthetic jet previously analyzed with PIV [18]. [11] performed an experimental investigation on two-dimensional impinging synthetic jets and managed to successfully separate the effects of the Reynolds and Stokes numbers.

The present work is focused on the interaction between the external flow and the SJA internal flow. In the ingestion phase, vorticity, turbulent kinetic energy and passive scalars (such as temperature or concentration of chemical species) enter again the cavity where they interact with the internal flow before being expelled. These effects, together with the moving membrane and the large size difference between the actuator and the external flow, add considerable complication and cost to the simulation of the devices.

Different models have been used to model flows with a SJA. In decreasing order of computational cost, they are:

- Model M1: the internal SJA flow is simulated and the movement of the membrane is described in a realistic way [15, 21, 22].

- Model M2: the internal flow is simulated but the time derivative of the membrane position respect to the bottom of the cavity is used as a velocity boundary condition [17]. With this approach it is difficult to assign correct values for turbulent quantities or passive scalars at the membrane during the expulsion cycle.

- Model M3: The cavity flow is not simulated and a SJA outlet velocity is imposed [23, 24]. Probably this is most used approach active flow control applications.

The goal of this paper is to compare the different SJA models, to assess up to which point it is necessary to simulate the jet actuator cavity, and to analyze the effect of considering or not a realistic membrane movement in the simulation. To do so, the discharge and impingement of a SJA into a hot wall is studied.

 ISBN: 978-84-617-8694-7

1.1 Governing numbers and phenomenology

For laminar flows, the incompressible Navier-Stokes equations are used to model the SJA flow. In dimensionless form they are:

$$\frac{\partial u_j}{\partial x_j} = 0, \tag{1}$$

$$\mathrm{Sr}\frac{\partial u_i}{\partial t} + \frac{\partial (u_i u_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\frac{1}{Re}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right], \tag{2}$$

$$\mathrm{Sr}\frac{\partial T}{\partial t} + \frac{\partial (u_j T)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\frac{1}{Re\,Pr}\frac{\partial T}{\partial x_j}\right]. \tag{3}$$

For the case of turbulent flows, even at the moderate Reynolds numbers, the computing cost associated with the direct integration of Navier-Stokes equations (DNS) [33] is too high, specially considering that (as will be seen) a large number of actuator cycles has to be solved to reach a stationary state. Instead, a URANS approach is used, where the turbulent time scales of the flow are filtered to obtain:

$$\frac{\partial \overline{u}_j}{\partial x_j} = 0, \tag{4}$$

$$\mathrm{Sr}\frac{\partial \overline{u}_i}{\partial t} + \frac{\partial (\overline{u}_i \overline{u}_j)}{\partial x_j} = -\frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\frac{1}{Re}\left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i}\right) - \overline{u_i' u_j'}\right], \tag{5}$$

$$\mathrm{Sr}\frac{\partial \overline{T}}{\partial t} + \frac{\partial (\overline{u}_j \overline{T})}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\frac{1}{Re\,Pr}\frac{\partial \overline{T}}{\partial x_j} - \overline{u_j' T'}\right] \tag{6}$$

Where $\overline{\phi}(t) = \frac{1}{\Delta t}\int_t^{t+\Delta t} \phi dt$. The correlations $\overline{u_i' u_j'}$ and $\overline{u_i' T'}$ can not be obtained from the averaged flow and have to be modelled. In our case, the $k-\omega$ SST model has been used to do so. For brevity, the reader is referred to [27] for a description of the model and to [28] for the implementation details. In [20], numerical simulations of SJA with $k-\omega$ SST at $Re = 305$ and $Re = 508$ are show to be in good agreement with experimental results.

Incompressible regime is assumed as the ratio of the Helmholtz frequency of the actuator and the drive frequency is less than 0.5 [25, 26]. Richardson number has been assumed to be low enough as to disregard the buoyancy effect.

Prandtl number is $Pr = (\rho \nu c_p)/k$, a value of 0.71 has been assumed. Reynolds number is defined along the standard set by Smith and Glezer [6], $\mathrm{Re} = \frac{\rho U_0 d}{\mu}$, where d is the orifice diameter (or width, for rectangular actuators as in our case) and U_0 a characteristic velocity defined in terms of the stroke length L_0 as $U_0 = L_0 f$, with f being the drive frequency. The stroke length is defined as $L_0 = \frac{1}{d}\int_0^{\tau/2}\int_0^d u(x,0,t)dx\ dt$, where $u(x,0,t)$ is the instantaneous velocity at the orifice and τ is the period. The stroke length times the orifice surface is the

volume of fluid displaced during the expulsion part of the cycle. The Strouhal number Sr is $\mathrm{Sr} = \frac{2\pi f d}{U_0} = \frac{\mathrm{Sk}^2}{\mathrm{Re}}$. Alternatively [11, 17], the Stokes number $\mathrm{Sk} = \sqrt{\frac{\rho 2\pi f d^2}{\mu}}$ can be used to characterize the flow instead of the Strouhal number.

An important parameter that defines the jet behaviour is its formation criteria [7, 8],

$$\mathrm{JFC} = \frac{1}{\mathrm{Sr}_{\overline{U}}} = \frac{\mathrm{Re}_{\overline{U}}}{\mathrm{Sk}^2_{\overline{U}}} > K, \tag{7}$$

which is based on a time and space averaged velocity $\overline{U}$ during on the expulsion stroke ($\overline{U} = 2U_0$). If JFC is below K, the vortices expelled by the SJA are ingested back and the jet is not formed. For the two-dimensional rectangular jets considered in the present work, K can be approximated to 2 [7].

If a detailed description of the SJA membrane is included in the simulations, its position is modeled as $y(x,t) = -\delta(x)\cos(2\pi f t)$, where $\delta(x)$ is a diaphragm shape function. A mean amplitude can be defined as

$$\overline{A} = \frac{1}{W}\int_{-W/2}^{W/2} \delta(x)dx, \tag{8}$$

where W is the actuator cavity width. Under these circumstances, the characteristic velocity U_0 can be related to the mean amplitude and the drive frequency $U_0 = 2\overline{A}fW/d$, thus forbidding the decoupling between f and U_0. Also, under this definition, the jet formation criteria becomes

$$\mathrm{JFC} = \frac{2}{\pi}\left(\frac{\overline{A}}{d}\right)\left(\frac{W}{d}\right), \tag{9}$$

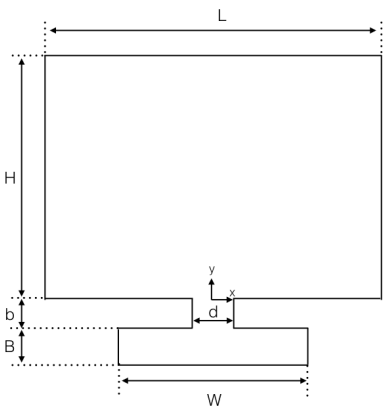
a pure geometrical parameter. High amplitudes and large jet cavity aspect ratios favour the formation of jets, independently of the frequency. Changing the value of the drive frequency enables increasing both Re and Sk in a way that the jet formation criteria remains the same. Therefore, changing the excitation frequency not only changes the jet period but also the velocity in which the jet is expelled.

2 Configuration studied

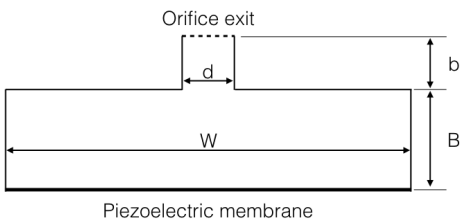
A rectangular actuator (Fig. 1) in a domain homogeneous in the z direction has been considered. The medium is assumed to be wide enough ($L = 60$) as to not interfere with the jet, but small H values of 5 and 10 have been imposed, in the range of the optimal distances for cooling applications [29]. The actuator cavity width W has been chosen to impose a jet formation criteria of $JFC = 3$ and a mean amplitude $\overline{A}/d = 0.2$ (equations 8 and 9). The other dimensions of the SJA are based on Liu [31], with $b/d = 0.3$ and $B/d = 1.67$. Two Reynolds numbers have been studied, $Re = 50$ and $Re = 500$.

 ISBN: 978-84-617-8694-7

Non-slip boundary conditions are imposed at the top ($y = H$) and bottom ($y = 0$) of the discharge cavity as well as at the actuator walls ($y < 0$ and $y = \pm d/2$), except for the active bottom wall later described. Free-flow boundary conditions have been prescribed at all the vertical boundaries with $y > 0$. Respect to the energy equation, the cavity top wall is hot ($T = 1$), the bottom wall cold ($T = 0$) and the lateral boundaries adiabatic ($dT/dt = 0$) where the flow leaves the domain and cold where it enters. The SJA walls ($y < 0$) are assumed to be at $T = 0$.



(a) Schematic view of the studied configuration (not to scale).



(b) Detail of the actuator (not to scale).

Figure 1: Computational domain and actuator.

The SJA has been implemented in the aforementioned three different ways:

- M1, with a moving membrane of position $y(x,t) = -\delta(x)\cos(2\pi ft)$.
- M2, imposing velocity boundary conditions at the SJA bottom as $v = 2\pi f\delta(x)\sin(2\pi ft)$. A cosine shape function has been used, $\delta(x) = \delta_C \cos\left(\pi \frac{x}{W}\right)$, where as δ_C is a scaling parameter that is set so $\overline{A}$ can have the desired value. Other membrane position functions can be found in the literature [4, 16, 21].
- M3, disregarding the SJA and imposing the velocity at the orifice exit as $u(x,0,t) = 2\pi f\overline{A}\sin(2\pi ft)W/d$ and $T = 0$.

2.1 Solution procedure and grid convergence

The configuration is solved using the finite volume method by means of the software *Code_Saturne*. The PISO algorithm is selected to solve the pressure-velocity coupling. No turbulence model is used to solve the low Reynolds numbers ($Re = 50$), while $k-\omega$ SST has

been used for $Re = 500$. Each simulation is allowed to run from quiescent initial conditions until a stationary state is reached. A large number of actuator cycles (≈ 200) is needed. The solution obtained is then transferred to a finer mesh and used as initial condition. This reduces the number of actuator cycles needed to reach again a stationary state to about ≈ 30. As an example of the grid convergence studies, Nusselt number distributions obtained with three different meshes for $Re = 50$ and $H = 10$ are shown in Fig. 2.

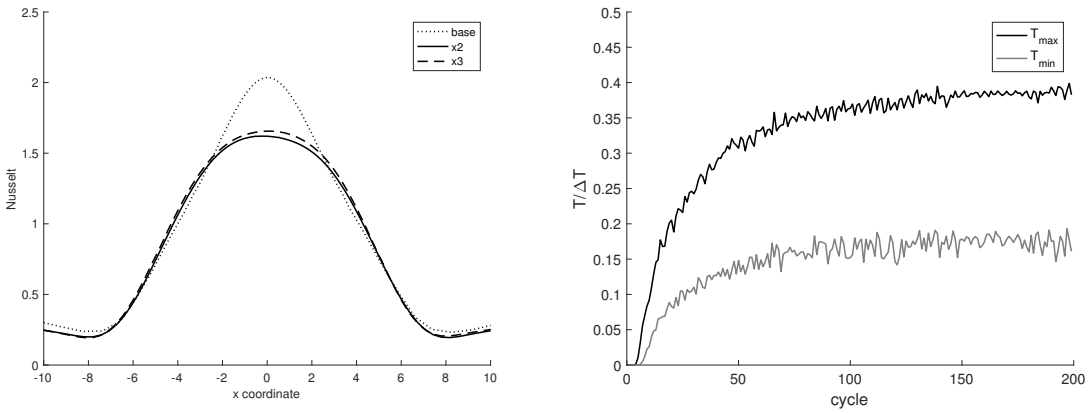


Figure 2: Left: Nusselt numbers obtained with the different meshes for Model 1, $Re = 50$ and $H = 10$, with 4348, 18424 and 41528 CV. Right: Maximum and minimum temperature at the actuator neck for $Re = 500$, as a function of the SJA cycle.

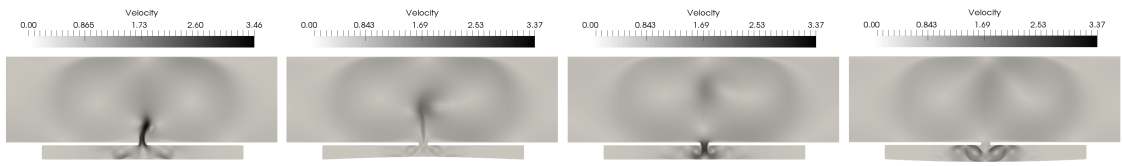
3 Results and Discussion

3.1 Phase and time averaged flow

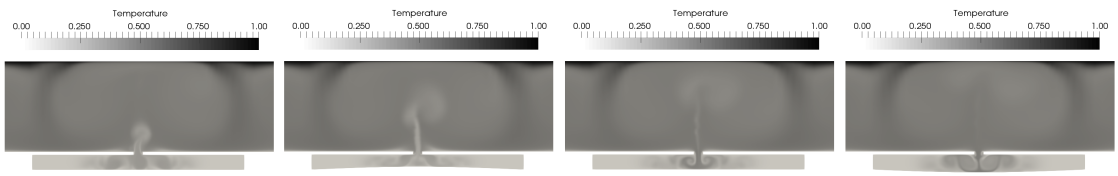
Fig. 3 shows a sequence of phase averaged velocity, temperature and turbulent kinetic energy maps that are representative of the jet sequence once the stationary state has been reached. Due to the motion of the membrane, during the forward stroke (second column), a pair of vortices are generated in the actuator lips and expelled to the cavity. If the jet formation criteria is high enough, when the suction stroke begins (third column) the vortices are too far to be ingested back and therefore generate a nonzero momentum flux in the streamwise direction. Also, another pair of vortices are created inside the cavity. During the ingestion (fourth column), k and T from the external flow are admitted in the SJA cavity, where they interact with the internal flow to be expelled back (first column). To illustrate the interaction between the internal and the external flows, the evolution of the maximum and minimum temperatures in the actuator neck is shown in Fig. 2 (right). The maximum

 ISBN: 978-84-617-8694-7

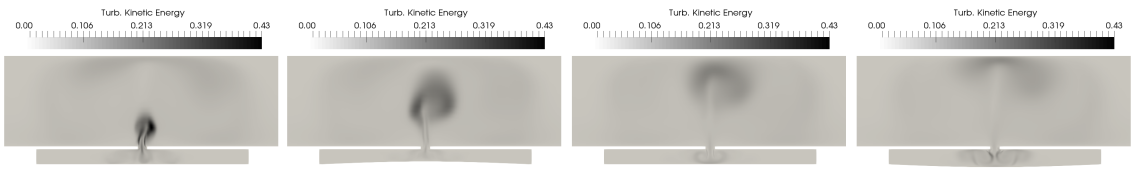
temperature corresponds to the ingestion phase. As can be seen, after a few cycles the fluid entering the SJA is quite hot and despite the cooling in the SJA cavity (where the walls are assumed to be at $T = 0$), when it exits at a temperature $T \approx 0.18$. This value, that has an effect on the cooling efficiency, depends on the interaction between both flows can not be imposed as a boundary condition without simulating the SJA chamber.



(a) Velocity (non-dimensionalized by U_0).



(b) Temperature (non-dimensionalized by ΔT).



(c) Turbulent kinetic energy (non-dimensionalized by U_0^2).

Figure 3: Sequences of velocity, temperature and turbulent kinetic energy fields during a representative cycle for $Re = 500$. From left to right $\phi = 0$, $\phi = 90$, $\phi = 180$ and $\phi = 270$.

If a time average is performed, instead of phase averages, the overall flow field can be obtained, as can be seen in Fig. 4. For $Re = 500$, $H = 10$, a series of large vortices emerge from the SJA strokes, that transport energy from the hot to the cold wall. At first glance, the large central jet would suggest that a fluid is entering the domain; however, close inspection of the streamlines reveals that the net mass flow is zero.

3.2 Effect of simulating the actuator cavity

The different models of the synthetic jet actuator have been compared by assessing the difference in the vertical velocities at different distances from the actuator outlet and the time averaged Nusselt number, for $Re = 50$ and $H/d = 10$. As can be seen in Fig. 5 (left), as the distance from the actuator increases, the velocity profile becomes more uniform and

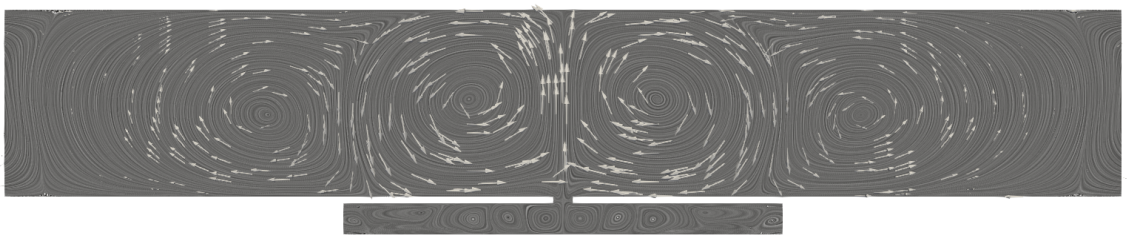


Figure 4: Streamlines for $Re = 500$, $H = 10$ and M1.

the difference between the models is smaller. However, at the hot wall ($H = 10$), there is a significant difference in the Nusselt number distribution (Fig. 5, right), specially between M3 (that doesn't solve for the cavity) and M1 and M2. To find out the reason of this difference in the Nusselt values, despite the similar velocity profiles, vertical temperature profiles at the maximum ingestion and expulsion phases have been represented in Fig. 6. Model M3, that only solves the domain for $y > 0$ (where it imposes an arbitrary value of $T = 0$), predicts a temperature too low near the hot wall, that overestimates the Nusselt number. This difference would be smaller if at least the correct mean value of the outlet temperature could be imposed in M3, but this value can not be obtained without solving first the interaction between the SJA cavity and the external flow.

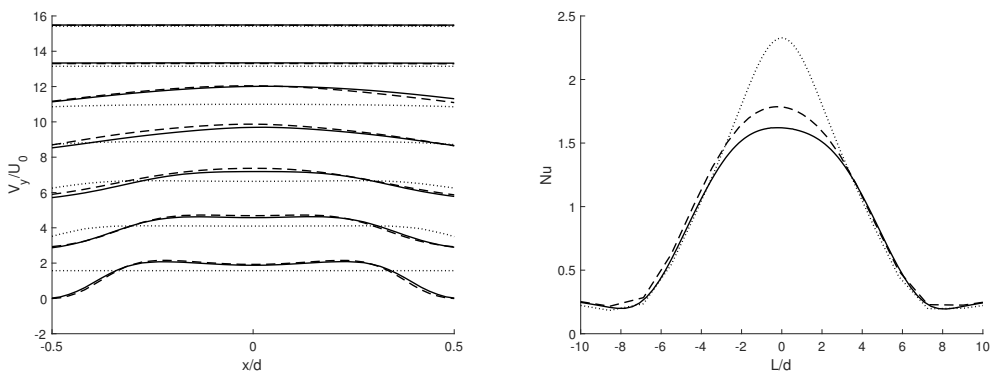

Figure 5: Comparison of the three implementations of the SJA for $Re = 50$, $H = 10$. Implementation 1: Solid line; 2: Dashed line; 3: Dotted line. Left: Vertical velocity profiles at $y = 0, 0.5, 1, 1.5, 2, 5, 8$ (each shifted 2.5 up units to avoid superposition with the previous). Right. Time averaged Nusselt numbers at the hot wall.

 ISBN: 978-84-617-8694-7

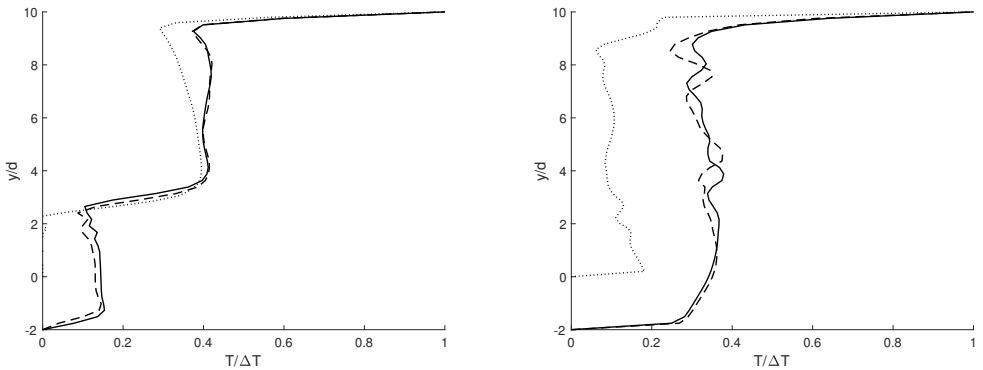

Figure 6: Comparison of the three implementations of the SJA for $Re = 50$, $H = 10$. Implementation 1: Solid line; 2: Dashed line; 3: Dotted line. Left: Phase averaged vertical temperature profiles at the maximum expulsion. Right: Phase averaged vertical temperature profiles at the maximum ingestion.

4 Conclusions

A SJA impinging into a hot wall has been studied, considering three different models: Moving membrane (M1), velocity boundary conditions and cavity (M2) and boundary conditions at the exit orifice (M3). Domains of two different vertical sizes ($H = 5$ and $H = 10$), and two different Reynolds numbers ($Re = 50$ and $Re = 500$) have been studied.

The resulting flows are quite complex, and a large number of actuator cycles has to be solved in order to reach a stationary state. All the implementations can solve the basic features of the external flow created by the SJA. Moreover, as the distance from the actuator outlet is increased, the velocity profiles predicted by the three implementations become very similar.

However, when the Nusselt number and the temperature profiles predicted by the different models are analyzed, there are significant differences. The reason seems to be related with the value of the temperature that has to be imposed at the SJA outlet in M3. Moreover, it is quite possible that similar effects are found in other passive scalars such as concentration in mixing applications or turbulent kinetic energy. While it remains to be studied if such differences are actually important for active flow control applications, M2 seems a good compromise between accuracy and cost. Although many of the features of the internal SJA flow can not be well predicted due to the simplified boundary conditions imposed at the membrane in M2, the errors introduced by these assumptions will decrease in the external flow.

Abstract

The aim of this talk is to approximate solution for solving minimization problems via best proximity point theorems and variational principle in generalized distance functions by giving an algorithm for determining such an is furnished. Also, we give a necessary and sufficient conditions for finding the existence of best proximity point and minimal elements with illustrative example of our main results.

Key words: Best proximity point, Generalized distance functions, Minimization problems, Minimal elements.

1 Introduction

In 1989, Bakhtin [2] (see also Czerwik [3]) introduced the concept of a b-metric space and proved some fixed point theorems for some contractive mappings in b-metric spaces which are generalizations of Banach's contraction principle in metric spaces.

Definition 1.1 *Let X be a nonempty set and $s \geq 1$ be a given real number. A functional $d : X \times X \to [0, \infty)$ is called a b-metric if, for all $x, y, z \in X$, the following conditions are satisfied:*

1. *$d(x, y) = 0$ if and only if $x = y$;*

 ISBN: 978-84-617-8694-7

2. $d(x,y) = d(y,x)$;

3. $d(x,z) \leq s[d(x,y) + d(y,z)]$.

A pair (X,d) is called a *b-metric space* with coefficient s. Since, every metric space is a b-metric space with $s = 1$ and hence the class of b-metric spaces is larger than the class of metric spaces. In 1996, Kada et al. [5] introduced some generalized metric which is difference from b-metric space and called w-distance as follow:

Definition 1.2 *Let (X,d) be a metric space. A function $p : X \times X \longrightarrow [0,\infty)$ is said to be the w-distance on X if the following are satisfied:*

1. *$p(x,z) \leq p(x,y) + p(y,z)$ for all $x,y,z \in X$;*

2. *for any $x \in X$, $p(x,\cdot) : X \longrightarrow [0,\infty)$ is lower semi-continuous (i.e., if $x \in X$ and $y_n \longrightarrow y \in X$, then $p(x,y) \leq \liminf_{n\longrightarrow\infty} p(x,y_n)$;*

3. *for any $\varepsilon > 0$, there exists $\delta > 0$ such that $p(z,x) \leq \delta$ and $p(z,y) \leq \delta$ imply $d(x,y) \leq \varepsilon$.*

They also improved Caristi's fixed point theorem, Ekeland's variational principle and the nonconvex minimization theorem of Takahashi [6]. Later, Shioji et al. [7] studied the relationship between weakly contractive mappings and weakly Kannan mappings under the conditions, the w-distance and the symmetric w-distance. In 2012, Imdad and Rouzkard [8] proved some fixed point theorems in a complete metric space equipped with a partial ordering via the w-distance.

Later, In 2014, Hussain et al. [4] introduced the concept of the wt-distance in generalized b-metric spaces, which is a generalization of the w-distance.

Definition 1.3 *Let (X,d) be a b-metric space with constant $s \geq 1$. A function $P : X \times X \longrightarrow [0,\infty)$ is called the wt-distance on X if the following are satisfied:*

1. *$P(x,z) \leq s(P(x,y) + P(y,z))$ for all $x,y,z \in X$;*

2. *for any $x \in X$, $P(x,\cdot) : X \longrightarrow [0,\infty)$ is s-lower semi-continuous (i.e., if $x \in X$ and $y_n \longrightarrow y \in X$, then $P(x,y) \leq \liminf_{n\longrightarrow\infty} sP(x,y_n)$;*

3. *for any $\varepsilon > 0$, there exists $\delta > 0$ such that $P(z,x) \leq \delta$ and $P(z,y) \leq \delta$ imply $d(x,y) \leq \varepsilon$.*

Recently, Abdou et al. [1] proved some common fixed point theorems in Menger probabilistic metric type spaces by using the wt-distance.

In this talk, we prove the existence of best proximity point of some nonlinear mappings in complete metric spaces via the w-distance and also give some examples to for support our

 ISBN: 978-84-617-8694-7

results. Furthermore, we prove some Ekeland's variational principle in *wt*-distance and also, we give a necessary and sufficient conditions with an approximate algorithms for finding the existence of minimal elements to establish enhanced Ekeland's variational principle. Our result improve, extend and generalize several results given by some authors in literatures.

Abstract

In this work, we present some results on Nonlinear Programming that generalize the classical theorems of the Lagrange multipliers, Kuhn–Tucker and Fritz John, and, moreover, they are sharp, in the sense that the validity of each of them is equivalent to the fact that a certain family of functions associated to the nonlinear problem under consideration satisfies a weak convexity condition. These results are derived from adequate versions of the Hahn–Banach theorem.

Key words: Hahn–Banach theorem, Nonlinear Optimization.
MSC 2000: 90C30, 46A22.

1 Hahn–Banach, Mazur–Orlicz and Nonlinear Programming

The development of Convex Analysis has always been together with that of Optimization, benefiting reciprocally. A remarkable example is the Hahn–Banach theorem and its geometric reformulations –the seminal versions of the theorems of the alternative such as Gordan's theorem or Farkas' lemma, the convex separation theorem– which have definitely become some of the most important tools in the study of problems on Linear and Nonlinear Programming.

First, we make use of a generalization of the Hahn–Banach theorem, known as the Mazur–Orlicz theorem, [8, 9, 14, 15, 17], which states that if C is a convex subset of a real vector space in which a sublinear (subadditive and positively homogeneous) functional is defined, then it is possible to find a linear functional less than it and in such a way that their infimum on C coincide. As a consequence, we derive some existence results along the

 ISBN: 978-84-617-8694-7

lines of the theorems of König of the maximum and the supremum [6, 7], which establish the concept of optimal convexity for its validity: the *infsup-convexity*, a weak concept of convexity that arose in minimax theory ([5, 13, 16]). Specifically, the more general result states that given two nonempty sets X and Λ, $f : X \longrightarrow \mathbb{R}$ and $(f_\lambda)_{\lambda\in\Lambda}$ a family of real valued functions defined on X such that

$$x \in X \;\Rightarrow\; (f_\lambda(x))_{\lambda\in\Lambda} \in \ell^\infty(\Lambda),$$

then, the family $(f_\lambda - f)_{\lambda\in\Lambda}$ is infsup-convex on X if, and only if, for each $\alpha \in \mathbb{R}$ with

$$x \in X \;\Rightarrow\; f(x) + \alpha \leq \sup_{\lambda\in\Lambda} f_\lambda(x),$$

there exists a bounded and linear functional $\Phi : \ell^\infty(\Lambda) \longrightarrow \mathbb{R}$ such that

$$\Phi \leq \sup_{\Lambda}$$

and

$$x \in X \;\Rightarrow\; f(x) + \alpha \leq \Phi((f_\lambda(x))_{\lambda\in\Lambda}).$$

When applying the König-type results we establish general versions of the theorems of the Lagrange multipliers, Fritz John and Kuhn–Tucker for an optimization problem with an arbitrary number of constraints,

$$\inf_{x\in F} f(x),$$

with

$$F := \left\{ x \in X : \; \sup_{\lambda\in\Lambda} f_\lambda(x) \leq 0, \; \sup_{\omega\in\Omega} |g_\omega(x)| = 0 \right\},$$

X being a nonempty set, Λ and Ω sets, $f : X \longrightarrow \mathbb{R}$ a given funtion and $(f_\lambda)_{\lambda\in\Lambda}$ and $(g_\omega)_{\omega\in\Omega}$ families of real valued functions on X. Such results not only extend some known statements [1, 2, 3, 4, 18], but also are sharp in terms of the infsup-convexity of certain families of functions. Some particular cases have been established in [10, 11, 12].

Abstract

In this work, we show that there exists a theory of functions with quaternionic values and of two real variables, which is determined by a Cauchy-Riemann-type operator with quaternionic variable coefficients and that is intimately related to the well-known Mathieu functions. As a result, we introduce the *Quaternionic Mathieu Functions* and explain their connections to the solutions of the Heat-Conduction equation in the elliptical confocal coordinate system.

Key words: Quaternionic analysis, Heat-Conduction equation, elliptical confocal coordinates, Mathieu functions, hyperholomorphic functions.

1 Introduction

The majority of functions used in technical and applied mathematics were originated as the result of investigating practical problems. A relevant example is the *Mathieu functions*, which are solutions to the ordinary differential equations arising in the separation of the Helmholtz equation in two dimensions using *elliptical confocal coordinates*. These functions were introduced by Émile Léonard Mathieu in 1868 in his "*Mémoire sur le mouvement vibratoire d'une membrane de forme elliptique*" in connection with the study of the vibrational modes of a stretched membrane with an elliptic boundary [3]. Since that time Mathieu functions have been widely used in many areas of classical and modern physics, engineering and applied mathematics.

 ISBN: 978-84-617-8694-7

Mathieu functions occur in two main categories of physical problems: on one hand, in applications involving elliptical geometries, for example in the analysis of the vibrating modes in elliptical membranes, the propagating modes in elliptical pipes and the oscillations of water in a lake of elliptical shape. On the other hand, Mathieu functions may arise in problems involving periodic motion, such as the trajectory of an electron in a periodic array of atoms, the mechanics of the quantum pendulum, and the oscillations of floating vessels. Recently, in the works of Sato [8, 9] it is mentioned the importance of computing the thermal stresses resulting from the considerable temperature differences in solids bounded by ellipses. In particular, in [8] it is shown that the resulting solution of the heat conduction problem of a cylinder can be obtained in the form of an infinite Mathieu function series. Those papers deal with the heat conduction problem of an infinite and a confocal elliptical cylinder in which the effect of its surface resistance is included. In the above analysis the condition is that the cylinder surface is keeping heated or cooled at a constant temperature. The method of separation of variables is then applied to solving the *Heat-Conduction equation* using the elliptical cylinder coordinate system and the corresponding boundary conditions are accordingly satisfied by using the orthogonality of the Mathieu functions. Despite the existence of many applications and classical properties such as identities, recursions and asymptotics, Mathieu functions are barely mentioned in modern textbooks, and even older texts that gave some account of Mathieu functions are now out-of-print. One reason for the absence of theory of Mathieu functions in the existing literature compared to that for other special functions is because the behavior of Mathieu functions is relatively rich and, consequently, more difficult to understand. Another reason is probably the complicated and various notations that exist in the literature.

A higher-dimensional extension of the Mathieu functions to the framework of *Quaternionic Analysis* was firstly considered in [2]. Analogues of the basic integral formulae of complex analysis for this version of quaternionic function theory were established, which turned out to be in the same relation with the Schrödinger operator with a special potential as the usual holomorphic functions in one complex variable, or *quaternionic hyperholomorphic functions*, are with the corresponding Laplace operator. A major part of the present work is concerned with exploring what analytical properties of the Quaternionic Mathieu Functions (QMFs) arise from this extension. According to our current knowledge, central questions regarding a proper definition of the QMFs and general properties such as orthogonality relations and identities, and their connections to the solutions of the Heat-Conduction equation in the elliptical coordinate system remain untouched so far. We honestly think that the QMFs introduced in this paper give, through the factorization of the Heat-Conduction operator, a finer structure of the classical Mathieu functions. This understanding may be fruitful both to enrich the understanding of the properties of these functions in higher dimensions and as tools in such applications of quaternionic analysis in mathematical physics and related fields.

2 Heat-Conduction Equation in Elliptical Confocal Coordinates

As the present problem considers no temperature change along the lenght of an infinite hollow confocal elliptical cylinder, the heat-conduction equation within can be written in rectangular coordinates (x, y) as

$$\left(\Delta - \frac{1}{\kappa}\frac{\partial}{\partial t}\right)[\theta] := \frac{\partial^2\theta}{\partial x^2} + \frac{\partial^2\theta}{\partial y^2} - \frac{1}{\kappa}\frac{\partial\theta}{\partial t} = 0, \tag{1}$$

where $\theta(x, y, t)$ is the *temperature*, t the *time* and κ the *thermal diffusivity* given by $\kappa = K/(\rho\, C)$ with *thermal conductivity* K, *density* ρ and *specific heat* C, which are assumed to be constant. The problem of heat conduction under consideration can be rigorously analyzed by introducing the *elliptical confocal coordinates* (ξ, η), which are related to the rectangular coordinates by the relation

$$x + iy = c\cosh(\xi + i\eta) = c\cosh\xi\cos\eta + ic\sinh\xi\sin\eta,$$

where c denotes the *semi-focal length*, ξ is the *radial coordinate* which varies from zero along the line of foci to ξ_0 at the rings, and η is the *angular coordinate* which varies from 0 to 2π in passing once round an ellipse. We note that $c^2 = a^2 - b^2$ in which $a = 2c\cosh\xi_0$ and $b = 2c\sinh\xi_0$ represent the *semi-major* and *semi-minor axis length* of a family of confocal ellipses within the hollow cylinder bounded by the outer surface $\xi = \xi_0$:

$$\frac{x^2}{c^2\cosh^2\xi_0} + \frac{y^2}{c^2\sinh^2\xi_0} = 1. \tag{2}$$

We note first that the *heat-conduction operator*

$$\Delta - \frac{1}{\kappa}\frac{\partial}{\partial t}$$

acts on the space of functions $\mathcal{C}^2(\mathbb{R}^2) \times \mathcal{C}^1(\mathbb{R}_0^+)$. In the present study, we consider its restriction onto $\mathcal{C}^2(\Omega_{x,y}) \times \mathcal{C}^1(\mathbb{R}_0^+)$, where

$$\Omega_{x,y} := \mathbb{R}^2 \setminus \{(x, y) \in \mathbb{R}^2 \,|\, x = 0 \vee y = 0\}.$$

Henceforth we consider a domain Ξ in a copy of $\mathbb{R}^2$ with the coordinates (ξ, η). Now, we define a change of variables in the domain Ξ, i.e., there exists a mapping

$$\varphi : (\xi, \eta) \in \Xi \mapsto \varphi(\xi, \eta) = (x = \varphi_1(\xi, \eta), y = \varphi_2(\xi, \eta)) \in \Omega_{x,y},$$

such that $\varphi \in \mathcal{C}^2(\Xi)$ makes a one-to-one correspondence between both domains. Now, assume that $\psi = (\psi_1(x, y), \psi_2(x, y))$ is the inverse mapping, $\psi : \Omega_{x,y} \mapsto \Xi$, i.e., so that $\varphi(\psi(x, y)) = (x, y)$ for any $(x, y) \in \Omega_{x,y}$ and $\psi(\varphi(\xi, \eta)) = (\xi, \eta)$ for any $(\xi, \eta) \in \Xi$.

 ISBN: 978-84-617-8694-7

We introduce the operators of the change of variables:

$$W_\varphi : u \in \mathcal{C}^2(\Omega_{x,y}) \mapsto u \circ \varphi =: \tilde{u} \in \mathcal{C}^2(\Xi),$$
$$W_\psi = W_\varphi^{-1} : \tilde{u} \in \mathcal{C}^2(\Xi) \mapsto \tilde{u} \circ \psi =: u \in \mathcal{C}^2(\Omega_{x,y}).$$

It is of interest to point that W_φ is an isomorphism of $\mathcal{C}^2(\Omega_{x,y})$ onto $\mathcal{C}^2(\Xi)$, whereas W_ψ is an isomorphism of $\mathcal{C}^2(\Xi)$ onto $\mathcal{C}^2(\Omega_{x,y})$. Next, let A be an arbitrary linear operator acting on $\mathcal{C}^2(\Omega_{x,y})$ and B be an arbitrary operator acting on $\mathcal{C}^2(\Xi)$. We define the operators $\widetilde{A}$ and $\widetilde{B}$ as follows:

$$W_\varphi A W_\psi =: \widetilde{A} \quad \text{and} \quad W_\psi B W_\varphi =: \widetilde{B}.$$

Obviously, $\widetilde{A}$ acts on $\mathcal{C}^2(\Xi)$ while $\widetilde{B}$ acts on $\mathcal{C}^2(\Omega_{x,y})$.

Let $\mathcal{L}(\mathcal{C}^2(\Omega_{x,y}))$ and $\mathcal{L}(\mathcal{C}^2(\Xi))$ denote the algebras of all linear operators acting on the respective function spaces. Hence the mapping

$$A \in \mathcal{L}(\mathcal{C}^2(\Omega_{x,y})) \mapsto W_\varphi A W_\psi = \widetilde{A} \in \mathcal{L}(\mathcal{C}^2(\Xi))$$

is an isomorphism of algebras.

Taking $A = \Delta - \frac{1}{\kappa}\frac{\partial}{\partial t}$, a direct observation shows that

$$W_\varphi A W_\psi = W_\varphi \Delta W_\psi - \frac{1}{\kappa} W_\varphi \frac{\partial}{\partial t} W_\psi.$$

Furthermore, for any $\tilde{u} \in \mathcal{C}^2(\Xi)$ we find that

$$W_\varphi \frac{\partial}{\partial t} W_\psi[\tilde{u}] = W_\varphi \frac{\partial}{\partial t}[u] = W_\varphi \left[\frac{\partial}{\partial t} u\right] = \widetilde{\frac{\partial}{\partial t}} u = \frac{\partial}{\partial t}\tilde{u},$$

which leads to

$$W_\varphi \frac{\partial}{\partial t} W_\psi = \frac{\partial}{\partial t} I,$$

where I is the identity operator.

We call attention to the fact that

$$\begin{aligned} W_\varphi \Delta W_\psi &= W_\varphi \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) W_\psi \\ &= W_\varphi \frac{\partial^2}{\partial x^2} W_\psi + W_\varphi \frac{\partial^2}{\partial y^2} W_\psi. \end{aligned}$$

We now finally apply all the above to the aforementioned elliptical confocal change of variables:

$$\begin{cases} \varphi_1(\xi,\eta) &= c\cosh\xi\cos\eta, \\ \varphi_2(\xi,\eta) &= c\sinh\xi\sin\eta. \end{cases} \tag{3}$$

 ISBN: 978-84-617-8694-7

Straightforward computations show that

$$W_{\varphi}\left(\Delta-\frac{1}{\kappa}\frac{\partial}{\partial t}\right)W_{\psi}=\frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\left[\mathcal{W}_{\xi,\eta}-\frac{c^2(\cosh^2\xi-\cos^2\eta)}{\kappa}\frac{\partial}{\partial t}\right], \tag{4}$$

where

$$\mathcal{W}_{\xi,\eta}:=\frac{\partial^2}{\partial\xi^2}+\frac{\partial^2}{\partial\eta^2}. \tag{5}$$

Applying (4) to (1) leads to the equation

$$\frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\left[\mathcal{W}_{\xi,\eta}[\theta]-\frac{c^2(\cosh^2\xi-\cos^2\eta)}{\kappa}\frac{\partial\theta}{\partial t}\right]=0, \tag{6}$$

with $\theta=\theta(\xi,\eta,t)$. Then (6) is the two-dimensional Heat-Conduction equation (1) expressed in elliptical confocal coordinates.

The preceding conclusions are true if (3) is a one-to-one correspondence. Hence we assume henceforth that the operator

$$\mathcal{W}_{\xi,\eta}-\frac{c^2(\cosh^2\xi-\cos^2\eta)}{\kappa}\frac{\partial}{\partial t}$$

acts on $C^2(\Omega_{\xi,\eta})\times\mathcal{C}^1(\mathbb{R}_0^+)$, where

$$\Omega_{\xi,\eta}:=(0,\xi_0)\times(0,2\pi)\bigcup\{(0,\eta)\,|\,\eta\in(0,\pi)\}. \tag{7}$$

Upon introducing the symbol θ_o as the *constant temperature of the surrounding medium*, the *boundary condition* along the cylinder surface throughout heating ($\theta>\theta_o$) or coolling ($\theta<\theta_o$) is

$$\frac{\partial\theta}{\varrho\partial\xi}=-\frac{H}{K}(\theta-\theta_o),\ \text{ at }\ \xi=\xi_0, \tag{8}$$

in which H denotes the *convective heat-transfer coefficient*, and $\varrho^2:=c^2(\cosh^2\xi-\cos^2\eta)$. The *initial condition* is

$$\theta=\theta_0,\ \text{ at }\ t=0. \tag{9}$$

In the present study we are interested in the analysis of Eq. (6) and of its solutions under the conditions (8) and (9). Setting $\vartheta:=\theta-\theta_o$, Eqs. (6), (8) and (9) can be written as

$$\frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\left[\mathcal{W}_{\xi,\eta}[\vartheta]-\frac{c^2(\cosh^2\xi-\cos^2\eta)}{\kappa}\frac{\partial\vartheta}{\partial t}\right]=0, \tag{10}$$

$$\frac{\partial\vartheta}{\varrho\partial\xi}=-\frac{H}{K}\vartheta,\ \text{ at }\ \xi=\xi_0, \tag{11}$$

$$\vartheta=\vartheta_0,\ \text{ at }\ t=0. \tag{12}$$

 ISBN: 978-84-617-8694-7

As usual, we use the method of separation of variables to find a solution of the Heat-Conduction equation (10). Let the desired form of the solution be

$$\vartheta(\xi,\eta,t)=\zeta(\xi,\eta)T(t),$$

where ζ is a function of ξ and η, and T is a function of t alone. Substituting this expression into (10), leads to the following two separate equations for $\zeta(\xi,\eta)$ and $T(t)$:

$$\frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\Big[\mathcal{W}_{\xi,\eta}[\zeta]+4q\left(\cosh^2\xi-\cos^2\eta\right)\zeta\Big]=0, \tag{13}$$

$$\frac{\partial T}{\partial t}+\kappa\alpha^2T=0, \tag{14}$$

where α denotes the separation constant and $q:=\frac{\alpha^2c^2}{4}$ is a real (positive) parameter. A direct observation shows that Eq. (14) has solution

$$T(t)=e^{-\kappa\alpha^2t}.$$

Suppose now that

$$\zeta(\xi,\eta)=\psi(\xi;q)\phi(\eta;q)$$

is a solution of Eq. (13), where ψ is a function of ξ alone, and ϕ a function of η alone. We obtain the two *second-order ordinary differential equations with variable coefficients*:

$$\frac{\partial^2\phi}{\partial\eta^2}+(a-2q\cos 2\eta)\,\phi=0, \tag{15}$$

$$\frac{\partial^2\psi}{\partial\xi^2}-(a-2q\cosh 2\xi)\,\psi=0, \tag{16}$$

where a is the *separation constant*. A solution of (13) comprises the product of any two functions which are solutions of (15) and (16), respectively, *for the same values of a and q*. Since a may have any value, the number of solutions is unlimited.

Eqs. (15) and (16) are known as the *ordinary* and the *modified Mathieu equations*. However, in applications involving elliptical confocal coordinates, Eqs. (15) and (16) are better identified as the *angular* and *radial Mathieu equations*. Their solutions are, respectively, the *angular Mathieu functions* and the *radial Mathieu functions*. As a matter of fact, since a and q are arbitrary constants, one has two families of ordinary differential equations parametrized by the same parameters a and q.

Remark 2.1 *We shall remark that if in (15) we write $\pm i\xi$ for η, then (15) is transformed into (16), while the latter is transformed into (15) if $\pm i\eta$ is written for ξ.*

 ISBN: 978-84-617-8694-7

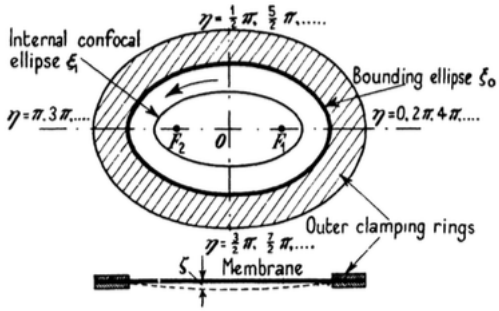

Fig. 2: Diagram for membranal problem, from which the Mathieu functions originated [4].

Referring to Fig. 2, if we start at $\eta = 0$ and move counter-clockwise round a confocal ellipse $\xi = \xi_1 < \xi_0$ the displacement $\zeta(\xi, \eta)$ at any instant alters continuously. It follows that ζ is single-valued and periodic in the coordinate η. The period is π or 2π in η, so that

$$\zeta(\xi, \eta) = \zeta(\xi, \eta + \pi) \quad \text{or} \quad \zeta(\xi, \eta) = \zeta(\xi, \eta + 2\pi)$$

as the case may be. In [7] it is shown that the solutions of Eq. (15), having period π or 2π consist entirely of cosine or sine terms, and not a combination of the two. Moreover, in [6] it is shown that if one solution is even, the other must be odd. Thus two independent even or two independent odd solutions cannot occur. We denote the *even* and the *odd angular Mathieu functions* of order m by

$$\phi_m(\eta; q) := \begin{cases} ce_m(\eta; q), & m = 0, 1, 2, \ldots \\ se_m(\eta; q), & m = 1, 2, 3, \ldots \end{cases} \tag{17}$$

or a constant multiple thereof.

Since m may be any positive integer, there is an infinite number of solutions of type $ce_m(\eta, q)$ and $se_m(\eta, q)$; the parity and periodicity of ce_m and se_m are exactly the same as their trigonometric counterparts, namely, ce_m is an even function and se_m an odd function of η, and they have period π when m is even, or period 2π when m is odd.

3 Preliminaries

Let $\mathbb{H}$ be the set of real quaternions [5]. Each *quaternion* $\mathbf{w}$ is represented in the form

$$\mathbf{w} := w_0 + w_1\mathbf{i} + w_2\mathbf{j} + w_3\mathbf{k}.$$

The set $\{w_i\}$ is in $\mathbb{R}$ and $\{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$ are the *quaternionic imaginary units*, which obey the usual laws of multiplication

$$\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$$

and the usual component-wise defined addition.

 ISBN: 978-84-617-8694-7

Similarly to the complex case the *scalar* and *vector parts* of $\mathbf{w}$, $\mathrm{Sc}(\mathbf{w})$ and $\mathrm{Vec}(\mathbf{w})$, are defined as the w_0 and $w_1\mathbf{i}+w_2\mathbf{j}+w_3\mathbf{k}$ terms, respectively. For a quaternionic number $\mathbf{w}$ we consider its *conjugate* $\overline{\mathbf{w}}$ defined by $\overline{\mathbf{w}} := w_0 - \mathrm{Vec}(\mathbf{w})$, and the *norm* $|\mathbf{w}|$ of $\mathbf{w}$ is defined by

$$|\mathbf{w}| = (\mathbf{w}\overline{\mathbf{w}})^{1/2} = (\overline{\mathbf{w}}\mathbf{w})^{1/2} = \left(\sum_{i=0}^{3} w_i^2\right)^{1/2}.$$

In the sequel, let Ω be a domain in $\mathbb{R}^2$ (open and connected) bounded by $\Omega_{\xi,\eta}$ given as (7), with a piecewise smooth boundary. We say that

$$\mathbf{f}:\Omega\to\mathbb{H}, \qquad \mathbf{f}(x,y) := [\mathbf{f}(x,y)]_0 + [\mathbf{f}(x,y)]_1\mathbf{i} + [\mathbf{f}(x,y)]_2\mathbf{j} + [\mathbf{f}(x,y)]_3\mathbf{k}$$

is a *quaternionic-valued function*, where $[\mathbf{f}]_i$ $(i=0,1,2,3)$ are real-valued functions defined in Ω. We will focus on a special class of quaternionic-valued functions analogous to complex holomorphic functions and connected with them via the following concept.

Definition 3.1 *For a given $q>0$, a function $f\in C^1(\Omega,\mathbb{H})$ is called $\mathcal{D}_q$-hyperholomorphic if it is a solution of the differential equation $\mathcal{D}_q[f]=0$ with variable and quaternionic coefficients, where*

$$\mathcal{D}_q := \frac{2\sqrt{q}}{c} + \frac{1}{c(\cosh^2\xi-\cos^2\eta)}\left[(\mathbf{i}\sinh\xi\cos\eta+\mathbf{j}\cosh\xi\sin\eta)\frac{\partial}{\partial\xi}\right.$$
$$\left. + (\mathbf{j}\sinh\xi\cos\eta-\mathbf{i}\cosh\xi\sin\eta)\frac{\partial}{\partial\eta}\right]. \tag{18}$$

Analogously, for a solution of the equation $\overline{\mathcal{D}}_q[f]=0$ where

$$\overline{\mathcal{D}}_q := \frac{2\sqrt{q}}{c} - \frac{1}{c(\cosh^2\xi-\cos^2\eta)}\left[(\mathbf{i}\sinh(\xi)\cos\eta+\mathbf{j}\cosh\xi\sin\eta)\frac{\partial}{\partial\xi}\right.$$
$$\left. + (\mathbf{j}\sinh\xi\cos\eta-\mathbf{i}\cosh\xi\sin\eta)\frac{\partial}{\partial\eta}\right] \tag{19}$$

a reasonably natural name is $\mathcal{D}_q$-anti-hyperholomorphic function.

For a given $q>0$, it can be easily checked that the operators (18) and (19) factorize the operator induced by Eq. (13):

$$\mathcal{W}_{\xi,\eta} + 4q(\cosh^2\xi-\cos^2\eta) =: \mathcal{W}$$

in the sense that

$$\mathcal{D}_q\overline{\mathcal{D}}_q = \overline{\mathcal{D}}_q\mathcal{D}_q = \frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\mathcal{W},$$

where $\mathcal{W}_{\xi,\eta}$ is given by (5).

 ISBN: 978-84-617-8694-7

The above means that $\mathcal{D}_q$-hyperholomorphic functions play indeed the same role for the $\mathcal{W}$ operator as the usual holomorphic functions in one complex variable, or quaternionic hyperholomorphic functions, play for the corresponding Laplace operator [1]. At the same time, there exists a deep difference since the operators (18) and (19) have *variable* and *non-constant coefficients*, and it is well-known that function theories using such operators are much more sophisticated.

Consider now the space of all square integrable quaternionic-valued functions on Ω such that each component is in the usual $L_2(\Omega)$ and define

$$L_2(\Omega,\mathbb{H}) := \left\{ \mathbf{f} \,|\, \mathbf{f}:\Omega\to\mathbb{H},\ \|\mathbf{f}\|_{L_2(\Omega,\mathbb{H})} := \left(\int_\Omega |\mathbf{f}(x,y)|^2 dxdy\right)^{1/2} < \infty \right\}.$$

It follows that the space $L_2(\Omega,\mathbb{H})$ endowed with the *right quaternionic inner product*

$$< \mathbf{f}, \mathbf{g} >_{L_2(\Omega,\mathbb{H})} := \int_\Omega \overline{\mathbf{f}(x,y)}\, \mathbf{g}(x,y)\, dxdy \tag{20}$$

is a $\mathbb{H}$-*linear Hilbert space* under right multiplication by quaternion numbers.

4 The Quaternionic Mathieu Functions (QMFs)

4.1 Definition and properties of QMFs

We now show how to directly relate the solutions of Eqs. (15) and (16) with the above established hyperholomorphic function theory. The strategy adopted is the following: we start by considering a null-solution to the operator

$$\frac{1}{c^2(\cosh^2\xi-\cos^2\eta)}\Big[\mathcal{W}_{\xi,\eta} + 4q(\cosh^2\xi-\cos^2\eta)\Big]$$

where $\mathcal{W}_{\xi,\eta}$ is given by (5).

We identify such a solution $\zeta(\xi,\eta)=\psi(\xi;q)\phi(\eta;q)$ as of the form

$$\begin{cases} \zeta_m^e(\xi,\eta;q) := Ce_m(\xi;q)ce_m(\eta;q), \quad m=0,1,2,\ldots \\ \zeta_m^o(\xi,\eta;q) := Se_m(\xi;q)se_m(\eta;q), \quad m=1,2,\ldots \end{cases}$$

where the corresponding values of q and m must be the same as those entering the angular equation (15), as q and m together determine the separation constant a. For the sake of simplicity, we denote by ζ_m any Mathieu function of the set

$$\{\zeta_m^e,\ \zeta_m^o : m=0,1,2,\ldots\}. \tag{21}$$

 ISBN: 978-84-617-8694-7

Definition 4.1 (QMFs) *For a given $q > 0$, the family of pairs*

$$\{\, \boldsymbol{\zeta}_m,\, \overline{\boldsymbol{\zeta}_m} : \, m = 1, 2, \dots \},$$

where we set

$$\boldsymbol{\zeta}_m := \frac{c}{4\sqrt{q}}\, \overline{\mathcal{D}}_q[\zeta_m] \quad \text{and} \quad \overline{\boldsymbol{\zeta}_m} := \frac{c}{4\sqrt{q}}\, \mathcal{D}_q[\zeta_m]$$

is called Quaternionic Mathieu Functions (QMFs).

Remark 4.1 *A direct observation shows that*

$$\mathcal{D}_q[\boldsymbol{\zeta}_m] = \frac{1}{4\sqrt{q}}\, \frac{1}{c(\cosh^2\xi - \cos^2\eta)} \Big[\mathcal{W}_{\xi,\eta} + 4q(\cosh^2\xi - \cos^2\eta)\Big][\zeta_m] = 0,$$

and

$$\overline{\mathcal{D}}_q[\overline{\boldsymbol{\zeta}_m}] = \frac{1}{4\sqrt{q}}\, \frac{1}{c(\cosh^2\xi - \cos^2\eta)} \Big[\mathcal{W}_{\xi,\eta} + 4q(\cosh^2\xi - \cos^2\eta)\Big][\zeta_m] = 0.$$

Hence each element of (21) can be decomposed into

$$\zeta_m^e = \boldsymbol{\zeta}_m^e + \overline{\boldsymbol{\zeta}_m^e} \qquad \Big(\text{resp.},\ \zeta_m^o = \boldsymbol{\zeta}_m^o + \overline{\boldsymbol{\zeta}_m^o}\Big)$$

where $\boldsymbol{\zeta}_m^e$ (resp. $\boldsymbol{\zeta}_m^o$) are $\mathcal{D}_q$-hyperholomorphic functions, and $\overline{\boldsymbol{\zeta}_m^e}$ (resp. $\overline{\boldsymbol{\zeta}_m^o}$) are $\mathcal{D}_q$-anti-hyperholomorphic functions.

Thus, we have the following result.

Lemma 4.1 *For a given $q > 0$, the QMFs are of the following form:*

$$\begin{aligned}
\boldsymbol{\zeta}_m(\xi,\eta) \;=\; & \frac{1}{2}\psi(\xi)\phi(\eta) \\
& + \mathbf{i}\, \frac{c}{4\sqrt{q}}\, \frac{1}{(\cos^2\eta - \cosh^2\xi)} \left[\sinh\xi\cos\eta\,\psi'(\xi)\phi(\eta) - \cosh\xi\sin\eta\,\psi(\xi)\phi'(\eta)\right] \\
& + \mathbf{j}\, \frac{c}{4\sqrt{q}}\, \frac{1}{(\cos^2\eta - \cosh^2\xi)} \left[\cosh\xi\sin\eta\,\psi'(\xi)\phi(\eta) + \sinh\xi\cos\eta\,\psi(\xi)\phi'(\eta)\right]
\end{aligned}$$

and

$$\begin{aligned}
\overline{\boldsymbol{\zeta}_m(\xi,\eta)} \;=\; & \frac{1}{2}\psi(\xi)\phi(\eta) \\
& - \mathbf{i}\, \frac{c}{4\sqrt{q}}\, \frac{1}{(\cos^2\eta - \cosh^2\xi)} \left[\sinh\xi\cos\eta\,\psi'(\xi)\phi(\eta) - \cosh\xi\sin\eta\,\psi(\xi)\phi'(\eta)\right] \\
& - \mathbf{j}\, \frac{c}{4\sqrt{q}}\, \frac{1}{(\cos^2\eta - \cosh^2\xi)} \left[\cosh\xi\sin\eta\,\psi'(\xi)\phi(\eta) + \sinh\xi\cos\eta\,\psi(\xi)\phi'(\eta)\right]
\end{aligned}$$

where $\psi(\xi)$ is a solution of Eq. (16) and $\phi(\eta)$ is a solution of Eq. (15).

 ISBN: 978-84-617-8694-7

Referring to Fig. 2, at any point $(0,\eta)$ and the corresponding point $(0,-\eta)$ across the line segment $\xi = 0$, we have continuity of displacement and gradient in crossing the interfocal line orthogonally.

Theorem 4.1 (a) *continuity of displacement, i.e.* $\boldsymbol{\zeta}(0,\eta) = \boldsymbol{\zeta}(0,-\eta)$;

(b) *continuity of gradient, i.e.* $\dfrac{\partial}{\partial\xi}\left[\boldsymbol{\zeta}(\xi,\eta)\right]_{\xi\to 0} = -\dfrac{\partial}{\partial\xi}\left[\boldsymbol{\zeta}(\xi,-\eta)\right]_{\xi\to 0}$.

The *orthogonality* of the QWFs for the same q but different a over confocal ellipses with respect to the quaternionic inner product (20) is given in the following.

Theorem 4.2 *For a given $q>0$, the set $\{\boldsymbol{\zeta}_m^e, \boldsymbol{\zeta}_m^o : m = 1,2,\dots\}$ is orthogonal over the confocal ellipses (2) in the sense of the quaternionic inner product (20).*

4.2 Traveling wave function in the confocal elliptical cylinder

The QMFs will now be used to define the total wave function produced in a medium of arbitrary q under conditions (11) and (12). Since each QMF is linked to a specific characteristic constant a, the complete in-medium function $\boldsymbol{\vartheta}(\xi,\eta,t)$ is obtained by multiplying each QMF by the appropriate t-dependent exponential for which the associated a values cause them to satisfy the boundary conditions (11) and (12). Thus the *total wave function in the medium* is

Definition 4.2 (Total Wave Function) *For a given $q>0$, the total wave function associated with the QMFs is defined by*

$$\boldsymbol{\vartheta}(\xi,\eta,t) := \sum_{m=1}^{\infty} \boldsymbol{\zeta}_m(\xi,\eta) e^{-\kappa\alpha_m^2 t}\boldsymbol{\beta}_m \tag{22}$$

for integral quaternionic constants $\boldsymbol{\beta}_m$.

The coefficients in (22) *may* be evaluated numerically using the orthogonality of the underlying QMFs. Using the unknown constants $\boldsymbol{\beta}_m$, the initial condition (12) reads now as follows:

$$\boldsymbol{\vartheta}_0 = \sum_{m=1}^{\infty} \boldsymbol{\zeta}_m(\xi,\eta)\boldsymbol{\beta}_m. \tag{23}$$

Integrating, with respect to ξ from 0 to ξ_0 and to η from 0 to 2π, both sides of the equation obtained by multiplying from the left Eq. (23) by $c^2(\cosh^2\xi - \cos^2\eta)\overline{\boldsymbol{\zeta}_p(\xi,\eta)}$, it follows that

$$\begin{aligned}&\left[\int_0^{2\pi}\int_0^{\xi_0} \overline{\boldsymbol{\zeta}_p(\xi,\eta)} c^2(\cosh^2\xi - \cos^2\eta) d\xi d\eta\right]\boldsymbol{\vartheta}_0\\ &= \sum_{m=0}^{\infty}\left[\int_0^{2\pi}\int_0^{\xi_0} \overline{\boldsymbol{\zeta}_p(\xi,\eta)}\boldsymbol{\zeta}_m(\xi,\eta) c^2(\cosh^2\xi - \cos^2\eta) d\xi d\eta\right]\boldsymbol{\beta}_m,\quad p = 1,2,\dots.\end{aligned}$$

 ISBN: 978-84-617-8694-7

From Theorem 4.2, we readily have

$$\boldsymbol{\beta}_m = \boldsymbol{f}_m(\xi_0)\boldsymbol{\vartheta}_0, \quad m = 1, 2, \ldots$$

where

$$\boldsymbol{f}_m(\xi_0) := \frac{\displaystyle\int_0^{2\pi}\int_0^{\xi_0} \overline{\boldsymbol{\zeta}_m(\xi,\eta)}c^2(\cosh^2\xi - \cos^2\eta)d\xi d\eta}{\displaystyle\int_0^{2\pi}\int_0^{\xi_0} |\boldsymbol{\zeta}_m(\xi,\eta)|^2 c^2(\cosh^2\xi - \cos^2\eta)d\xi d\eta}.$$

The authors are currently attempting to explore the properties of the function (22) and its transition to circular membranes in more detail.

Abstract

This paper presents a framework for the automatic identification of the composition of small portions of music files. The task is performed by aligning the portion of audio with the stored MIDI scores. The system provides a ranked list of the compositions that best match the audio query, as well as their similarity measures and their aligned MIDI files. Preliminary results show the precision and robustness of the proposal.

Key words: Audio-to-MIDI Alignment, Dynamic Time Warping, Audio Identification

1 Introduction

Over the last years, a large amount of multimedia content has been placed on the Internet and made accessible through streaming sites. Many of the available files include performances of well-known classical music pieces, but the identity of the compositions is not always annotated. In this scenario, it is of great interest to identify automatically the composition corresponding to a given audio excerpt. This task involves computing the similarity between the audio input and every entry in a database of musical pieces, finally choosing the entry with the highest similarity. Since two performances of the same composition may

 ISBN: 978-84-617-8694-7

differ in tempo or interpretation, and usually the input audio is only a small portion of the whole piece, the common way to compute this similarity is through audio alignment techniques.

Audio alignment can be defined as the synchronization between two musical sequences which may have differences in interpretation. Alignment tools have been widely used in other related applications, such as cover song identification [1], query-by-tapping [2] or query-by-humming [3]. Most of the recent works are focused on the alignment between a musical score (such as MIDI or any other symbolic representation) and an audio excerpt [4, 5, 6]. Based on MIDI-to-audio alignment, a large number of approaches have been proposed to identify a query of a music excerpt using a large database of music score representations [7, 8, 9, 3]. In these cases, the alignment result is used as a criteria to measure how well the content in a MIDI score matches an input audio segment, such that the audio can be correctly identified if the correct composition is contained in the database. In the context of classical music, it is possible to gather large collections of accurately transcribed MIDI files, enabling to construct a reliable database for identification purposes.

To measure the similarity between the audio and the score, a set of features that characterize the musical content is first extracted from the audio signal. Features proposed by authors are often related to the target application, and a large variety of them can be found, such as chroma vectors [8, 1, 10, 11], beat-tracking [12], decaying locally adaptive normalized chroma onset (DLNCO) [5], peak structure distance (PSD) [13, 4] or measures derived from analysis with Non-negative Matrix Factorization (NMF) [14].

The alignment is performed by finding the best match between the extracted feature sequence and the score. Commonly, the process consists in filling a similarity matrix (or cost matrix) of the form $\mathbf{D}(\tau, t)$, containing distance values between discrete times τ in the MIDI and discrete times t in the audio. The most common approach to find the correspondence between both temporal axes is dynamic time warping (DTW) [11, 15, 16]. DTW uses dynamic programming to find an alignment such that the sum of the distance between aligned time instants is minimized. This output global distance is a natural measure of similarity between two sequences, and can be used to decide the best matching in a corpora of MIDI files. Consequently, for audio-to-MIDI matching applications, the performance of the system heavily depends on the robustness of the alignment core, particularly on its ability to compensate changes in tempo and interpretation.

In this paper we propose an audio-to-MIDI matching approach that identifies a music excerpt query among a database of classical music MIDI scores. The alignment kernel is based on our robust system proposed in [17, 18], employing a fast spectral factorization algorithm and DTW. As a result, the system provides a ranked list of the compositions that best match the audio query, as well as their similarity measures and their aligned MIDI files.

 ISBN: 978-84-617-8694-7

2 Proposed audio-to-MIDI matching system

The proposed framework for audio-to-MIDI matching is composed of two main modules. The MIDI preprocessing module must be carried out beforehand for each MIDI file in the database, with the aim of learning a set of parameters that adequately represent each score. The matching module performs the alignment between the input audio excerpt and each entry of the MIDI database, returning a confidence alignment measure.

2.1 MIDI Preprocessing Module

The aim of this module is to adequately represent the information given by a MIDI file to be used for alignment purposes. This task is performed only once, when a new MIDI entry is incorporated to the database, and not during the matching stage. The input MIDI score can be represented by a binary matrix $\mathbf{GT}(n,\tau)$, where τ is the time-frame index referenced to the score (MIDI time) and n are the notes in MIDI scale. This matrix has dimensionality $N \times L_m$, where N is the total number of notes in the composition and L_m is the number of frames in MIDI time. If the score contains different instruments, N is obtained as the sum of the different notes per instrument.

Each unique occurrence of individual or concurrent notes will be denoted here as a *score unit*. K is the number of units in the score and will be most likely smaller than the number of notes ($K << N$). In terms of score units, the score matrix $\mathbf{GT}(n,\tau)$ can be decomposed as follows

$$\mathbf{GT}(n,\tau) = \mathbf{Q}(n,k)\mathbf{R}(k,\tau), \tag{1}$$

where $\mathbf{Q}(n,k)$ is the binary notes-to-units matrix, k the index of each unique unit and $\mathbf{R}(k,\tau)$ represents the binary activation of each unit. Observe that $\mathbf{Q}(n,k)$ informs about the notes belonging to each unit, whereas $\mathbf{R}(k,\tau)$ retains the MIDI time activation per unit.

Since our alignment algorithm is based on spectral decomposition, the preprocessing module learns in advance a single spectral pattern for each score unit. To this end, a synthetic signal is first generated from the score using a MIDI synthesizer. Let us denote the magnitude spectrogram of the synthetic signal as $\mathbf{Y}(f,\tau)$, with f being the frequency bin index. This signal is then decomposed according to the following model:

$$\mathbf{Y}(f,\tau) \approx \hat{\mathbf{Y}}(f,\tau) = \mathbf{B}(f,k)\mathbf{G}(k,\tau), \tag{2}$$

where $\hat{\mathbf{Y}}(f,\tau)$ is the estimated spectrogram, $\mathbf{G}(k,\tau)$ matrix represents the gain of the spectral pattern for unit k at frame τ, and $\mathbf{B}(f,k)$ matrix represents the spectral patterns for all the units defined in the score. The parameters are estimated using NMF with β-divergence and multiplicative update rules, where $\mathbf{G}(k,\tau)$ is initialized to $\mathbf{R}(k,\tau)$, and $\mathbf{B}(f,k)$ to random positive numbers.

As a result of the preprocessing step, the system stores the matrices $\mathbf{R}(k,\tau)$ and $\mathbf{B}(f,k)$ for the MIDI file.

 ISBN: 978-84-617-8694-7

2.2 MIDI-to-audio Alignment Module

To perform the alignment between the input signal and a certain MIDI, the first step is the computation of a similarity measure between the audio and the different units defined by the score. In our approach, this measure is given by the distortion between the frequency transform of the input and the spectral patterns learned per unit.

Lets denote the frequency-domain input signal vector at time t as $\mathbf{x}_t(f)$, and the k-th unit spectral pattern as $\mathbf{b}_k(f)$. Assuming a signal model in which only a single pattern can be active at t, the gain $g_{k,t}$ that minimizes the β-divergence between the input frame and pattern k is computed by [19]:

$$g_{k,t} = \frac{\sum_f \mathbf{x}_t(f)\mathbf{b}_k(f)^{(\beta-1)}}{\sum_f \mathbf{b}_k(f)^{\beta}}. \tag{3}$$

Finally, the distortion matrix for each unit at each frame is defined by

$$\mathbf{\Phi}(k,t) = D_\beta\left(\mathbf{x}_t(f)|g_{k,t}\mathbf{b}_k(f)\right), \tag{4}$$

where $D_\beta(\cdot)$ is the β-divergence function and β can take values in the range $\in [0,2]$.

As can be inferred, the distortion matrix $\mathbf{\Phi}(k,t)$ provides us information about the similitude of each k-th unit spectral pattern with the real signal spectrum at each frame t. Using this information, we can directly compute the cost matrix between the MIDI time τ and the time of the input signal t as

$$\mathbf{D}(\tau,t) = \mathbf{R}^T(\tau,k)\mathbf{\Phi}(k,t), \tag{5}$$

where superscript "T" stands for matrix transposition. This matrix has dimensions $T_m \times T_r$, where T_r is the number of frames of the input signal.

To perform the alignment, the optimum path across matrix $\mathbf{D}(\tau,t)$ is obtained with DTW. Essentially, DTW consists in filling recursively a warping matrix $\mathbf{C}$ as follows:

$$\mathbf{C}(\tau,t) = \min \left\{ \begin{array}{c} \mathbf{C}(\tau-1,t-1) + \mathbf{D}(\tau,t) \\ \mathbf{C}(\tau-2,t-1) + \sigma_{2,1}\mathbf{D}(\tau,t) \\ \vdots \\ \mathbf{C}(\tau-\alpha_\tau,t-1) + \sigma_{\alpha_\tau,1}\mathbf{D}(\tau,t) \\ \mathbf{C}(\tau-1,t-2) + \sigma_{1,2}\mathbf{D}(\tau,t) \\ \vdots \\ \mathbf{C}(\tau-1,t-\alpha_t) + \sigma_{1,\alpha_t}\mathbf{D}(\tau,t) \end{array} \right\} \tag{6}$$

where the step size at each dimension has a range from 1 to α_τ and 1 to α_t, respectively. α_τ and α_t are the maximum step size at each dimension. Parameter σ controls the bias toward

 ISBN: 978-84-617-8694-7

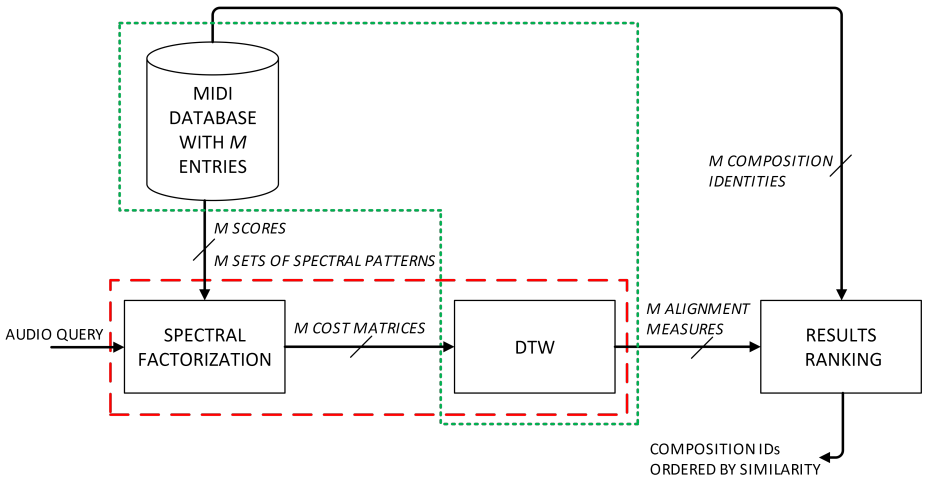

Figure 1: Block diagram of the proposed audio-to-MIDI matching engine.

diagonal steps as $\sigma_{x,y} = \sqrt{x^2 + y^2}$. $\mathbf{C}(\tau, t)$ is the accumulated cost of the minimum-cost path up to (τ, t), and $\mathbf{C}(\tau, 1) = \mathbf{D}(\tau, 1)\ \forall \tau$.

Once the warping matrix has been filled, it is possible to find the minimum-cost path $\mathbf{w} = w_1, ..., w_l, ..., w_L$, where each w_l is an ordered pair (τ_l, t_l) meaning that instant τ_l must be aligned with t_l. The path is obtained by tracing the recursion backwards from $\mathbf{C}(\tau_L, T_r)$, where $\tau_L = \arg\min_\tau \mathbf{C}(\tau, T_r)$. Since the audio query is usually a small fragment of the whole composition, the first and last elements of the path can be at any point along the τ axis. Globally, the path has to satisfy the following three conditions:

i Boundary condition: $w_1 = (\tau, 1)$ and $w_L = (\tau, T_r)$.

ii Monotonicity condition: $\tau_{l+1} \geq \tau_l$ and $t_{l+1} \geq t_l$.

iii Step size condition: $\tau_{l+1} \leq \tau_l + \alpha_\tau$ and $t_{l+1} \leq t_l + \alpha_t$.

This approach has the advantage of being computationally simple, and can be applied to perform audio-to-score matching over large datasets. For a certain score, the value $\mathbf{C}(\tau_L, T_r)$ can be considered as a confidence measure expressing the quality of the matching.

Figure 1 shows a block diagram of the system. In response to an audio query (typically, a excerpt of a few seconds), the system computes the alignment confidence measure $\mathbf{C}(\tau_L, T_r)$ for each MIDI in the database, returning a list of results ordered according to this value.

In [20] the software ReMAS (Real-time Musical Accompaniment System) designed to track the reproduction of a musical piece with the aim to match the score position into its symbolic representation on a digital sheet was presented. ReMAS shows that it is possible

to exploit efficiently several cores of an ARM® processor, or a GPU accelerator, reducing the processing time per frame in a few milliseconds in most of the cases. On the other hand, [21] proposes a parallel online DTW solution based on a client–server architecture implemented for multi-core architectures (86, 64 and ARM®). Looking at Figure 1, the blocks within the rectangle of dashed red lines have a high degree of similarity to ReMAS, whilst the shape of dashed green lines does so with [21]. Thereby the framework proposed in this work aims to adapt, extend and test the parallel heterogeneous algorithms of [21] and [20] to the new problem.

3 EXPERIMENTS AND RESULTS

The MIDI database for our audio-to-MIDI matching system has been obtained from the web *www.piano-midi.de*. It is composed of about 1123 minutes of score with 679986 played notes in 336 files. It contains several classical music pieces by 23 classical composers.

The system has been evaluated with 63 real audio performances downloaded from the Internet. For each audio file, six segments of 5, 10, 15, 20, 25 and 30 seconds with random start times along the file were selected and entered as a query into the system. Table 1 shows the percentage of searches in which the correct composition is in the 1st position of the list of results. As shown, for very short queries of only 5s, the correct composition is detected as the best result for the $85,7\%$ of the audio files. This accuracy rises to 98,4% for queries with a duration of 25s or longer.

Table 1: Accuracy measures (%)

5s	**10s**	**15s**	**20s**	**25s**	**30s**
85,7	93,6	95,2	96,8	98,4	98,4

Abstract

This contribution deals with an adaptation of the Poincaré–Lindstedt method for the determination of periodic orbits in three–dimensional nonlinear differential systems. We describe here a general symbolic algorithm to implement the method in a specific symbolic system which works with modified Poisson series. The sufficient conditions to make secular terms dissapear from the approximate series solution are given here.

Key words: Lotka–Volterra, periodic orbits, Poincaré–Lindstedt method, symbolic computation.

1 Introduction

The Poincaré–Lindstedt technique is a classical perturbation method used to continue a periodic orbit with respect to a small perturbation parameter, when fixing the amplitude (or the energy) of the system. This method has been used extensively to the analysis of a wide variety of systems in many branches of science: from galactic ([11], [12]) to atomic models ([9]), and covering also applications in population biology, ecology and mathematical biology ([1]). Nowadays, many researchers ([2], [4], [5], [6], [10] and [14] to cite some examples) make use of this method to study dynamical systems.

However, the efforts devoted to the application of the Poincaré–Lindstedt technique to systems of differential equations presenting a periodic orbit have not been so abundant. In [13], an approximation to the periodic solutions of the general Lotka–Volterra prey–predator system is obtained using the Poincaré–Lindstedt method. In [8], the method of Poincaré–Lindstedt is adapted to compute periodic solutions in perturbed two–dimensional systems. In particular, an approximate solution to a Lotka–Volterra model for two species

 ISBN: 978-84-617-8694-7

is computed. The computation of periodic solutions in Lotka–Volterra systems is an open problem where the Poincaré–Lindstedt method could play a key role in the computation of periodic orbits and the understanding of the way the phase space is structured not only in two species systems.

The aim of this paper is to present a general algorithm for implementing the standard Poincaré–Lindstedt method to three–dimensional perturbed systems of differential equations of first order. This adaptation is successfully applied to compute periodic solutions in Lotka–Volterra systems modeling a three–species food chain interaction. In the following section, we describe how to adapt the standard method to three–dimensional systems of the Lotka–Volterra type and give sufficient conditions to make secular terms dissapear from the solution. This result is key to set the stage to adapt the perturbation method to three–dimensional systems of differential equations.

2 Adaptation of the Poincaré–Lindstedt Method for Three–Dimensional Systems

Let us consider the problem defined by the following nonlinear differential system of first order,

$$\begin{aligned} \dot{x} + \alpha_{12} y &= \epsilon\, f_1(x,y,z)\,, \\ \dot{y} - \alpha_{21} x + \alpha_{23} z &= \epsilon\, f_2(x,y,z)\,, \\ \dot{z} - \alpha_{32} y &= \epsilon\, f_3(x,y,z)\,, \end{aligned} \tag{1}$$

where $0 < \epsilon \ll 1$ is a small parameter and functions $f_1(x,y,z)$, $f_2(x,y,z)$ and $f_3(x,y,z)$ can be arranged as follows,

$$\begin{aligned} f_1(x,y,z) &= \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{1,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\,, \\ f_2(x,y,z) &= \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{2,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\,, \\ f_3(x,y,z) &= \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{3,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\,. \end{aligned} \tag{2}$$

where $f_{1,\nu_2,q-\nu_1,\nu_1-\nu_2}$, $f_{2,\nu_2,q-\nu_1,\nu_1-\nu_2}$ and $f_{3,\nu_2,q-\nu_1,\nu_1-\nu_2} \in \mathbb{R}$ for $0 \le q \le M$, $0 \le \nu_1 \le q$, $0 \le \nu_2 \le \nu_1$ and $M \in \mathbb{N}$.

If the unperturbed system ($\epsilon = 0$) has periodic solutions and ϵ is a measure of the size of the perturbing terms, then the trajectories for the full system will remain pretty close to those of the non–perturbed system, for any finite period of time $t_0 < t < t_0 + \alpha$ ($\alpha > 0$) with an error not larger than $O(\alpha)$. In general, even a small perturbation is enough to

 ISBN: 978-84-617-8694-7

destroy periodicity, that is, nonlinearity will finish with most of the periodic orbits of the unperturbed system, but some of them may persist. The Poincaré–Lindstedt technique is used to find those periodic solutions by expanding the solution of the system in the form

$$\begin{aligned} x(t) &= x_0(T) + \epsilon\, x_1(T) + \epsilon^2\, x_2(T) + \cdots , \\ y(t) &= y_0(T) + \epsilon\, y_1(T) + \epsilon^2\, y_2(T) + \cdots , \\ z(t) &= z_0(T) + \epsilon\, z_1(T) + \epsilon^2\, z_2(T) + \cdots , \end{aligned} \tag{3}$$

where $x_\nu = x_\nu(T)$, $y_\nu = y_\nu(T)$ and $z_\nu = z_\nu(T)$ are 2π–periodic in T, and $T = \omega t$ is the stretched time variable, with

$$\omega = 1 + \epsilon\omega_1 + \epsilon^2\omega_2 + \cdots , \tag{4}$$

being ω_ν real constants. Thus, the nonlinear period is $2\pi/\omega$.

To apply this technique, one has to start by rewriting (1) in terms of the new independent variable T, to obtain

$$\begin{aligned} \omega x' + \alpha_{12} y &= \epsilon \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{1,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2} , \\ \omega y' - \alpha_{21} x + \alpha_{23} z &= \epsilon \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{2,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2} , \\ \omega z' - \alpha_{32} y &= \epsilon \sum_{0\le q\le M} \sum_{0\le \nu_1\le q} \sum_{0\le \nu_2\le \nu_1} f_{3,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2} . \end{aligned} \tag{5}$$

Here, $\dot{}$ stands for d/dt and $'$ for d/dT. If expansions (3) and (4) are substituted into (5), and terms in equal powers of ϵ are collected, we get an equation for each order of the approximation in the expansions (3). In order to simplify the expression of these equations, let us introduce here the following notation: S_ν denotes the ν–th order coefficient of the expansion of S, so that

$$S = S_0 + \epsilon S_1 + \epsilon^2 S_2 + \cdots .$$

For instance, if $S = x^2$, then $(x^2)_0 = x_0 x_0$, $(x^2)_1 = 2x_0 x_1$, and in general, $(x^2)_q = \sum_{0\le\nu\le q} x_\nu x_{q-\nu}$. This notation eases the way to express the formulae for the computation of the coefficients of the expansion of the solution at any order.

The solution to (1) is constructed from the order zero, which corresponds with the unperturbed problem, and can be written as

$$\begin{aligned} \omega_0 x_0' + \alpha_{12} y_0 &= 0 , \\ \omega_0 y_0' - \alpha_{21} x_0 + \alpha_{23} z_0 &= 0 , \\ \omega_0 z_0' - \alpha_{32} y_0 &= 0 . \end{aligned} \tag{6}$$

 ISBN: 978-84-617-8694-7

The first order system is given by

$$\begin{aligned}
\omega_0 x_1' + \alpha_{12} y_1 &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{1,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x_0^{\nu_2} y_0^{q-\nu_1} z_0^{\nu_1-\nu_2} - \omega_1 x_0' \,, \\
\omega_0 y_1' - \alpha_{21} x_1 + \alpha_{23} z_1 &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{2,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x_0^{\nu_2} y_0^{q-\nu_1} z_0^{\nu_1-\nu_2} - \omega_1 y_0' \,, \\
\omega_0 z_1' - \alpha_{32} y_1 &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{3,\nu_2,q-\nu_1,\nu_1-\nu_2}\, x_0^{\nu_2} y_0^{q-\nu_1} z_0^{\nu_1-\nu_2} - \omega_1 z_0' \,.
\end{aligned} \tag{7}$$

The order Q of the expansion is obtained by solving the system

$$\begin{aligned}
\omega_0 x_Q' + \alpha_{12} y_Q &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{1,\nu_2,q-\nu_1,\nu_1-\nu_2}\, \left[x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\right]_{Q-1} - \\
&\quad - \sum_{1\le\nu\le Q-1} x_\nu' \omega_{Q-\nu} - \omega_Q x_0' \,, \\
\omega_0 y_Q' - \alpha_{21} x_Q + \alpha_{23} z_Q &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{2,\nu_2,q-\nu_1,\nu_1-\nu_2}\, \left[x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\right]_{Q-1} - \\
&\quad - \sum_{1\le\nu\le Q-1} y_\nu' \omega_{Q-\nu} - \omega_Q y_0' \,, \\
\omega_0 z_Q' - \alpha_{32} y_Q &= \sum_{0\le q\le M}\ \sum_{0\le\nu_1\le q}\ \sum_{0\le\nu_2\le\nu_1} f_{3,\nu_2,q-\nu_1,\nu_1-\nu_2}\, \left[x^{\nu_2} y^{q-\nu_1} z^{\nu_1-\nu_2}\right]_{Q-1} - \\
&\quad - \sum_{1\le\nu\le Q-1} z_\nu' \omega_{Q-\nu} - \omega_Q z_0' \,.
\end{aligned} \tag{8}$$

At each order p of the perturbation method, one has to calculate x_p, y_p, z_p and ω_p from the equation above, but also x_p', y_p', z_p' and the collection of products $(x^{\nu_1} y^{\nu_2} z^{\nu_3})_p$ for each $\nu_1, \nu_2, \nu_3 \in \mathbb{Z}$ such that $0 \le \nu_1, \nu_2, \nu_3 \le M$, in order to compute the right–hand side of equation (8) for the $(p+1)$–th order of the perturbation method. At the p–th order of the Poincaré–Lindstedt approximation, one first fits the value of ω_p to assure that no secular terms exist, expressing it as a function of some constants which depend on the initial conditions of the problem. This is done by applying the proposition 1, given below. Once ω_p has been obtained, x_p, y_p and z_p can be computed by solving the system (8).

 ISBN: 978-84-617-8694-7

Proposition 1 *The differential system*

$$\begin{aligned}
\omega_0 x' + \alpha_{12} y &= A\cos T + B\sin T + \sum_{n>1}(A_n \cos nT + B_n \sin nT)\,, \\
\omega_0 y' - \alpha_{21} x + \alpha_{23} z &= C\cos T + D\sin T + \sum_{n>1}(C_n \cos nT + D_n \sin nT)\,, \\
\omega_0 z' - \alpha_{32} y &= E\cos T + F\sin T + \sum_{n>1}(E_n \cos nT + F_n \sin nT)\,,
\end{aligned} \tag{9}$$

where

$$\omega_0 = \sqrt{\alpha_{12}\alpha_{21} + \alpha_{23}\alpha_{32}}\,,$$

has no secular terms if

$$\begin{aligned}
\omega_0 C + \alpha_{23} F - \alpha_{21} B &= 0\,, \\
\omega_0 D - \alpha_{23} E + \alpha_{21} A &= 0\,.
\end{aligned}$$

Proof. Let us take, without loss of generality,

$$A_n = B_n = C_n = D_n = D_n = E_n = F_n = 0\,,$$

for any $n > 1$. The solution $x(t)$ to (9) can be written as

$$\begin{aligned}
x(t) &= \frac{1}{\omega_0^2}\left(\alpha_{12}\omega_0 k_3 - \frac{\alpha_{12}\alpha_{21} + 2\alpha_{23}\alpha_{32}}{2\omega_0} B - \frac{\alpha_{12}}{2} C - \frac{\alpha_{12}\alpha_{23}}{2\omega_0} F\right)\cos T + \\
&+ \frac{1}{\omega_0^2}\left(\frac{\alpha_{12}\alpha_{21}}{2\omega_0} A + \frac{\alpha_{12}}{2} D - \frac{\alpha_{12}\alpha_{23}}{2\omega_0} E\right) T\cos T - \\
&- \frac{1}{\omega_0^2}\left(\alpha_{12}\omega_0 k_2 + \alpha_{12} D - \frac{\alpha_{23}\alpha_{32}}{\omega_0} A - \frac{\alpha_{12}\alpha_{23}}{\omega_0} E\right)\sin T - \\
&- \frac{1}{\omega_0^2}\left(-\frac{\alpha_{12}\alpha_{21}}{2\omega_0} B + \frac{\alpha_{12}}{2} C + \frac{\alpha_{12}\alpha_{23}}{2\omega_0} F\right) T\sin T + k_1\,,
\end{aligned}$$

where k_1, k_2 and k_3 are integration contants depending on the initial conditions of the problem. The condition to make the secular term $T\cos T$ dissapear is given by

$$\frac{\alpha_{12}}{2} D - \frac{\alpha_{12}\alpha_{23}}{2\omega_0} E + \frac{\alpha_{12}\alpha_{21}}{2\omega_0} A = 0\,,$$

that is,

$$\omega_0 D - \alpha_{23} E + \alpha_{21} A = 0\,.$$

In the same way, the condition to make the secular term $T\sin T$ dissapear is given by

$$\frac{\alpha_{12}}{2} C - \frac{\alpha_{12}\alpha_{21}}{2\omega_0} B + \frac{\alpha_{12}\alpha_{23}}{2\omega_0} F = 0\,,$$

 ISBN: 978-84-617-8694-7

that is,

$$\omega_0 C + \alpha_{23} F - \alpha_{21} B = 0\,.$$

This procedure can be carried out also for $y(t)$ and $z(t)$, obtaining the same set of conditions. ■

3 Application to Lotka–Volterra Systems

In 1925, Lotka ([7]) proposed a differential equation model to describe the population dynamics of two interacting species, a predator and its prey. A species $x(t)$ serves as food to another species $y(t)$, so that, in this sense, $x(t)$ becomes transformed into $y(t)$. The formulation of Volterra was as follows: A species $y(t)$ feeds on a species $x(t)$, which, in turn feeds on some source presented in such large excess that the mass of this source may be considered constant during the period of time under consideration. Then, under this assumption, we have that the rate of increase of $x(t)$ per unit of time is equal to the difference between the mass of newly formed of $x(t)$ per unit of time and the mass of $x(t)$ destroyed by $y(t)$ per unit of time. The Lotka–Volterra model for two species consists of the following differential equations:

$$\begin{aligned} \dot{x} &= x(r_1 - a_{12}x_2)\,, \\ \dot{y} &= y(-r_2 + a_{21}x_2)\,. \end{aligned} \tag{10}$$

Here, $y(t)$ and $x(t)$ represent, respectively, the predator population and the prey population as functions of time. The parameters $r_1, r_2, a_{12}, a_{21} > 0$ are interpreted as follows: r_1 represents the natural growth rate of the prey in the absence of predators, a_{12} represents the effect of predation on the prey, r_2 is the natural death rate of the predator in the absence of prey, and a_{21} the efficiency and propagation rate of the predator in the presence of prey.

In this section, in order to illustrate the effectiveness of the perturbation procedure, we will focus our interest in a linear three species food chain where the lowest level prey, x is preyed upon by a mid–level species, y who, in turn, is preyed upon by a top level predator z. The equations of the system are

$$\begin{aligned} \dot{x} &= x(r_1 - a_{12}y)\,, \\ \dot{y} &= y(-r_2 + a_{21}x - a_{23}z)\,, \\ \dot{z} &= z(-r_3 + a_{32}y)\,. \end{aligned} \tag{11}$$

Here, $r_1, r_2, r_3 > 0$ and $a_{12}, a_{21}, a_{23}, a_{32} > 0$. The parameters r_1, r_2, a_{12} and a_{21} have the same meaning as in the Lotka–Volterra equations for two species, a_{23} represents the effect of predation on species y by species z, r_3 the natural death rate of the predator z in the absence of prey, and a_{32} stands for the efficiency and propagation rate of the predator z in

 ISBN: 978-84-617-8694-7

the presence of prey. Since populations are non–negative, we will restrict our attention to the non–negative octant $\Omega = \{(x, y, z) : \ x \geq 0\,,\ y \geq 0\,,\ z \geq 0\} \subset \mathbb{R}^3$, and the positive octant $\Omega^+ = \{(x, y, z) : \ x > 0\,,\ y > 0\,,\ z > 0\} \subset \mathbb{R}^3$. Each coordinate plane is invariant with respect to (11) (see for instance [3]).

Let us study now the equilibrium points of (11). This system has equilibrium points in the interior of Ω^+ if

$$\begin{aligned} r_1 - a_{12}y &= 0\,, \\ -r_2 + a_{21}x - a_{23}z &= 0\,, \\ -r_3 + a_{32}y &= 0\,. \end{aligned}$$

By solving these equations, we get that

$$y = \frac{1}{a_{12}} r_1\,, \quad r_3 a_{12} = r_1 a_{32}\,,$$

and

$$x = \frac{1}{a_{21}} r_2 + \frac{a_{23}}{a_{21}} z\,.$$

Thus, it results straightforward to find that there is ray of equilibrium points of the form

$$P_\lambda \left(\frac{r_2}{a_{21}} + \frac{a_{23}}{a_{21}}\lambda, \frac{r_1}{a_{12}}, \lambda \right)\,,$$

with $\lambda \in \mathbb{R}$, in the case $r_3 a_{12} = r_1 a_{32}$. The Jacobian matrix of the system in any of these equilibrium points is given by

$$A(P_\lambda) = \begin{pmatrix} 0 & -a_{12}(r_2 + a_{23}\lambda)/a_{21} & 0 \\ a_{21}r_1/a_{12} & 0 & -a_{23}r_1/a_{12} \\ 0 & a_{32}\lambda & 0 \end{pmatrix}\,,$$

with eigenvalues

$$\begin{aligned} \lambda_1 &= 0\,, \\ \lambda_2 &= +\frac{1}{a_{12}} \sqrt{-a_{12}r_1 \left(a_{23}a_{32}\lambda + r_2 a_{12} + a_{23}a_{12}\lambda\right)}\,, \\ \lambda_3 &= -\frac{1}{a_{12}} \sqrt{-a_{12}r_1 \left(a_{23}a_{32}\lambda + r_2 a_{12} + a_{23}a_{12}\lambda\right)}\,. \end{aligned}$$

As the three eigenvalues have zero real part, each such equilibrium point has a three–dimensional center manifold, which does not help us determine the dynamics near these fixed points. The numerical exploration of the solutions suggests that the system contains invariant surfaces. In particular, it can be proved that the surfaces $z = Kx^{-r_3/r_1}$ are

 ISBN: 978-84-617-8694-7

invariant in Ω^+. These surfaces are filled with periodic orbits enclosing the ray of quilibrium points P_λ (see [3]).

In order to determine these periodic orbits, we perturb the system around the equilibrium point $(r_2/a_{21} + \lambda a_{23}/a_{21}, r_1/a_{12}, \lambda)$,

$$\begin{aligned} x(t) &= \frac{r_2}{a_{21}} + \frac{a_{23}}{a_{21}}\lambda + \epsilon X(t)\,, \\ y(t) &= \frac{r_1}{a_{12}} + \epsilon Y(t)\,, \\ z(t) &= \lambda + \epsilon Z(t)\,, \end{aligned}$$

to obtain the perturbed system

$$\begin{aligned} \dot{X} &= -\frac{a_{12}}{a_{21}}\left(r_2 + a_{23}\lambda\right) Y - \epsilon\, a_{12} XY\,, \\ \dot{Y} &= r_1\frac{a_{21}}{a_{12}} X - r_1\frac{a_{23}}{a_{12}} Z + \epsilon\left(a_{21}XY - a_{23}YZ\right), \\ \dot{Z} &= a_{32}\lambda Z + \epsilon\, a_{32} YZ\,. \end{aligned}$$

The introduction of stretched time variable $T = \omega t$ gives

$$\begin{aligned} \omega x' &= -\frac{a_{12}}{a_{21}}\left(r_2 + a_{23}\lambda\right) y - \epsilon\, a_{12} xy\,, \\ \omega y' &= r_1\frac{a_{21}}{a_{12}} x - r_1\frac{a_{23}}{a_{12}} z + \epsilon\left(a_{21}xy - a_{23}yz\right), \\ \omega z' &= a_{32}\lambda y + \epsilon\, a_{32} yz\,, \end{aligned} \tag{12}$$

after recalling $X = x$, $Y = y$ and $Z = z$ for the sake of simplicity. In order to apply the Poincaré–Lindstedt technique as described in section 2, we expand the solution of the system and ω as expressed in equations (3) and (4),

$$\begin{aligned} x(T) &= x_0(T) + \epsilon x_1(T) + \epsilon^2 x_2(T) + \cdots\,, \\ y(T) &= y_0(T) + \epsilon y_1(T) + \epsilon^2 y_2(T) + \cdots \\ z(T) &= z_0(T) + \epsilon z_1(T) + \epsilon^2 z_2(T) + \cdots \end{aligned}$$

and

$$\omega = \omega_0 + \epsilon\omega_1 + \epsilon^2\omega_2 + \cdots$$

By substituting these expasions into equation (12), and collecting terms in equal powers of ϵ, we get an equation for each order of the approximation. The order zero is given by

$$\begin{aligned} \omega_0 x_0' &= -\frac{a_{12}}{a_{21}}\left(r_2 + a_{23}\lambda\right) y_0\,, \\ \omega_0 y_0' &= r_1\frac{a_{21}}{a_{12}} x_0 - r_1\frac{a_{23}}{a_{12}} z_0\,, \\ \omega_0 z_0' &= a_{32}\lambda y_0\,. \end{aligned} \tag{13}$$

 ISBN: 978-84-617-8694-7

The solution to (13) is

$$\begin{aligned} x_0(T) &= \frac{a_{23}}{a_{21}}A + \frac{(r_2+a_{23}\lambda)a_{12}}{a_{21}\omega_0}B\cos T - \frac{(r_2+a_{23}\lambda)a_{12}}{a_{21}\omega_0}C\sin T\,, \\ y_0(T) &= C\cos T + B\sin T\,, \\ z_0(T) &= A - \frac{a_{32}\lambda}{\omega_0}B\cos T + \frac{a_{32}\lambda}{\omega_0}C\sin T\,, \end{aligned} \tag{14}$$

where A, B and C depend on the initial conditions of the solution. The derivatives of x_0, y_0 and z_0 are

$$\begin{aligned} x_0'(T) &= -\frac{(r_2+a_{23}\lambda)a_{12}}{a_{21}\omega_0}C\cos T - \frac{(r_2+a_{23}\lambda)a_{12}}{a_{21}\omega_0}B\sin T\,, \\ y_0'(T) &= B\cos T - C\sin T\,, \\ z_0'(T) &= \frac{a_{32}\lambda}{\omega_0}C\cos T + \frac{a_{32}\lambda}{\omega_0}B\sin T\,. \end{aligned} \tag{15}$$

The first order system is given by

$$\begin{aligned} \omega_0 x_1' + \frac{a_{12}}{a_{21}}\left(r_2+a_{23}\lambda\right)y_1 &= -a_{12}x_0y_0 - \omega_1 x_0'\,, \\ \omega_0 y_1' - r_1\frac{a_{21}}{a_{12}}x_1 + r_1\frac{a_{23}}{a_{12}}z_1 &= a_{21}x_0y_0 - a_{23}y_0z_0 - \omega_1 y_0'\,, \\ \omega_0 z_1' - a_{32}\lambda y_1 &= a_{32}y_0z_0 - \omega_1 z_0'\,. \end{aligned}$$

The substitution of equations (14) and (15) in the first order system yields

$$\begin{aligned} &\omega_0 x_1' + \frac{a_{12}}{a_{21}}\left(r_2+a_{23}\lambda\right)y_1 = \\ &= \frac{a_{12}}{a_{21}\omega_0}C\left(\omega_1(r_2+a_{23}\lambda) - \omega_0 a_{23}A\right)\cos T + \\ &\quad + \frac{a_{12}}{a_{21}\omega_0}B\left(\omega_1(r_2+a_{23}\lambda) - \omega_0 a_{23}A\right)\sin T - \\ &\quad - \frac{a_{12}^2BC}{a_{21}\omega_0}(r_2+a_{23}\lambda)\cos 2T + \frac{a_{12}^2}{2a_{21}\omega_0}\left((C^2-B^2)(r_2+a_{23}\lambda)\right)\sin 2T\,, \\ &\omega_0 y_1' - \frac{a_{21}r_1}{a_{12}}x_1 + \frac{a_{23}r_1}{a_{12}}z_1 = \\ &= -\omega_1 B\cos T + \omega_1 C\sin T + \frac{BC}{\omega_0}\left(a_{12}(r_2+a_{23}\lambda) + a_{23}a_{32}\lambda\right)\cos 2T + \\ &\quad + \frac{B^2-C^2}{2\omega_0}\left(a_{12}r_2 + (a_{12}+a_{32})a_{23}\lambda\right)\sin 2T\,, \\ &\omega_0 z_1' - a_{32}\lambda y_1 = \\ &= \frac{a_{32}}{\omega_0}C(A\omega_0 - \omega_1\lambda)\cos T + \frac{a_{32}}{\omega_0}B(A\omega_0 - \omega_1\lambda)\sin T - \\ &\quad - \frac{a_{32}^2\lambda}{\omega_0}BC\cos 2T + \frac{a_{32}^2\lambda}{2\omega_0}(C^2-B^2)\sin 2T\,. \end{aligned} \tag{16}$$

 ISBN: 978-84-617-8694-7

The application of proposition 1 to the system (16) gives

$$\omega_1 = -\frac{r_1 a_{23} A\,(a_{12} - a_{32})\,\omega_0}{a_{12}(\omega_0^2 + r_1 r_2) + \lambda r_1 a_{23}(a_{12} + a_{32})}\,.$$

From the analysis of this example, it follows that the application of the Poincaré–Lindstedt method involves working with expressions and procedures that should be automated to avoid mistakes in the algebraic manipulation of those developments.

4 Computation of a periodic orbit in a three–dimensional Lotka–Volterra model

Let us consider the system

$$\begin{aligned} \dot{x} &= x(1-y)\,, \\ \dot{y} &= y(-2+x-z)\,, \\ \dot{z} &= z(-1+y)\,. \end{aligned} \tag{17}$$

The equilibrium points of the system are $(2+\lambda, 1, \lambda)$, $\lambda \in \mathbb{R}^+$. Let us take, for instance, $\lambda = 1/2$, and the equilibrium point $(5/2, 1, 1/2)$. Following the procedure employed in section 3, equation (17) is transformed into

$$\begin{aligned} \omega x' &= -\frac{5}{2}y - \epsilon yz\,, \\ \omega y' &= x - z + \epsilon(xy - yz)\,, \\ \omega z' &= \frac{1}{2}y + \epsilon yz\,. \end{aligned} \tag{18}$$

We compute ω_0 from the unperturbed system ($\epsilon = 0$), $\omega_0 = \sqrt{3}$. By substituting (3) and (4) into equation (18), and collecting terms in equal powers of ϵ, we get an equation for each order of the series solution. In Figure 1, we compare between the numerical solution to equation (17) with initial conditions $x(0) = 2.864670867$, $y(0) = 1.187254264$, $z(0) = 0.669094392$, obtained by using a fourth order Runge–Kutta method, and a fifth order approximation to the solution computed through the Poincaré–Lindstedt method.

5 Conclusion

In this paper, a symbolic algorithm for a general application of the Poincaré–Lindstedt method for the computation of periodic solutions in three–dimensional differential systems of first order has been presented. We have adapted the standard method to three–dimensional nonlinear systems, giving the sufficient conditions to avoid the occurrence of secular terms in the perturbation series solution. The algorithm has been used to compute periodic solutions in a three–dimensional Lotka–Volterra system modeling a chain food interaction.

Abstract

Some procedures of approximation of three-dimensional data on a grid are summarized. The first part proposes a generalization of a discrete periodic approximation defined by Dunham Jackson. The functions used have the advantage of owning an analytical explicit expression in terms of the samples (specific values) of the original function or the data. In the second part we deal with a continuous approximation function for the same problem, defined through an integral. Some results of the rate of convergence and bounds of the approximation error are presented, with the single hypothesis of continuity of the original function.

Key words: Trigonometric approximation, trigonometric interpolation, smoothing, surface fitting

1 Introduction

In 1885 Weierstrass proved that every continuous function defined in a compact interval is approximated by a polynomial with arbitrary precision. This fact motivated the scientists of later generations and, specially, Dunham Jackson, American mathematician who published his work in the first decades of the twentieth century. This author wrote several books ([7], [9]) and numerous articles (see for instance [4], [5], [6], [8]) on polynomial and trigonometric approximation of continuous and discontinuous functions. His writings led to transcendental mathematical outcomes as for instance the inequalities named after him, which describe the degree of approximation of a continuous function by means of polynomials (algebraic and trigonometric). For instance, if

$$d_n^*(f) = d(f, \mathcal{P}_n)$$

 ISBN: 978-84-617-8694-7

represents the uniform distance from f to the space of polynomials of degree (order) at most n, the following inequalities hold ([2]).

Theorem 1.1. *For all f continuous with period 2π ($f \in \mathcal{C}[-\pi,\pi]$) which satisfy a Lipschitz condition $|f(x)-f(y)| \leq \lambda|x-y|$,*

$$d_n^*(f) \leq \frac{\pi\lambda}{2(n+1)}.$$

Theorem 1.2. *For all f continuous with period 2π ($f \in \mathcal{C}[-\pi,\pi]$)*

$$d_n^*(f) \leq \omega\left(\frac{\pi}{(n+1)}\right),$$

where $\omega(\delta)$ is the modulus of continuity of f.

Hereafter we evoke the procedures used by Jackson for periodic functions, generalizing the approximants in the two dimensional case. One of the formulae proposed is an explicit model in terms of the data on a two-dimensional grid. Some error bounds are deduced for more general exponents of the basic functions, and the convergence is proved with the single hypothesis of continuity on a compact interval, unlike the standard trigonometric interpolation.

2 Two-dimensional discrete approximant of Jackson type

In this Section we consider a trigonometric fitting mapping for functions or data defined on a grid on the two-dimensional interval $[-\pi,\pi]\times[-\pi,\pi]$, assuming periodicity in both variables. They are inspired (generalizing them) in approximations of Jackson, and they are defined explicitly in terms of the data (function values). Due to this fact, we name them discrete approximants, in order to distinguish them from other functions defined in later Section.

Let us consider a set of three-dimensional data on a grid:

$$\{(x_i, y_j, f(x_i,y_j)) : i = 1,2,\ldots,m; j = 1,2,\ldots,n\},$$

where $x_{i+1}-x_i = \pi/m$, $i = 1,2,\ldots,2m-1$; $y_{j+1}-y_j = \pi/n$, $j = 1,2,\ldots,2n-1$.

Let T^1 represent the unit circle and let us consider $f \in \mathcal{C}(T^1\times T^1)$ (continuous and periodic with period 2π in both variables), and an exponent $\gamma > 0$ ([6]). The approximation of f on a grid is defined by the expression:

$$\mathcal{J}_{mn\gamma}(f)(x,y) = K_{mn\gamma}(x,y)\sum_{i=1}^{2m}\sum_{j=1}^{2n} f(x_i,y_j)\left|\frac{\sin\left(\frac{1}{2}m(x_i-x)\right)}{m\sin\left(\frac{1}{2}(x_i-x)\right)}\right|^{\gamma}\left|\frac{\sin\left(\frac{1}{2}n(y_j-y)\right)}{n\sin\left(\frac{1}{2}(y_j-y)\right)}\right|^{\gamma},$$

 ISBN: 978-84-617-8694-7

where

$$K_{mn\gamma}^{-1}(x,y)=\sum_{i=1}^{2m}\sum_{j=1}^{2n}\left|\frac{\sin\left(\frac{1}{2}m(x_i-x)\right)}{m\sin\left(\frac{1}{2}(x_i-x)\right)}\right|^{\gamma}\left|\frac{\sin\left(\frac{1}{2}n(y_j-y)\right)}{n\sin\left(\frac{1}{2}(y_j-y)\right)}\right|^{\gamma}.$$

In the case $\gamma=4$, one has

$$K_{mn4}^{-1}(x,y)=\sum_{i=1}^{2m}\left(\frac{\sin\left(\frac{1}{2}m(x_i-x)\right)}{m\sin\left(\frac{1}{2}(x_i-x)\right)}\right)^4\sum_{j=1}^{2n}\left(\frac{\sin\left(\frac{1}{2}n(y_j-y)\right)}{n\sin\left(\frac{1}{2}(y_j-y)\right)}\right)^4=H_m^{-1}H_n^{-1}.$$

H_m (or H_n) is a constant such that ([6]) for all m:

$$1/2\leq H_m<3/4.$$

Consequently, K_{mn4} is a constant such that for all m, n :

$$1/4\leq K_{mn4}<9/16.$$

$\mathcal{J}_{mn4}(f)$ is a trigonometric polynomial of order at most $2(m-1)$ in x and $2(n-1)$ in y. If γ is a multiple of 2, the function is a trigonometric rational.

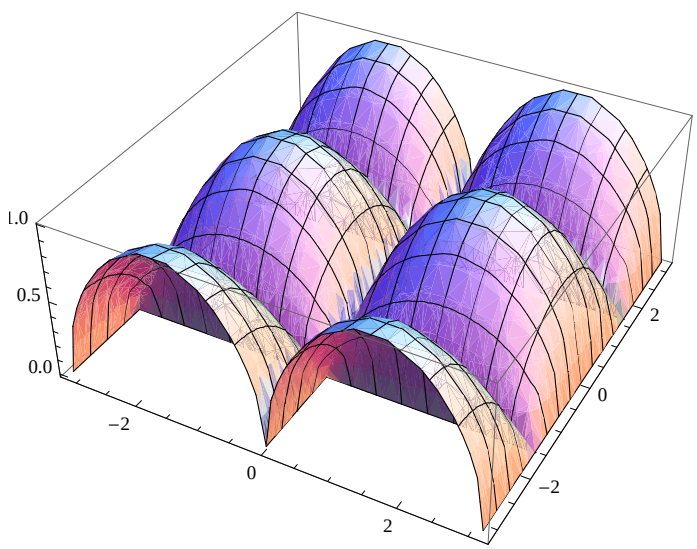

Figure 1: Graph of the function $f(x,y)=\sqrt{|\sin(x)\cos(y)|}$ in the square $[-\pi,\pi]\times[-\pi,\pi]$.

Lemma 2.1. *For all* $m=1,2,\ldots;\ \gamma>0,$ *and* $v\in\mathbb{R}$:

$$\left|\frac{\sin(mv)}{m\sin(v)}\right|^{\gamma}\leq 1.$$

 ISBN: 978-84-617-8694-7

Theorem 2.2. *For any continuous function* $f \in \mathcal{C}(T^1 \times T^1)$, $\gamma > 2$ *and* $(x, y) \in T^1 \times T^1$,

$$|\mathcal{J}_{mn\gamma}(f)(x,y) - f(x,y)| \leq \omega\left(\frac{\pi}{4m} + \frac{\pi}{4n}\right) C'(\gamma) \leq \omega\left(\frac{1}{m} + \frac{1}{n}\right) C(\gamma),$$

where $C'(\gamma)$, $C(\gamma)$ *do not depend on* m, n.

Remark 2.3. If $\gamma > 2$, the rate of convergence of the error when the partition is indefinitely refined is that of the modulus $\omega(\frac{1}{m} + \frac{1}{n})$ (it does not depend on the exponent γ).

Remark 2.4. For any continuous function $f \in \mathcal{C}(T^1 \times T^1)$ and $\gamma > 2$, the approximant $\mathcal{J}_{mn\gamma}(f)$ converges uniformly to f as m and n tend to infinity.

Remark 2.5. The uniform convergence on the compact interval implies the convergence in the p-norm for any $1 \leq p < \infty$.

Remark 2.6. If f satisfies a Lipschitz condition of order q $(0 < q \leq 1)$, then there is a wider range of convergence values: $\gamma > 1 + q$. The case $\gamma = 2$ is within this interval.

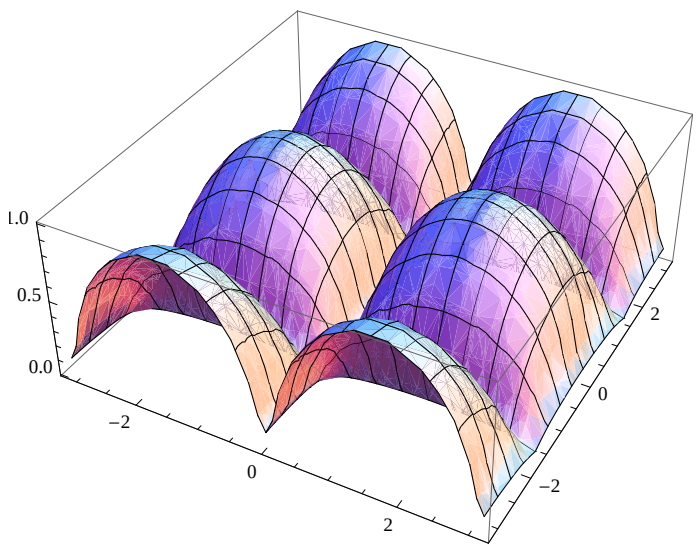

Figure 2: Graph of the discrete approximant of $f(x, y) = \sqrt{|\sin(x)\cos(y)|}$ for $m = 10$, $n = 10$ and $\gamma = 5$ in the square $[-\pi, \pi] \times [-\pi, \pi]$.

Let us denote by

$$\|\mathcal{J}_{mn\gamma}\|$$

the norm of the operator $\mathcal{J}_{mn\gamma}$ with respect to the uniform (supremum) norm $\|\cdot\|_\infty$ in $\mathcal{C}(T^1 \times T^1)$.

 ISBN: 978-84-617-8694-7

Theorem 2.7. *For $m, n \in \mathbb{N}$ and $\gamma > 2$, $\|\mathcal{J}_{mn\gamma}\| = 1$.*

Remark 2.8. The operator $\mathcal{J}_{mn\gamma}$ is linear and bounded. It does not amplify the errors in the z-values since let $f, \widetilde{f}$ be the functions corresponding to data (x_i, y_j, z_{ij}) and $(x_i, y_j, \widetilde{z}_{ij})$. Considering the linearity and the norm of the approximation operator:

$$\|\mathcal{J}_{mn\gamma}(f) - \mathcal{J}_{mn\gamma}(\widetilde{f})\|_\infty \leq \|f - \widetilde{f}\|_\infty.$$

3 Two dimensional continuous approximants of Jackson type

We consider here the approximant of a continuous and periodic function $f \in \mathcal{C}(2\pi)$. This model was proposed by Jackson in the article "On approximation by trigonometric sums and polynomials" ([5]). We consider a more general case, where the exponent 4 appearing in the paper is replaced by any positive exponent $\gamma > 0$:

$$\mathcal{F}_{m\gamma}(f)(x) = h_{m\gamma} \int_{-\pi/2}^{\pi/2} f(x+2u) \left| \frac{\sin(mu)}{m \sin(u)} \right|^\gamma du,$$

where

$$h_{m\gamma}^{-1} = \int_{-\pi/2}^{\pi/2} \left| \frac{\sin(mu)}{m \sin(u)} \right|^\gamma du. \tag{3.1}$$

If $\gamma = 4$, $\mathcal{F}_{m\gamma}(f)$ is a trigonometric polynomial of order at most $2(m-1)$. In the general case the kernels

$$\left| \frac{\sin(mu)}{m \sin(u)} \right|^\gamma$$

have an "order" of $\gamma(m-1)/2$ (although we admit here non-integer values of the exponent). If $\gamma = 2q$, where $q \in \mathbb{N}$, $\mathcal{F}_{m\gamma}(f)$ is a trigonometric polynomial or order at most $q(m-1)$.

Lemma 3.1. *If $p < -1$ and $\gamma > -(p+1)$ then*

$$K_{p\gamma} = \int_0^{+\infty} u^p |\sin(u)|^\gamma du \leq \frac{1}{(p+\gamma+1)} - \frac{1}{(p+1)}.$$

If $\gamma > 2$,

$$i_{m\gamma}^1 = \int_0^{\pi/2} u \left| \frac{\sin(mu)}{m \sin(u)} \right|^\gamma du \leq \frac{1}{m^2} \left(\frac{\pi}{2} \right)^\gamma \left(\frac{1}{2} - \frac{1}{2-\gamma} \right),$$

and if $\gamma > 1$,

$$i_{m\gamma}^0 = \int_0^{\pi/2} \left| \frac{\sin(mu)}{m \sin(u)} \right|^\gamma du \leq \frac{1}{m} \left(\frac{\pi}{2} \right)^\gamma \left(1 - \frac{1}{1-\gamma} \right).$$

 ISBN: 978-84-617-8694-7

If $\gamma > 0$,

$$h_{m\gamma} \leq \frac{m}{2} C_\gamma,$$

where

$$C_\gamma^{-1} = \int_0^{\pi/2} \left(\frac{\sin(u)}{u} \right)^\gamma du. \tag{3.2}$$

Table 1: Approximation errors of function values for different choices of m, n and γ, using the discrete model.

		$\gamma = 4$	$\gamma = 4.5$	$\gamma = 5$
$m = n = 5$	$\lvert \sin(\pi/3)\cos(\pi/6) \rvert$	0.0781323	0.0700892	0.0637317
$m = n = 10$	$\lvert \sin(\pi/3)\cos(\pi/6) \rvert$	0.0214228	0.0213215	0.0226161
$m = n = 5$	$\sqrt{\lvert \sin(\pi/3)\cos(\pi/6) \rvert}$	0.0572732	0.0507959	0.0458076
$m = n = 10$	$\sqrt{\lvert \sin(\pi/3)\cos(\pi/6) \rvert}$	0.0150111	0.0143546	0.0147956
$m = n = 5$	$\lvert \sin(\pi/3)\cos(4\pi/9) \rvert$	-0.124229	-0.120218	-0.117719
$m = n = 10$	$\lvert \sin(\pi/3)\cos(4\pi/9) \rvert$	0.000659161	0.0014973	0.00138685
$m = n = 5$	$\sqrt{\lvert \sin(\pi/3)\cos(4\pi/9) \rvert}$	-0.127787	-0.125574	-0.124311
$m = n = 10$	$\sqrt{\lvert \sin(\pi/3)\cos(4\pi/9) \rvert}$	0.100651	0.100422	0.099083

Let us consider now a biperiodic function $f \in \mathcal{C}(I_x \times I_y)$ or $f \in \mathcal{C}(T^1 \times T^1)$. Let p, q, m, n such that

$$2(p-1) \leq m \leq 2p, \quad 2(q-1) \leq n \leq 2q. \tag{3.3}$$

Let us define the operator

$$\mathcal{G}_{pq\gamma}(f)(x,y) = H_{pq\gamma} \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} f(x+2u, y+2v) G_{pq\gamma}(u,v) du dv,$$

where

$$G_{pq\gamma}(u,v) = \left| \frac{\sin(pu)\sin(qv)}{p\sin(u) q \sin(v)} \right|^\gamma,$$

and

$$H_{pq\gamma}^{-1} = \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} G_{pq\gamma}(u,v) du dv = h_{p\gamma}^{-1} h_{q\gamma}^{-1},$$

where $h_{p\gamma}^{-1}, h_{q\gamma}^{-1}$ are defined by the expression (3.1).

Hereafter we present bounds for the uniform error committed in this two-dimensional approximation. For it, we present the following Lemmas.

 ISBN: 978-84-617-8694-7

Lemma 3.2. *For p, q, m, n as in (3.3),*

$$u \geq \frac{1}{p} \Rightarrow \omega(u) \leq 4pu\omega\left(\frac{1}{m}\right),$$

$$v \geq \frac{1}{q} \Rightarrow \omega(v) \leq 4qv\omega\left(\frac{1}{n}\right).$$

Lemma 3.3. *Let us consider the following integrals:*

$$C^0_{pq\gamma} = \int_0^{\pi/2}\int_0^{\pi/2} G_{pq\gamma}(u,v)dudv,$$

$$C^{1u}_{pq\gamma} = \int_0^{\pi/2}\int_0^{\pi/2} uG_{pq\gamma}(u,v)dudv,$$

$$C^{1v}_{pq\gamma} = \int_0^{\pi/2}\int_0^{\pi/2} vG_{pq\gamma}(u,v)dudv.$$

Then, for $\gamma > 2$,

$$C^0_{pq\gamma} = H^{-1}_{pq\gamma}/4,$$

$$pC^{1u}_{pq\gamma}H_{pq\gamma} < \frac{1}{2}\left(\frac{\pi}{2}\right)^{\gamma}\left(\frac{1}{2} - \frac{1}{2-\gamma}\right)C_\gamma,$$

$$qC^{1v}_{pq\gamma}H_{pq\gamma} < \frac{1}{2}\left(\frac{\pi}{2}\right)^{\gamma}\left(\frac{1}{2} - \frac{1}{2-\gamma}\right)C_\gamma,$$

where C^{-1}_γ is defined in (3.2).

Theorem 3.4. *If $\gamma > 2$, $f \in \mathcal{C}(T^1 \times T^1)$ and $(x, y) \in T^1 \times T^1$, the two-dimensional approximation satisfies the following inequality*

$$|\mathcal{G}_{pq\gamma}(f)(x,y) - f(x,y)| \leq K_\gamma \omega\left(\frac{1}{m} + \frac{1}{n}\right),$$

where K_γ is a constant depending only on γ.

Remark 3.5. If $\gamma > 2$, the two-dimensional approximant $\mathcal{G}_{pq\gamma}(f)$ is convergent to $f \in \mathcal{C}(T^1 \times T^1)$ as m, n tend to infinity. The rate of convergence is that of $\omega(\frac{1}{m} + \frac{1}{n})$.

Remark 3.6. For functions satisfying a Lipschitz condition of order β, the range of convergence values of γ is extended to $\gamma > \beta + 1$.

The statements about the norm of the operator (Theorem 2.7 and Remark 2.8) are valid for $\mathcal{G}_{pq\gamma}$ as well.

Abstract

When modelling extreme events there are a few primordial parameters among which we refer to the *extreme value index*, denoted by ξ, and the *extremal index*, denoted by θ. The *extreme value index* measures the right tail-weight of the underlying distribution and the *extremal index* characterizes the degree of local dependence in the extremes of a stationary sequence. Most of the semi-parametric estimators of these parameters present the well known type of behaviour: nice asymptotic properties but a high variance for small k, the number of upper order statistics used in the estimation, and an increasing bias with k. Recently, computer intensive procedures have revealed to be highly fruitful in extreme value parameter estimation. The role of computer intensive methodologies and adaptive algorithms for an adequate estimation of the aforementioned parameters are here revisited. Real data illustrations will also be provided.

Key words: extremal index, extreme value index, extreme value theory, resampling procedures.

MSC 2000: AMS codes (optional)

1 Introduction and preliminaries

Extreme Value Theory (EVT) aims to study and to predict the occurrence of extreme or even rare events, outside of the range of available data. These events are part of the real world but environmental extreme or rare events may have a massive impact on everyday life and may have catastrophic consequences for human activities.

 ISBN: 978-84-617-8694-7

The classical assumption in EVT, is that we have a set of independent and identically distributed (i.i.d.) random variables (r.v.'s), $X_1, \ldots, X_n$, from an unknown cumulative distribution function (c.d.f.) F and we are concerned with the limit behaviour of $M_n \equiv X_{n:n} = \max(X_1, \ldots, X_n)$ as $n \to \infty$. Whenever it is possible to linearly normalize M_n so that we get a non-degenerate limit, as $n \to \infty$, such a limit is of the type of the extreme value (EV) d.f.,

$$EV_\xi(x) := \begin{cases} \exp[-(1+\xi x)^{-1/\xi}], & 1+\xi x > 0 \quad \text{if} \quad \xi \neq 0 \\ \exp[-\exp(-x)], & x \in \mathbb{R} \qquad\quad \text{if} \quad \xi = 0. \end{cases} \tag{1}$$

We then say that F is in the domain of attraction for maxima of EV_ξ, denoting this by $F \in D_{\mathcal{M}}(EV_\xi)$. The parameter ξ is the *extreme value index* (EVI) and it measures essentially the weight of the right tail function, $\overline{F} = 1 - F$. The estimation of ξ, in (1), is then of primordial importance not only by itself but also because it is the basis for the estimation of all other parameters of extreme events.

In most fields of applications, the independence assumption is not valid. Stationary sequences are realistic for many real problems and dependence in stationary sequences can assume several forms. Provided that a stationary sequence $\{X_n\}_{n\geq 1}$ has limited long-range dependence at extreme levels, the maxima of this sequence follow the same distributional limit law as the associated independent sequence, $\{Y_n\}_{n\geq 1}$, but with other values for the parameters of EV d.f., Leadbetter *et al.*, (1983). Let us assume to be working with a strictly stationary sequence of r.v.'s, $\{X_n\}_{n\geq 1}$, with marginal d.f. F, under the long range dependence condition **D** (Leadbetter *et al.*, 1983) and the local dependence condition **D"** (Leadbetter and Nandagopalan, 1989). The stationary sequence $\{X_n\}_{n\geq 1}$ is said to have an extremal index (EI) θ, $0 < \theta \leq 1$, if for each $\tau > 0$, we can find a sequence of levels $u_n = u_n(\tau)$ such that, with $\{Y_n\}_{n\geq 1}$ the associated i.i.d. sequence (i.e. from the same F),

$$\mathbb{P}\left(Y_{n:n} \leq u_n\right) = F^n(u_n) \underset{n\to\infty}{\longrightarrow} e^{-\tau} \quad \text{and} \quad \mathbb{P}\left(X_{n:n} \leq u_n\right) \underset{n\to\infty}{\longrightarrow} e^{-\theta\tau}. \tag{2}$$

Under the validity of those conditions the *extremal index* can also be defined as

$$\theta = \frac{1}{\text{limiting mean size of clusters}} = \lim_{n\to\infty} \mathbb{P}(X_2 \leq u_n | X_1 > u_n) = \lim_{n\to\infty} \mathbb{P}(X_1 \leq u_n | X_2 > u_n), \tag{3}$$

where $u_n :\ F(u_n) = 1 - \tau/n + o(1/n),$ as $n \to \infty$, with $\tau > 0$, fixed.

D and **D**" are straightforwardly valid for iid data, and $\theta = 1$.

2 EVI and EI estimation and computational procedures

Under a semi-parametric framework it is only necessary to assume that $F \in D_{\mathcal{M}}(EV_\xi)$ and the estimators of EVI are based on the k largest observations. Considering heavy-tailed parents, the sample $(X_1, X_2, \cdots X_n)$ and the associated sample of ascending order statistics

 ISBN: 978-84-617-8694-7

(o.s.'s), $(X_{1:n} \leq \ldots \leq X_{n:n})$, the most famous classical EVI-estimator is the Hill estimator (Hill, 1975), here denoted $H(k)$ and given by

$$H(k) := \frac{1}{k} \sum_{i=1}^{k} \{\ln X_{n-i+1:n} - \ln X_{n-k:n}\}, \qquad k = 1, 2, \ldots, n-1. \tag{4}$$

Consistency of (4) is achieved if $X_{n-k:n}$ is an *intermediate* o.s., i.e., if $k \equiv k_n \to \infty$ and $k/n \to 0$, as $n \to \infty$, but that estimator presents a very high variance for small values of k and a very high bias for large values of k. A simple class of second-order *minimum-variance reduced-bias* (MVRB) EVI-estimators is the one in Caeiro *et al.* (2005). This class, here denoted $\overline{H}(k)$, depends upon the estimation of second-order parameters (β, ρ) and has the functional form:

$$\overline{H}(k) := H(k)(1 - \widehat{\beta}(n/k)^{\widehat{\rho}}/(1 - \widehat{\rho})), \tag{5}$$

with $H(k)$ the Hill estimator in (4), and where $(\widehat{\beta}, \widehat{\rho})$ needs to be an adequate consistent estimator of (β, ρ), as given, for example, in Gomes and Pestana (2007). Gomes *et al.* (2013) considered to remove the non-null asymptotic bias through the use of the Generalized Jackknife (GJ) methodology, Gray and Schucany (1972), by using an adequate pair of EVI-estimators to build a reduced-bias affine combination of them. As an example, we can refer to a class of GJ–EVI estimators, parameterised in a tuning parameter $\alpha \in (0, 1)$, defined as

$$\overline{H}^{GJ}(k) := \frac{\overline{H}(k) - \alpha^{2\hat{\rho}} \overline{H}(\lfloor \alpha k \rfloor)}{1 - \alpha^{2\hat{\rho}}}, \tag{6}$$

where $\lfloor x \rfloor$ denotes, as usual, the integer part of x.

Concerning the θ parameter, the classical up-crossing, UC-estimator, $\widehat{\Theta}^{UC}$ (Nandagopalan, 1990), is a naive estimator that comes directly as an empirical counterpart of (3),

$$\widehat{\Theta}^{UC}(u_n) := \frac{\sum_{i=1}^{n-1} I\left(X_i \leq u_n < X_{i+1}\right)}{\sum_{i=1}^{n} I(X_i > u_n)}, \tag{7}$$

for a suitable threshold u_n, where $I(A)$ denotes, as usual, the indicator function of A. Consistency of this estimator is obtained provided that the high level u_n is a normalized level, i.e. if with $\tau \equiv \tau_n$ fixed, the underlying d.f. F verifies $F(u_n) = 1 - \tau/n + o(1/n)$, $n \to \infty$ and $\tau/n \to 0$.

Gomes *et al.*(2008) considered the level u_n as a deterministic level $u \in [X_{n-k:n}, X_{n-k+1:n}[$ and derived a reduced-bias GJ estimator of order 2, based on the estimator $\widehat{\Theta}^{UC}$ computed at the three levels, k, $\lfloor k/2 \rfloor + 1$ and $\lfloor k/4 \rfloor + 1$, given by

$$\widehat{\Theta}_n^{GJ} := 5\widehat{\Theta}^{UC}(\lfloor k/2 \rfloor + 1) - 2(\widehat{\Theta}^{UC}(\lfloor k/4 \rfloor + 1) + \widehat{\Theta}^{UC}(k)). \tag{8}$$

Adaptive choice of thresholds k or u_n, through the bootstrap methodology and also through some heuristic computational procedures have been studied in several works, such as Gomes *et al.* (2012) and Neves *et al.* (2015), to cite only a few.

Those procedures will be reviewed here.

Some notes on the convergence of GMRES for compact operator equations

Paolo Novati[1]

[1] *Department of Mathematics and Geosciences, University of Trieste, Italy*

emails: novati@units.it

Abstract

We study some properties of GMRES for solving infinite dimensional linear equations involving compact operators. These problems are intrinsically ill-posed since a compact operator does not admit a bounded inverse. We study the convergence and the regularization properties with respect to the decay rate of the singular values of the operator.

Key words: Linear ill-posed problem, Compact operator, Hilbert-Schmidt operator, Arnoldi algorithm, GMRES
MSC 2000: 47A52, 65F10

1 Introduction

We consider linear equations of the type

$$Af = g, \tag{1}$$

where f and g belong to a separable Hilbert space $\mathcal{H}$, and $A : \mathcal{H} \to \mathcal{H}$ is a compact linear operator. Even assuming that A is not of finite rank, the problem (1) is ill-posed since a compact operator does not possess a bounded inverse. For this reason, after a suitable discretization the arising algebraic linear system is generally solved in the least square sense through some kind of regularization such as the popular Tikhonov method (see e.g. [4, Chapter 5] for an overview) or by means of iterative methods that are known to be 'self-regularizing' such as the CG in the Hermitian case and the LSQR ([8]) or the CGLS in the general nonhermitian one. The main drawback of the CGLS and the LSQR is that they need to work with the operator adjoint A^* that in some important applications is not

 ISBN: 978-84-617-8694-7

known since A is only defined through its action. For this reason the Arnoldi based methods such as the well-known GMRES have been recently employed in this field and they have been shown to be a valid alternative to the transpose based method. In this sense, the first attempt was presented in [2]. We also quote here [3] for a recent survey.

In this work, working in the continuous framework defined by (1), we give a theoretical justification of some important features of the Arnoldi based methods, that are commonly considered true from experimentation in the finite dimensional setting. Denoting by $\{\sigma_n\}_{n\in\mathbb{N}}$ the sequence of the singular values of A (not of finite rank) arranged in decreasing order of magnitude we demonstrate that if $\{\sigma_n\}_{n\in\mathbb{N}} \in \ell_2$ (as it occurs in many practical situations) then the GMRES converges to the exact solution of (1). The rate of convergence is also put in relation with the extendibility of the Krylov subspaces that can be measured in terms of the decay rate of the singular values.

2 Background

Let $\mathcal{H}$ be a separable Hilbert space (it admits a countable orthonormal basis $\{\varphi_n\}_{n\in\mathbb{N}}$), with scalar product $<,>$ and norm $\|\cdot\|$ defined as

$$\|x\| = \langle x, x\rangle^{1/2}.$$

For any given $p > 0$, we denote by ℓ_p the set of the positive sequences $\{a_j\}_{j\geq 1}$ such that

$$\sum\nolimits_{j\geq 1} a_j^p < \infty.$$

Let $A : \mathcal{H} \to \mathcal{H}$ be a linear operator. Given $g \in \mathcal{H}$, we denote by $\mathcal{K}_m = \text{span}\{g, Ag, \ldots, A^{m-1}g\}$ the Krylov subspaces generated by A and g. Setting $N = \sup_m(\dim \mathcal{K}_m)$, the Arnoldi algorithm computes an orthonormal basis $\{w_1, ..., w_m\}$ of $\mathcal{K}_m$ for each $m \leq N$. In particular, we have

$$w_1 = \frac{g}{\|g\|}, \quad w_{m+1} = \frac{(I - P_m)Aw_m}{\|(I - P_m)Aw_m\|},$$

where P_m is the orthogonal projection onto $\mathcal{K}_m$. If, for some m, $(I - P_m)Aw_m = 0$, then $N = m$ and $w_{N+1} = 0$.

Now consider the sequence $\{f_m\}_{m\geq 1}$, $f_m \in \mathcal{K}_m$, such that the corresponding residual norm $\|Af_m - g\|$ is minimized over all the elements of $\mathcal{K}_m$, for $1 \leq m \leq N$. As before, if $N < \infty$, we have that $Af_N - g = 0$, so that, f_N is the solution of $Af = g$. Such a sequence can be constructed with the well known GMRES algorithm ($f_0 = 0$). It is also well known that $Af_m - g \perp A\mathcal{K}_m$, that is, $Q_mAf_m - g = 0$ where Q_m is the projection onto $\mathcal{K}_m$ orthogonal to $A\mathcal{K}_m$. The GMRES approximation is uniquely defined if the operator $Q_mA|_{\mathcal{K}_m} : \mathcal{K}_m \to \mathcal{K}_m$ is invertible for each $m \leq N$, and this condition is ensured if A is not of finite rank.

 ISBN: 978-84-617-8694-7

Theorem 1 *([9, Th.1.9.3]) Let $A : \mathcal{H} \to \mathcal{H}$ be a compact linear operator. Then there exists a decreasing sequence of positive real number $\{\sigma_n\}_{n\in\mathbf{S}}$ (finite or countably infinite and converging to 0) and two orthonormal sequences $\{\varphi_n\}_{n\in\mathbf{S}}$, $\{\psi_n\}_{n\in\mathbf{S}}$, such that*

$$Ax = \sum\nolimits_{n\in\mathbf{S}} \sigma_n \langle x, \varphi_n\rangle \psi_n, \quad x \in \mathcal{H}. \tag{2}$$

The sequence $\{\sigma_n\}_{n\in\mathbf{S}}$ is uniquely determined and consists of the eigenvalues of the positive self-adjoint operator $(A^*A)^{1/2}$ (the singular values of A) counted according to their multiplicities; $\{\varphi_n\}_{n\in\mathbf{S}}$ is the corresponding sequence of eigenvectors.

Assuming that a compact linear operator is not of finite rank, for each $g \in \mathcal{H}$, the equation $Af = g$ has a candidate solution f given by

$$f = \sum\nolimits_{n\geq 1} \frac{\langle g, \psi_n\rangle}{\sigma_n}\varphi_n.$$

Since $\|f\|^2 = \sum_{n\geq 1} \left|\frac{\langle g,\psi_n\rangle}{\sigma_n}\right|^2$ by Parseval identity, $f \in \mathcal{H}$ if and only if

$$\left\{\frac{|\langle g, \psi_n\rangle|}{\sigma_n}\right\}_{n\geq 1} \in \ell_2. \tag{3}$$

Assuming that $\{\sigma_n\}_{n\geq 1} \in \ell_p$, $p > 0$, by the generalized Hölder inequality (see e.g. [6, §2.7]) we have that

$$\{|\langle g, \psi_n\rangle|\}_{n\geq 1} \in \ell_{\frac{2p}{2+p}}. \tag{4}$$

Since $\frac{2p}{2+p} < p$, the condition (4) expresses what is commonly called Picard Condition, that is, the coefficients $|\langle g, \psi_n\rangle|$ must decay faster than the singular values, [4, §1.2.3].

3 Convergence analysis

Definition 2 *Let $A : \mathcal{H} \to \mathcal{H}$ be a bounded linear operator, and let $\{\varphi_n\}_{n\in\mathbb{N}}$ be any orthonormal basis of $\mathcal{H}$. If*

$$\sum\nolimits_{n\in\mathbb{N}} \|A\varphi_n\|^2 < \infty \tag{5}$$

then A is a Hilbert-Schmidt operator. We denote by $\mathcal{C}_2(\mathcal{H})$ this class.

Remark 3 *([9, Chapter 2]) Relation (5) ensures that a Hilbert-Schmidt operator is also compact. Moreover, for each orthonormal basis $\{\varphi_n\}_{n\in\mathbb{N}}$*

$$\sum\nolimits_{n\in\mathbb{N}} \|A\varphi_n\|^2 = \sum\nolimits_{j\in\mathbb{N}} \sigma_j^2$$

 ISBN: 978-84-617-8694-7

Theorem 4 *[7] Let $A : \mathcal{H} \to \mathcal{H}$ be a compact linear operator with a singular value expansion (2) and let $\{f_m\}_{m\geq 1}$ be the sequence of GMRES approximations. If g satisfies the condition (3) then $\|f_m - f\| \to 0$. Moreover, if $A \in \mathcal{C}_2(\mathcal{H})$ then there exists a non negative sequence $\{a_i\}_{i\geq 1} \in \ell_2$, such that*

$$\|Af_m - g\| \leq \left(\sum\nolimits_{i>m} a_i^2\right)^{1/2}. \tag{6}$$

The connection between the residuals of FOM and GMRES, expressed by the famous peak-plateau phenomenon (see e.g. [1]), ensures that the GMRES convergence implies the FOM convergence. This means that the sequence of FOM approximations is bounded, that is, we have $\|f_m\| \leq M$. As consequence, we have that the FOM residual (and hence the GMRES one) is bounded by $Mh_{m+1,m}$, where $h_{m+1,m} := \langle w_{m+1}, Aw_m\rangle = \|(I - P_m)Aw_m\|$. Indeed, since the FOM approximation satisfies $P_m\,(Af_m - g) = 0$, and $P_m g = g$, we have

$$\|Af_m - g\| = h_{m+1,m}\,|\langle f_m, w_m\rangle| \leq h_{m+1,m}\,\|f_m\|\,. \tag{7}$$

Definition 5 *Let $A : \mathcal{H} \to \mathcal{H}$ be a compact operator and let $p > 0$. Then A is p-nuclear and we write $A \in \mathcal{C}_p(\mathcal{H})$ if $\{\sigma_j\}_{j\in\mathbb{N}} \in \ell_p$.*

The above definition implies that Hilbert-Schmidt operators are 2-nuclear operators. We can state the following.

Theorem 6 *[7] Let $A \in \mathcal{C}_p(\mathcal{H})$ with $p > 0$. The following statements hold.*

1. *If $p \geq 1$ then $\{h_{j+1,j}\}_{j\in\mathbb{N}} \in \ell_p$.*
2. *If $\{h_{j+1,j}\}_{j\in\mathbb{N}}$ is non increasing then $\{h_{j+1,j}\}_{j\in\mathbb{N}} \in \ell_p$.*
3. *If $h_{j+2,j+1} \leq \left(\prod_{i=1}^{j} h_{i+1,i}\right)^{1/j}$, $j \geq 1$, then $\{h_{j+1,j}\}_{j\in\mathbb{N}} \in \ell_{p+\varepsilon}$ for each $\varepsilon > 0$.*

Theorem 7 *[7] Let $A \in \mathcal{C}_p(\mathcal{H})$, $p > 0$. If the condition (3) is satisfied then for the GMRES residual it holds*

$$\{\|Af_m - g\|\}_{m\geq 1} \in \ell_p. \tag{8}$$

Example 8 *In Figure 1 we consider the plot of the sequences $\{\|Af_m - g\|\}_{m\geq 1}$, $\{h_{m+1,m}\}_{m\geq 1}$, $\{\sigma_m\}_{m\geq 1}$, for two test problems taken from [5], that is, BAART and I-LAPLACE, that are linear systems arising from the discretization of Fredholm integral equations of the first kind. In both cases the singular values decay exponentially so that $\{\sigma_m\}_{m\geq 1} \in \ell_p$ for each $p > 0$.*

Abstract

Heterogeneous systems composed by a CPU and a set of different hardware accelerators are very compelling thanks to their excellent performance and energy consumption features. One of the most important problems of those systems is the workload distribution among their devices. This paper describes an extension of the Maat library to allow the co-execution of a data-parallel OpenCL kernel on a heterogeneous system composed by a CPU and an Intel Xeon Phi. Maat provides an abstract view of the heterogeneous system as well as a set of load balancing algorithms to squeeze the performance out of the node. Experimental results show that this approach always outperforms the baseline with only a Xeon Phi. Furthermore, the load balancing algorithm has a huge impact in the system performance, therefore, the right selection is essential.

Key words: Heterogeneous computing, co-execution CPU-Xeon Phi, load balancing, OpenCL

1 Introduction

One of the most important challenges of high performance computing today is to reach Exascale computers. Nowadays one of the most promising ways is the use of cluster-based architectures with nodes that have great computing capacity. These nodes are based on multi-core processors and include hardware accelerators, such as GPUs or Intel Xeon Phi.

Nonetheless these nodes introduce new challenges, because the use of accelerators turns them heterogeneous. Hence, the software development to efficiently exploit all the available resources has to take into account this heterogeneity. Therefore the use of a portable programming language on heterogeneous platforms is mandatory. Open Computing Language

 ISBN: 978-84-617-8694-7

(OpenCL) [1] is a framework for developing programs to be executed across heterogeneous platforms such as many-core and multi-core architectures.

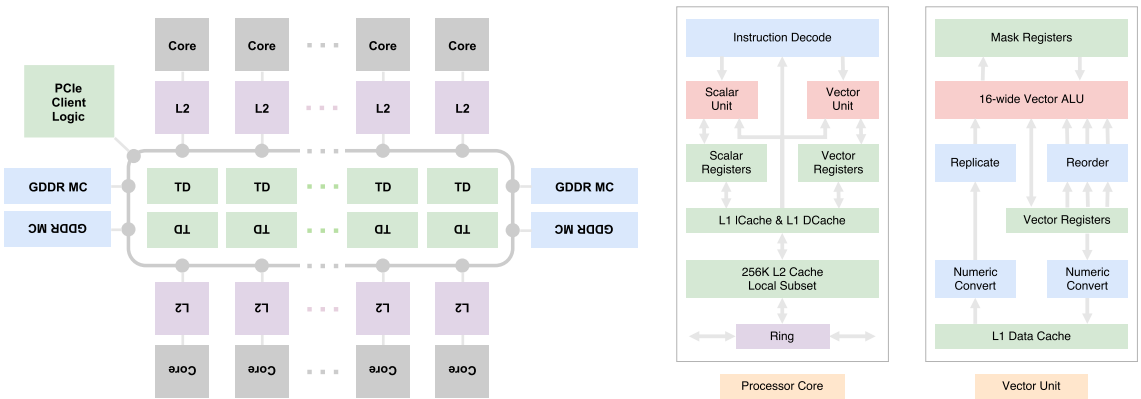
However, when using OpenCL, the programmer is responsible for explicitly selecting and managing the devices as well as for partitioning the data among them. Therefore load balancing becomes one of the most challenging problems, having a tremendous impact on performance and programmability. The objective of load balancing algorithms is distributing the workload proportionally to the devices' computational power. This problem is more acute in heterogeneous systems with irregular applications.

This paper extends Maat [2] to allow the co-execution of massively data-parallel kernels on heterogeneous systems composed by a multi-core CPU and an Intel Xeon Phi accelerator. Maat is an OpenCL library that provides the programmer with a unified and abstract view of the heterogeneous system that guarantees code portability. Furthermore, Maat provides a set of load balancing algorithms that allow the programmer to choose the most appropriate depending on the behaviour of the application at hand. In this paper a diverse set of applications it is considered. They are grouped as regular, when every work unit represents the same running time, and irregular, if different work units have different running times. This decision is critical in order to achieve the best performance, with different applications, as will be shown in section 5. Experimental results show speedups close to the maximum achievable, reaching an efficiency of more than 97% and 86% for both regular and irregular applications, respectively.

This topic has given rise to an interest in both understanding how to efficiently use this kind of devices and making their programming easier. The work presented in [3] studies the performance of the Xeon Phi through the use offload directive based approaches in a single heterogeneous node. [4] also addresses the use of directives with Xeon Phi, but in this case with a focus on dynamic load balancing. The authors of [5] also focus on improving the performance of an application running on a Xeon Phi, buy they deem load balancing unsuitable for the kind of computations of a Xeon Phi. As a result, they propose a load imbalancing based optimisation technique. To the problem of cooperatively executing a single task among the available devices, [6] proposes an analytical model to identify when co-execution is worth it in terms of performance. Finally, [7] presents a dynamic load balancing for the co-execution of a single data-parallel kernel. However, these two works do not consider the Xeon Phi as their target device.

The remainder of the paper is structured as follows. Section 2 introduces some basic concepts that are important to the article. Section 3 describes the main characteristics of the three load balancing techniques which are studied. Section 4 explains the extensions developed on Maat library. Next, in section 5 a performance evaluation of the three load balancing algorithms with different benchmarks is developed. Finally, section 6 summarises the main conclusions and future work.

 ISBN: 978-84-617-8694-7



(a) Block diagram architecture.

(b) Microarchitecture of a Xeon Phi's Core.

Figure 1: Intel Xeon Phi Architecture.

2 Background

The Intel Xeon Phi Knights Corner is a coprocessor to speed-up parallel applications; therefore it requires at least one processor in the system [8]. It is a cache-coherent shared memory many-core processor (SMP) based on the x86 architecture. The coprocessor is connected via the PCI express bus to other devices and the host, and they are not hardware cache coherent with other devices in the node. It consists of up to 61 cores connected by a high performance on-die bidirectional ring interconnect and 8 memory controllers supporting 16 GB of GDDR5 channels at most, with up to 352 GB/s bandwidth. Figure 1(a) shows the basic architecture of the MIC coprocessor.

The cores are in-order dual issue x86 processor 1.2 GHz cores, with 32 KB of data cache and 32 KB of instruction cache, with 64-bit support and as it is shown in the figure 1(b), it provides more interesting extensions:

- Four hardware threads on each core, resulting in up to 244 hardware threads available on a single device. They are primarily used to hide memory latencies implicit in an in-order microarchitecture. As such, it is much more important that applications use these multiple hardware threads on Intel Xeon Phi than on Xeon processors.
- Each core has a 512-KB L2 cache locally with high speed access to all other L2 caches, making a collective L2 cache size over 30 MB.
- Wide vectorization capability via 512-bit wide vector registers and functional units, which can execute SIMD instructions, with 16 single precision or 8 double precision operations simultaneously.

The Xeon Phi runs Linux operating system. Every card has its own IP address. The Xeon Phi supports many common tools for developing, debugging and executing parallel applications. It supports the standard parallel programming models, such as MPI and OpenMP.

3 Load balancing Algorithms

Since there is no load balancing strategy for data parallelism that can improve the execution of all applications, in this paper we propose a set of load balancing algorithms. The basis of these is that the load experienced by a computing device is only dependent on the amount of data it must process.

3.1 Static algorithm

This algorithm works before the task is executed by dividing the data-set in as many *packages* as devices are in the system. The division relies on knowing the computing power of the devices in advance. Then the execution time of each device can be equalised by proportionally dividing the data-set among the devices.

Considering a heterogeneous system with n devices. Each device i has *computational power* P_i, which is defined as the amount of work that a device can complete per time unit, including the communication overhead. These powers are parameters that must be given to the algorithm and can be extracted by a simple profiled execution. Then, the total computational power of the heterogeneous system is the sum of the individual powers of the devices $P_H = \sum_{i=1}^{n} P_i$.

The application will execute a kernel over W work-items, grouped in G work-groups of fixed size $L_s = \frac{W}{G}$. Since the work-groups do not communicate among themselves, it makes sense to distribute the workload taking the work-group as the atomic unit. Each device will have an execution time of T_i. Then the execution time of the heterogeneous system will be that of the last device to finish its work, or $T_H = max_{i=1}^{n} T_i$.

The goal of the Static algorithm is to determine the number of work-groups to assign each device, so that all the devices finish their work at the same time. This means finding a tuple $\{\alpha_1, ...\alpha_n\}$, where α_i is the number of work-groups assigned to the device i. For this reason, the expression used by the algorithm is:

$$\alpha_i = \left\lfloor \frac{P_i G}{\sum_{i=1}^{n} P_i} \right\rfloor$$

If there is not an exact solution with integers then $\sum_{i=1}^{n} \alpha_i < G$. In this case, the remaining work-groups are assigned to the most powerful device.

The beauty of the Static algorithm is that it minimises the number of synchronisation points. This makes it perform well when facing regular loads with known computing powers

 ISBN: 978-84-617-8694-7

that are stable throughout the data-set. However, it is not adaptable, so its performance might not be as good with irregular loads.

3.2 Dynamic algorithm

Some applications do not present a constant load during their executions. To adapt to their irregularities, the Dynamic algorithm divides the data-set in small packages of equal size. The number of packages is well above the number of devices in the heterogeneous system. During the execution of the kernel, a master thread in the host is in charge of assigning packages to the different devices, including the CPU, following the next strategy:

1. The master splits the G work-groups in packages, each with the package size specified by the programmer. This number must be a multiple of the work-group size. If the number of work-items is not divisible by the package size, the last package will be smaller.

2. The master launches one package on each device, including the host itself if it is desired.

3. The master waits for the completion of any package.

4. When device i completes the execution of a package:

   (a) The device returns the partial results corresponding to the processed package.

   (b) The master stores the partial results.

   (c) If there are outstanding packages, a new one is launched on device i.

   (d) If all the devices are idle and there are no more packages, the master jumps to step 5.

   (e) The master returns to step 3.

5. The master ends when all the packages have been processed and the results have been received.

This algorithm adapts to the irregular behaviour of some applications. However, each completed package represents a synchronisation point between the device and the host, where data is exchanged and a new package is launched. This overhead has a noticeable impact on performance. The Dynamic algorithm takes the size of the packages as a parameter.

 ISBN: 978-84-617-8694-7

3.3 HGuided algorithm

The previous strategies have their strong points and their weak spots. Although neither is the best for every application, both give hints toward an optimal data-division algorithm. The Heterogeneous Guided algorithm (*HGuided*) is an attempt to reduce the synchronisation points of the Dynamic while retaining most of its adaptiveness.

The same algorithm used in the Dynamic approach is applicable to the HGuided, except for how the data-set is divided. The HGuided algorithm makes larger packages at the beginning and reduces the size of the subsequent ones as the execution progresses. This reduces the number of synchronisation points and the corresponding overhead, while retaining a small package granularity towards the end of the execution to allow all devices to finish simultaneously.

Since it is an algorithm for heterogeneous systems the size of the packets is also dependent on the computing power of the devices. For instance, the size of the package for device i is calculated as follows:

$$packet\_size_H = \left\lfloor \frac{G_r P_i}{n \sum_{j=1}^{n} P_j} \right\rfloor$$

Where G_r is the number of pending work-groups and is updated with every package launch. The HGuided takes the computing powers of the devices as parameters. It also requires a minimum package size, which is a lower bound for the $packet\_size_H$.

4 Design and Implementation

Maat is a library that acts as an OpenCL wrapper to simplify the programming of heterogeneous devices and squeeze the performance out of them. Maat is specially designed to be used in large data-parallel applications and it provides the three load balancing algorithms presented previously. While OpenCL forces the programmer to consider the devices as individual entities, Maat defines an abstraction layer over all the accelerator devices in a machine. It presents a single virtual device to operate with; hiding the underlying hardware details. Thus, the library effectively divides a single task among all the real devices based on the load balancing algorithm selected by the programmer.

This single virtual device is accessed through a *super context*. It is created by the programmer specifying the target devices. In contrast to OpenCL contexts, a *super context* can hold devices from several different manufacturers. Maat offers a set of functions that resemble typical OpenCL calls, to manage the *super context*. The *super context* transparently manages the data structures of all the target devices, like the command queues.

While in OpenCL the programmer will need to allocate many buffers to communicate with the different target devices, Maat simplifies this task with the *super buffer*. When one

 ISBN: 978-84-617-8694-7

of these is created through the *super context*, the latter transparently allocates the required buffers on each target device. If the data will only flow from the host to the device, it is considered an *in super buffer*. Otherwise it is considered an *out super buffer*.

The common reading and writing procedure in *super buffers* assumes that each work-item will use the position indicated by its index. The copy is not performed until the kernel is launched in the device. Such behaviour is necessary in Dynamic and HGuided algorithms where there is no way of knowing in advance which device will compute what package of data. The *out super buffer* creation function requires two extra parameters to be able to automatically copy back the results from the device to the host: a pointer to where the results should be stored in the host memory and the size of the result obtained by each work-group. Therefore, the requirement of writing buffers based on the work-item index denotes the type of applications supported. This may seem a strong requirement, but not only common benchmarks but also many kernels widely used in the industry meet this condition.

OpenCL encapsulates the code to be executed by a device, in a data structure called kernel, which is bound to the device. Maat simplifies the kernel configuration and execution process by using the idea of *super kernel*. When such an entity is created, the *super context* transparently sets up a different kernel for each device. Similarly, parameter assignment to the *super kernel* is forwarded to all the kernels in the *super context*. The *super kernel* launch resembles that of a standard OpenCL kernel in that it receives exactly the same global work size, local work size and global work offset it would receive if working with a single device, achieving an easy portability of common OpenCL applications to Maat.

When a *super kernel* is enqueued, Maat transparently performs as many executions of individual kernels as required by the selected load balancing algorithm. Each execution will use the adequate OpenCL parameters to represent the correct package of work. The on-demand launch of additional packages in the Dynamic and HGuided algorithms has been implemented using OpenCL callbacks.

The callbacks have been adapted to perform non-blocking readings. Most of the logic has been transferred to functions managed by an independent thread in the host because the new Intel Xeon Phi's OpenCL driver behaves different from the CPU's regarding callbacks. This increases the performance because it simplifies the callbacks and the synchronisations are dead-lock free (host functions are triggered using *pthread_cond_wait*).

Finally, a final function that waits for the completion of every callback guarantees the correctness of the non-blocking calls and improves the performance due to the maximum interleaving of kernel execution with buffer management operations. This waiting call serves as a common interface between the three load balancing algorithms to monitor every performed callback, follow its event state and wait for its completion, simplifying the kernel execution of the three algorithms.

Table 1: Parameters for each application.

5 Evaluation

5.1 Experimental Setup

The machine on which the experimentation was carried out has two processor chips and one Intel Xeon Phi. The CPUs are Intel Sandy Bridge Xeon E5-2620, with six cores that can run two threads each at 2.0 GHz. It has hardware support for 24 threads, 15 MB of L3 cache memory and 16 GB of DDR3 main memory. The CPUs are connected via QPI, which allows OpenCL to detect them as a single device. Therefore, throughout the remainder of this document, any reference to the CPU includes both Xeon E5-2620 processors.

The Intel Xeon Phi coprocessor is a Knights Corner 7120P which consists of up to 61 cores connected by a high performance on-die bidirectional ring interconnect and 8 memory controllers supporting 16 GB of GDDR5 channels at most, with up to 352 GB/s bandwidth. It is connected to the system using an independent PCI 2.0 slot.

5.2 Benchmarks and Metrics

Four benchmarks have been chosen for the experiments. While Binomial, Gaussian and NBody are regular applications, Ray Tracing is irregular. The last one renders realistic images by modelling different light rays with independent threads each one involving an unpredictable amount of work depending on the number of times it bounces on the objects of the scene. Two different scenes with different complexity (resolution, lights and objects), referred as Ray1 and Ray2, have been considered for experimentation. As it will be seen later, by changing the input data, the behaviour of the application varies wildly, due to the irregular behaviour of the benchmark.

The parameters for each of the applications are shown in table 1. Each benchmark has been run using a problem size big enough to justify its distribution among all the available devices. Local work size has been set so the performance of the fastest device, namely the Xeon Phi, is maximised. The reason for this is that almost no performance difference was detected when varying local work size for the CPU.

The metric used to evaluate the performance of the algorithms is the total response time,

 ISBN: 978-84-617-8694-7

including the input data and results communications. From that, the speedup is calculated as the ratio between the execution time on the Phi and on the heterogeneous system. Due to the heterogeneity of the system and the different behaviour of the benchmarks, the maximum achievable speedups depend on each benchmark. These values were derived from the response time T_i of each device:

$$S_{max} = \frac{1}{max_{i=1}^{n}\{T_i\}} \sum_{i=1}^{n} T_i \tag{1}$$

Additionally, the efficiency of the heterogeneous system has been computed as the ratio between the maximum achievable speedup and the real observed speedup for each benchmark. $Eff = \frac{S_{real}}{S_{max}}$

The computational power needed for the Static and HGuided algorithms has been computed for each benchmark as follows. First, the response times of the benchmark have been measured in both the CPU and the Phi, including the time required to complete the kernel execution, performing the data distribution, kernel launch overhead and result collection. Then, considering the computational power of the CPU equal to 1, the computational power of the Phi is calculated, as the ratio among the CPU time and the Phi time: $P_{Phi} = \frac{T_{CPU}}{T_{Phi}}$.

5.3 Experimental Results

This section presents the performance results achieved in the heterogeneous system with different load balancing algorithms. The baseline to compare the results obtained with Maat on the heterogeneous system is the total response time of the benchmarks in a scenario with only one Xeon Phi. Therefore, the benefits presented in this section are due to the co-execution of the benchmarks on the CPU and the Phi simultaneously.

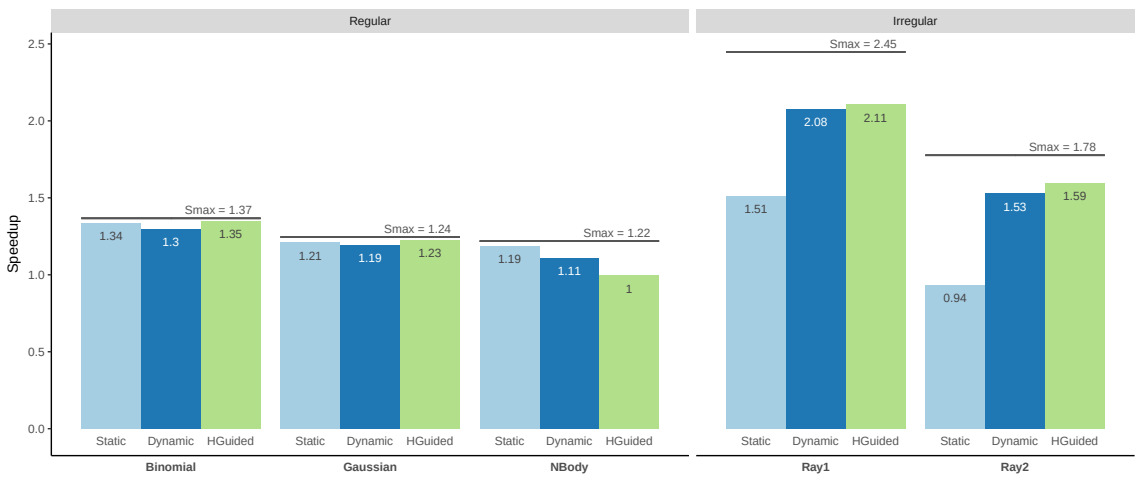

Figure 2: Speedups of the benchmarks with the three load balancing algorithms.

 ISBN: 978-84-617-8694-7

To give an idea of performance of the load balancing algorithms, the figure 2 shows the speedups reached by the Maat implementation of the benchmarks, compared with the baseline. The theoretical maximum speedup that can be obtained with each benchmark is shown as a horizontal line above the bars of each benchmark. The speedups reveal that, for all benchmarks, there is at least one algorithm that gives excellent results. This indicates that Maat can adapt to different kinds of loads obtaining outstanding performance. The gap between the measured and the theoretical maximum values is a consequence of the extra communication overhead.

Analysing the speedup measurements in detail, it can be seen that, Static and HGuided deliver excellent results in Binomial and Gaussian. However, while Static excels, HGuided decreases its performance with NBody due to the small ratio of computing time compared with communication time. The Static algorithm yields speedups very close to the maximum and it is the most consistent between the regular applications.

On the other hand, the analysis of the Ray Tracing, the irregular benchmark, shows that the HGuided method obtains the best results, followed nearly by the Dynamic. This method achieves a better load balance and reduces the communication overhead, because it divides the workload between a smaller number of packets than in the Dynamic algorithm.

Finally, the load balancing efficiency gives an idea of how well a load is balanced. A value of 100% represents that all the devices have been working all the time, thus achieving the maximum obtainable speedup. As shown in figure 3 the regular applications reach at least 97% of efficiency, while the irregular ones achieve an efficiency between 86% and 89%.

Coming up with a balanced work distribution is significantly harder for Ray due to the resolution of the rendered image and the complexity of interaction between the input

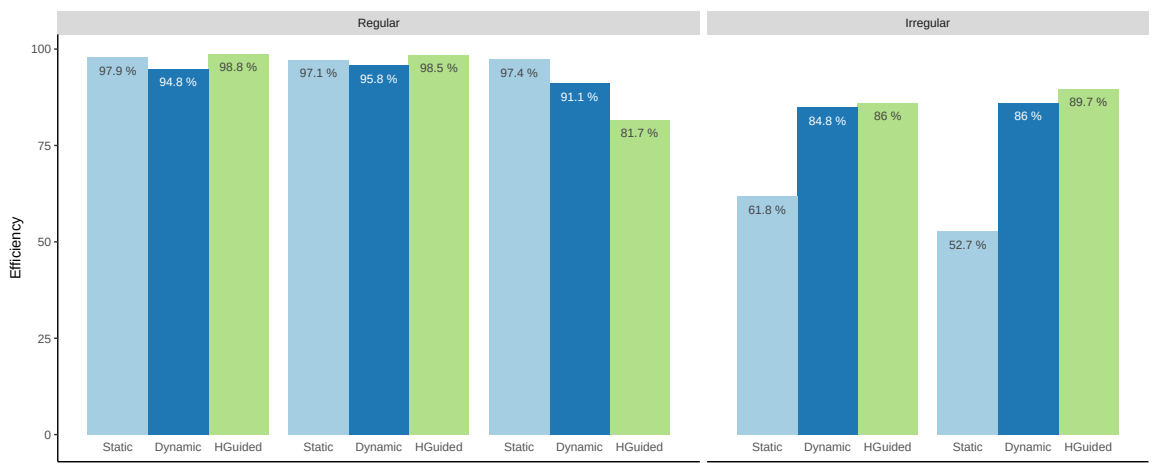

Figure 3: Balancing efficiency of the heterogeneous system.

 ISBN: 978-84-617-8694-7

scene and the ray tracing algorithm. However, it should be noted that if the correct load balancing algorithm is not used for each benchmark, the results can be quite bad. Thus we can see efficiencies around 50% in some cases, which imply a very poor use of resources.

6 Conclusions and Future Work

This paper extends the Maat library to allow the co-execution of massively data-parallel OpenCL kernels on heterogeneous systems composed by an Intel Xeon Phi coprocessor. A set of load balancing algorithms has been implemented, in order to give the best performance to both regular and irregular applications.

From the experimental results presented in this paper a set of conclusions can be remarked. The use of the whole heterogeneous system is always beneficial, from the performance point of view, at least with one of the load balancing methods. A second conclusion is that applications with different behaviour, regular or irregular ones, need different load balancing algorithms to get the best performance on the heterogeneous system. With respect to the algorithms, the Static approach is the most adequate for regular applications as it minimises overheads, although the HGuided is even better in specific cases. In the case of irregular applications the HGuided method excels and the use of Static is strongly discouraged as it may result in poor performance due to imbalance. Lastly, the Dynamic algorithm is a good all-around option when a priori information of the computing powers of the system is not available, but at the cost of more modest speedups and efficiencies.

Future work includes the optimisation of some implementation issues to reduce the synchronisation and communication overhead that are one of the most important challenges to improve the performance of Maat. Moreover, a study about the energy efficiency of the heterogeneous system will be developed.

Abstract

Analysis of variance (ANOVA) is one of the most frequently used statistical analysis in several research areas, namely in medical research. Despite its wide use, it has been applied assuming that sample dimensions are known. In this work we aim to carry out ANOVA like analysis of one-way fixed effects models, to situations where the samples sizes may not be previously known. Assuming that the samples were generated by Poisson counting processes we obtain the unconditional distribution of the test statistic, under the assumption that we have random sample sizes. The applicability of the proposed approach is illustrated considering a real data example on cancer registries. The results obtained suggested that false rejections may be avoid by applying our approach.

Key words: ANOVA, random sample sizes, fixed effects models, counting processes, cancer registries.
MSC 2000: 62J12, 62J10, 62J99

1 Introduction

Analysis of variance (ANOVA) is one of the most frequently used statistical analysis in practical applications. It is routinely used in several research areas, namely in medical research. Despite its wide use, it has been applied assuming that sample dimensions are

 ISBN: 978-84-617-8694-7

known. In this work we aim to carry out ANOVA like analysis of one-way fixed effects models, to situations where the samples sizes may not be previously known. This often occurs when there is a fixed time span for collecting the observations. An illustrative example of this is the collection of observations during a fixed time period in a study comparing, for example, several pathologies of patients arriving at a hospital, see e.g. [6, 7].

In these situations it is more appropriate, assuming there are m different levels, to consider the sample sizes as realizations, $n_1, ..., n_m$, of independent random variables, $N_1, ..., N_m$, [4, 5, 6, 7, 8].

This new approach must be based on an adequate choice of the distribution of $N_1, ..., N_m$. We assume that the numbers collected in non overlapping intervals are independent and simultaneous arrivals are not to be expected. We are thus led to consider, possible non homogeneous, Poisson counting processes. So for fixed collection periods our sample sizes $N_1, ..., N_m$ will have Poisson distribution with parameters $\lambda_1, ..., \lambda_m$. We put $N_i \sim P(\lambda_i)$, $i = 1, ..., m$. Moreover $n = \sum_{i=1}^{m} n_i$ will be a realization of the random variable

$$N = \sum_{i=1}^{m} N_i$$

which, through independence of N_i, $i = 1, ..., m$,

$$N \sim P(\lambda),$$

with $\lambda = \sum_{i=1}^{m} \lambda_i$. Furthermore the vector $\boldsymbol{n} = (n_1, ..., n_m)'$ will be a realization of $\boldsymbol{N} = (N_1, ..., N_m)'$.

We are interested in testing the hypothesis

$$H_0 : \mu_1 = ... = \mu_m,$$

which may be rewritten as

$$H_0 : \boldsymbol{A}\boldsymbol{\mu} = \boldsymbol{0}, \tag{1}$$

where $\boldsymbol{\mu}$ is the mean vector of the treatment means with components $\mu_1, ..., \mu_m$, and $\boldsymbol{A} = [\boldsymbol{I}_{m-1} | -\boldsymbol{1}_{m-1}]$, with $\boldsymbol{I}_c$ the $c \times c$ identity matrix and $\boldsymbol{1}_c$ the vector with c components equal to 1.

In the next section we present the test statistics and their conditional and unconditional distributions, under the assumption that we have random sample sizes. In section 3 the presented approach is illustrated through an application on real medical data, using cancer registries. We conclude this work with some closing remarks.

2 Statistic and their distributions

When $N_i = n_i$, $i = 1, ..., m$, we have the samples $Y_{i,1}, ..., Y_{i,n_i}$, $i = 1, ..., m$, with averages $\overline{Y}_{i,\bullet}$, $i = 1, ..., m$. Assuming that the observations are normal and independent with

 ISBN: 978-84-617-8694-7

variance σ^2, when $N_i = n_i$, $i = 1, ..., m$, the vector of treatment means, $\boldsymbol{Y}_\bullet$, which has components $\overline{Y}_{1,\bullet}, ..., \overline{Y}_{m,\bullet}$, will be normal with mean vector $\boldsymbol{\mu}$ and variance-covariance matrix $\sigma^2 D(\frac{1}{n_1}, ..., \frac{1}{n_m})$, where $D(\frac{1}{n_1}, ..., \frac{1}{n_m})$ is the diagonal matrix with principal elements $\frac{1}{n_1}, ..., \frac{1}{n_m}$.

So, when $N_i = n_i$, $i = 1, ..., m$, see for instance [2, 3], the sum of squares for testing the hypothesis $H_0 : \boldsymbol{A\mu} = 0$ will be

$$S_{num} = (\boldsymbol{AY}_\bullet)' \left(\boldsymbol{A} D \left(\frac{1}{n_1}, ..., \frac{1}{n_m} \right) \boldsymbol{A}' \right)^{-1} (\boldsymbol{AY}_\bullet), \tag{2}$$

which corresponds to the product by σ^2 of a noncentral chi-square with $g = m - 1$ degrees of freedom and non-centrality parameter

$$\delta(n) = \frac{1}{\sigma^2} (\boldsymbol{A\mu})' \left(\boldsymbol{A} D \left(\frac{1}{n_1}, ..., \frac{1}{n_m} \right) \boldsymbol{A}' \right)^{-1} (\boldsymbol{A\mu}). \tag{3}$$

We put $S_{num} \sim \sigma^2 \chi^2_{g,\delta(n)}$.

The sum of the sums for the errors will be given by, see e.g [1] and [9],

$$S = \sum_{i=1}^{m} \sum_{k=1}^{n_i} (Y_{i,k} - \overline{Y}_{i,\bullet})^2.$$

Moreover S will be the product by σ^2 of a central chi-square with

$$g(n) = n - m$$

degrees of freedom, $S \sim \sigma^2 \chi^2_{g(n)}$, and will be conditionally independent from S_{num}.

Therefore, when $N = n$, the conditional distribution of

$$\Im = \frac{S_{num}}{S}$$

will be a noncentral $\overline{F}$ distribution, which correspond to the distribution of the quotient of independent chi-squares with g and $g(n)$ degrees of freedom and non-centrality parameters $\delta(n)$ and 0, denoted by $\overline{F}(.|g, g(n), \delta(n))$.

Given $N = n$, when H_0 holds, $\delta(n) = 0$ and the conditional distribution of $\Im$ will be a central $\overline{F}$ distribution with g and $g(n)$ degrees of freedom, $\overline{F}(z|g, g(n))$.

2.1 The unconditional distribution

For carrying out the inference we will assume that $N_i \geq n_i^\bullet$, $i = 1, ..., m$, which means that we have a minimum dimension for each sample. In this case the global minimum dimension

 ISBN: 978-84-617-8694-7

will be $n^\bullet = \sum_{i=1}^m n_i^\bullet$. So, since we have m different treatments, denoting $\boldsymbol{n}^\bullet = (n_1^\bullet, ..., n_m^\bullet)'$, we consider

$$p_{\boldsymbol{n}^\bullet}(n) = pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet) = \sum_{n_1=n_1^\bullet}^{n-\sum_{i=2}^m n_i^\bullet} ... \sum_{n_\ell=n_\ell^\bullet}^{n-(\sum_{i=1}^{\ell-1} n_i+\sum_{i=\ell+1}^m n_i^\bullet)} ... \sum_{n_m=n-\sum_{i=1}^{m-1} n_i}^{n-\sum_{i=1}^{m-1} n_i} pr(\boldsymbol{N} = \boldsymbol{n}|\boldsymbol{N} \geq \boldsymbol{n}^\bullet),\ n_i = n_i^\bullet, ...,\ i = 1, ..., m, \tag{4}$$

where, through the independence of N_i, $i = 1, ..., m$,

$$pr(\boldsymbol{N} = \boldsymbol{n}|\boldsymbol{N} \geq \boldsymbol{n}^\bullet) = \prod_{i=1}^m pr(N_i = n_i|N_i \geq n_i^\bullet) = \prod_{i=1}^m \frac{pr(N_i = n_i)}{pr(N_i \geq n_i^\bullet)}$$
$$= \prod_{i=1}^m \frac{e^{-\lambda_i}(\lambda_i^{n_i}/n_i!)}{1 - \sum_{u_i=0}^{n_i^\bullet-1} e^{-\lambda_i}(\lambda_i^{u_i}/u_i!)} = \prod_{i=1}^m \frac{\lambda_i^{n_i}}{n_i!(e^{\lambda_i} - \sum_{u_i=0}^{n_i^\bullet-1} \frac{\lambda_i^{u_i}}{u_i!})},\ n_i = n_i^\bullet, \ldots,\ i = 1, \ldots, m. \tag{5}$$

Thus the unconditional distribution of $\Im$, when H_0 holds, will be given by, see e.g. [4] and [7],

$$\overline{\overline{F}}(z) = \sum_{n=n^\bullet}^\infty pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet)\overline{F}(z|g, g(n)) = \sum_{n=n^\bullet}^\infty p_{\boldsymbol{n}^\bullet}(n)\overline{F}(z|g, g(n)), \tag{6}$$

considering $p_{\boldsymbol{n}^\bullet}(n)$ as defined in (4).

When we known that $N \leq \overline{n}$, we may not consider in (6) the terms for $n > \overline{n}$, and we have $\overline{\overline{F}}(z)$ bounded by

$$\overline{\overline{F}}_{\overline{n}}(z) \leq \overline{\overline{F}}(z) \leq \overline{\overline{F}}^*_{\overline{n}}(z), \tag{7}$$

where

$$\overline{\overline{F}}_{\overline{n}}(z) = \sum_{n=n^\bullet}^{\overline{n}} pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet)\overline{F}(z|g, g(n)) \tag{8}$$

and

$$\overline{\overline{F}}^*_{\overline{n}}(z) = \overline{\overline{F}}_{\overline{n}}(z) + \sum_{n=\overline{n}+1}^\infty pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet). \tag{9}$$

So $\overline{n}$ denote the upper bound needed to control the truncation error of the unconditional distribution $\overline{\overline{F}}(z)$.

 ISBN: 978-84-617-8694-7

It is important to note that

$$\sum_{n=\overline{n}+1}^{\infty} pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^{\bullet}) = 1 - \sum_{n=n^{\bullet}}^{\overline{n}} pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^{\bullet}). \tag{10}$$

3 Application

In this section we evaluate our approach under a real data example. To construct this experiment we resort to a dataset which was provided by the Brazilian National Cancer Institute (INCA)[1]. The dataset gathers information regarding the age of patients with cancer disease. The data considered is from 2010 and refers to the City of São Paulo, Brazil.

In our model the factor considered is the *Type of Cancer*, with three levels: *Soft tissues of the thorax*, *Intestinal tract* and *Nasal cavity*. Table 1 illustrates the number of patients and the sample mean age for each type of cancer.

Table 1: Number of patients and sample means.

Type of Cancer	Number of patients	Sample means
Soft tissues of the thorax	18	49.50
Intestinal tract	22	61.7727
Nasal cavity	25	62.40

We will test the hypothesis

$$H_0 : \boldsymbol{A\mu} = 0,$$

with

$$\boldsymbol{A} = \begin{bmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \end{bmatrix}.$$

The numerator of the $\Im$ statistic is now given by

$$S_{num} = (\boldsymbol{AY}_{\bullet})' \left(\boldsymbol{A}D\left(\tfrac{1}{18}, \tfrac{1}{22}, \tfrac{1}{25}\right)\boldsymbol{A}'\right)^{-1} (\boldsymbol{AY}_{\bullet}) \ ,$$

which is, when H_0 holds, the product by σ^2 of a central chi-square with $g = m - 1 = 2$ degrees of freedom, $S_{num} \sim \sigma^2\chi^2_2$. So, we obtain

$$\left(\boldsymbol{A}D\left(\frac{1}{18}, \frac{1}{22}, \frac{1}{25}\right)\boldsymbol{A}'\right)^{-1} = \begin{bmatrix} 13.0154 & -6.0923 \\ -6.0923 & 14.5538 \end{bmatrix} \text{ e } \boldsymbol{Ay}_{\bullet} = \begin{bmatrix} -12.9000 \\ -0.6273 \end{bmatrix},$$

[1] http://www2.inca.gov.br/wps/wcm/connect/inca/portal/home

 ISBN: 978-84-617-8694-7

where $\boldsymbol{y}_\bullet$ has components $\overline{y}_{1,\bullet} = 49.50$; $\overline{y}_{2,\bullet} = 61.7727$; $\overline{y}_{3,\bullet} = 62.40$. Therefore for the numerator of the statistic we obtain

$$S_{num} = 2073.021.$$

The denominator of the statistic is, when $N = n$, the product by σ^2 of a central chi-square with $g(n) = n - 3$ degrees of freedom, $S \sim \sigma^2 \chi^2_{n-3}$. In this case we obtain

$$S = \sum_{j=1}^{18}(y_{1,j} - \overline{y}_{1,\bullet})^2 + \sum_{j=1}^{22}(y_{2,j} - \overline{y}_{2,\bullet})^2 + \sum_{j=1}^{25}(y_{3,j} - \overline{y}_{3,\bullet})^2 = 26632.364.$$

So, the statistic's value, $\Im_{Obs}$, is given by

$$\Im_{Obs} = \frac{2073.021}{26632.364} = 0.07784.$$

Given $N = n$, when H_0 holds, the common conditional distribution of $\Im$ is a central $\overline{F}$ distribution with $g = 2$ and $g(n) = 65 - 3 = 62$ degrees of freedom, since $n = 65$, $\overline{F}(z|2, 62)$.

The quantiles of the conditional and unconditional distribution were performed using R software. The quantiles, $z_{1-\alpha}$, of the conditional distribution are given in Table 2, which are obtained considering $z_\alpha = \frac{2}{62} f_{1-\alpha,2,62}$, where $f_{1-\alpha,2,62}$ corresponds to the $1-\alpha$ quantile of a central F distribution with 2 and 62 degrees of freedom. So we can conclude that using the common approach we reject H_0 for $\alpha = 0.1$, since $\Im_{Obs} > z_{1-\alpha}$, and we do not reject for $\alpha = 0.05$ and 0.01.

Table 2: The quantiles of the conditional distribution.

Values of α	0.1	0.05	0.01
$z_{1-\alpha}$	0.07711	0.10146	0.16016

To carry out the computation we are led to use our previous information assuming that $\lambda_i,\ i = 1, 2, 3$ correspond to the average numbers of occurrences per year. So we take $\lambda_1 = 18$; $\lambda_2 = 22$ and $\lambda_3 = 25$, which means that $N_1 \sim P(18)$, $N_2 \sim P(22)$ and $N_3 \sim P(25)$. Let us also assume that we have at least 5 observations per level, which means that $n_i^\bullet = 5,\ i = 1, 2, 3$, $n^\bullet = \sum_{i=1}^3 n_i = 15$ and consequently $\boldsymbol{n}^\bullet = (5, 5, 5)'$.

To compute the quantiles for the unconditional distribution we obtain the minimum value $\overline{n} = 97$ (considering in expression (8)) such that

$$\sum_{n=\overline{n}+1}^{\infty} pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet) = 1 - \sum_{n=n^\bullet}^{\overline{n}} pr(N = n|\boldsymbol{N} \geq \boldsymbol{n}^\bullet) < 10^{-4}. \tag{11}$$

 ISBN: 978-84-617-8694-7

Therefore, the infinite serie in (6) is truncated not considering the terms for $n > 97$. So, when H_0 holds, we have the distribution

$$\begin{aligned}\overline{\overline{F}}_{\overline{n}}(z) &= \sum_{n=15}^{97} p_{\boldsymbol{n}^\bullet}(n)\overline{F}(z|2,n-3) \\ &= \sum_{n=15}^{97}\sum_{n_1=5}^{n-10}\sum_{n_2=5}^{n-(n_1+5)}\sum_{n_3=n-(n_1+n_2)}^{n-(n_1+n_2)} pr(\boldsymbol{N}=\boldsymbol{n}|\boldsymbol{N}\geq\boldsymbol{n}^\bullet)\overline{F}(z|2,n-3),\end{aligned}$$

with

$$pr(\boldsymbol{N}=\boldsymbol{n}|\boldsymbol{N}\geq\boldsymbol{n}^\bullet) = \prod_{i=1}^{3}\frac{\lambda_i^{n_i}/n_i!}{e^{\lambda_i}-\sum_{u_i=0}^{4}\frac{\lambda_i^{u_i}}{u_i!}}.$$

The quantiles, $z^t_{1-\alpha}$, for the probability $1-\alpha$, of this distribution are presented in Table 3. Since $\Im_{Obs} < z^t_{1-\alpha}$, we can conclude that we do not reject H_0 for the usual level of significance. So these results lead us to take a contrary decision that we had taken using the conditional approach, for $\alpha = 0.1$.

Table 3: The quantiles of the unconditional distribution.

Values of α	0.1	0.05	0.01
$z^t_{1-\alpha}$	0.07856	0.10341	0.16341

4 Closing remarks

In this paper we resorted to the Poisson distributions as the adequate choice for the distributions of the sample sizes when such are unknown. We open room to a new field based on the assumption that we have a minimum dimension for each sample considering one-way ANOVA. Through the application presented we can confirm that the quantiles may exceed those of the common ANOVA when random sample sizes are considered, giving relevance to the unconditional approach in avoiding false rejections.

Preconditioning of Linear Systems Using LU Factors

Takeshi Ogita[1]

[1] *Division of Mathematical Sciences, Tokyo Woman's Christian University*

emails: ogita@lab.twcu.ac.jp

Abstract

This study aims to compute accurate numerical solutions of ill-conditioned linear systems. For this purpose, we have developed several preconditioning methods [2, 3]. We have shown that, using such preconditioning methods, the condition number of the coefficient matrix can be reduced efficiently, and an accurate solution of the linear system can be obtained. However, the computational cost for such preconditioning methods is considerably larger than the standard numerical algorithm such as LU factorization, since some matrix multiplication in higher-precision arithmetic is required. In this study, we modify this point by exploiting the structure of the coefficient matrix, and develop an accurate and efficient algorithm for solving ill-conditioned linear systems. As a result, the computational cost for the preconditioning can significantly be reduced with similar quality to the previous methods.

Key words: linear systems, preconditioning, accurate numerical algorithms
MSC 2000: 65F05, 65G50

1 Introduction

Let us consider solving a linear system

$$Ax = b, \quad A \in \mathbb{R}^{n\times n},\ b \in \mathbb{R}^n \tag{1}$$

using floating-point arithmetic. To solve (1) is one of the significant tasks in scientific computing.

Let $\mathbf{u}$ denote the rounding error unit, e.g., $\mathbf{u} = 2^{-53} \approx 10^{-16}$ for IEEE 754 binary64. The purpose of this study is to develop efficient methods for solving (1) in ill-conditioned cases such that

$$\kappa(A) \gtrsim \mathbf{u}^{-1},$$

 ISBN: 978-84-617-8694-7

where $\kappa(A)$ denotes the condition number of A defined by $\kappa(A) := \|A\| \cdot \|A^{-1}\|$.

When using ordinary floating-point arithmetic, such as IEEE 754 binary64 arithmetic, the difficulty of the problem is as follows. Let x^* be the exact solution of (1). Let $\widehat{x}$ be a computed solution of (1) obtained by some backward stable algorithm in floating-point arithmetic with the rounding error unit $\mathbf{u}$. Then, as a rule of thumb (cf. e.g., [1]), $\widehat{x}$ satisfies

$$\frac{\|\widehat{x} - x^*\|}{\|x^*\|} \approx p(n) \cdot \kappa(A) \cdot \mathbf{u},$$

where $p(n)$ is a modestly growing function of n. From this, we can see that approximate solutions may become inaccurate if $\kappa(A) \gtrsim \mathbf{u}^{-1}$.

To overcome the problem, we have the following two possibilities:

1. Preconditioning with higher-precision arithmetic
2. Multiple precision arithmetic (MP)

However, MP is significantly slower than ordinary floating-point arithmetic, and we prefer to utilize ordinary floating-point arithmetic in terms of computational speed. Moreover, for modestly well-conditioned problems, standard numerical algorithms often provide sufficiently good results in ordinary floating-point arithmetic. In such cases, the use of MP is not necessary. However, we do not know in advance how many digits suffice to achieve desired result accuracy. Thus, we prefer some preconditioning method utilizing the results obtained by a standard numerical algorithm in ordinary floating-point arithmetic. As a standard numerical algorithm, we assume that LU factorization with partial pivoting is used.

2 Preconditioning

We briefly review an approach of preconditioning methods. We choose some nonsingular matrix $M \in \mathbb{R}^{n \times n}$ such that

$$\kappa(MA) \approx \mathbf{u} \cdot \kappa(A).$$

As a choice of M, we use an approximate inverse of an LU factor of A as in [2, 3].

For simplicity, we omit a permutation matrix according to the partial pivoting. Suppose the Crout's version of LU factorization of A is done in ordinary floating-point arithmetic such that $A \approx LU$. Then, heuristics suggest that $\kappa(A) \approx \kappa(L)$. By setting $M := L^{-1}$, we obtain

$$\kappa(L^{-1}A) \approx \mathbf{u} \cdot \kappa(A)$$

as shown in [4]. In practice, an approximate inverse X_L of L is used instead of L^{-1}. Here, higher-precision arithmetic is necessary for computing $X_L \cdot A$. For example, we can use

 ISBN: 978-84-617-8694-7

high-precision dot product algorithm `Dot2` proposed in [5], which computes dot product as if computed in twice the working precision. Major computational cost in $\mathcal{O}(n^3)$ flops required for the preconditioning is as follows:

- LU factorization $A \approx LU$: $\frac{2}{3}n^3$ flops
- Triangular matrix inversion $X_L \approx L^{-1}$: $\frac{1}{3}n^3$ flops
- Matrix multiplication $X_L \cdot A$ in twice the working precision: $c \cdot n^3$ flops with relatively large constant c such that $10 \leq c \leq 22$.

Therefore, total computational cost for the preconditioning is considerably larger than LU factorization. Thus, we aim to reduce the cost.

Detailed discussions and numerical results will be presented in the talk.

Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR) for Univariate Linear Operators: Continuous Singular Value Decomposition

Ayla OKAN[1] and Metin DEMİRALP[2]

[1] *Informatics Institute, Computational Science and Engineering Department, İstanbul Technical University*

emails: aylaokan@itu.edu.tr, metin.demiralp@gmail.com

Abstract

This paper is concerned with the analysis of the linear integral operators whose kernels are a square integrable bivariate function over the square $[a,b]^2$. The basic aim is to use high dimensional modeling. Tridiagonal Kernel Enhanced Multivariance Products Representation (TKEMPR) has been a novel extension high dimensional modeling representation (HDMR) which has been derived form of the Enhanced Multivariance Products Representation (EMPR), proposed by Demiralp and his group.

1 Introduction

In this section, to make a strong background for TKEMPR, we will give the following main lines and basic technicalities of EMPR method.

The Enhanced Multivariance Products Representation (EMPR) for a given N-variate function $f(x_1,...,x_N)$ is given by the finite expansion

$$\begin{aligned} f(x_1,...,x_N) \;=\; & f_0 \prod_{i=1}^{N} s_i(x_i) + \sum_{j=1}^{N} f_j(x_j) \prod_{\substack{i=1 \\ i\neq j}}^{N} s_i(x_i) + \sum_{\substack{j_1,j_2=1 \\ j_1<j_2}}^{N} f_{j_1,j_2}(x_{j_1},x_{j_2}) \prod_{\substack{i=1 \\ i\neq j_1,j_2}}^{N} s_i(x_i) \\ & + \sum_{\substack{j_1,j_2,j_3=1 \\ j_1<j_2<j_3}}^{N} f_{j_1,j_2,j_3}(x_{j_1},x_{j_2},x_{j_3}) \prod_{\substack{i=1 \\ i\neq j_1,j_2,j_3}}^{N} s_i(x_i) + \cdots + f_{1,2,...,N}(x_1,x_2,...,x_N) \end{aligned} \tag{1}$$

 ISBN: 978-84-617-8694-7

where subindexed fs are respectively called constant, univariate, bivariate EMPR components. The s_is appearing in the formulation are univariate support functions[1, 2]. x_j stands for the j-th independent variable remaining in a closed interval on the real line $[\,a_i, b_i\,]$, $i = 1, ..., N$.

The main purpose of this representation is to determine the EMPR components. To this end, one needs to impose certain conditions like Sobol's vanishing integral conditions involving support functions[3]. To determine these terms, the normalization conditions

$$\int_{a_i}^{b_i} dx_i W_i(x_i) = 1, \quad \int_{a_i}^{b_i} dx_i W_i(x_i) \left(s_i(x_i)\right)^2 = 1; \quad 1 \leq i \leq N \tag{2}$$

and the vanishing–under–integration conditions

$$\int_{a_i}^{b_i} dx_i W_i\left(x_i\right) s_i\left(x_i\right) f_{i_1 \ldots i_k}\left(x_{i_1}, ..., x_{i_k}\right) = 0, \quad x_i \in \left(x_{i_1}, ..., x_{i_k}\right), \quad 1 \leq i \leq k \leq N \tag{3}$$

are assumed to hold. These conditions allow us to obtain the EMPR terms as the following forms

$$f_0 = \int_{a_1}^{b_1} dx_1 W_1(x_1) ... \int_{a_N}^{b_N} dx_N W_N(x_N) \prod_{j=1}^{N} s_j(x_j) f\left(x_1, ..., x_N\right) \tag{4}$$

$$\begin{aligned} f_i(x_i) \;=\; & \int_{a_1}^{b_1} dx_1 W_1(x_1) ... \int_{a_{i-1}}^{b_{i-1}} dx_{i-1} W_{i-1}(x_{i-1}) \int_{a_{i+1}}^{b_{i+1}} dx_{i+1} W_{i+1}(x_{i+1}) ... \int_{a_N}^{b_N} dx_N W_N(x_N) \\ & \times \prod_{\substack{j=1 \\ j \neq i}}^{N} s_j(x_j) f(x_1, ..., x_N) - s_i f_0 \end{aligned} \tag{5}$$

$$\begin{aligned} f_{i_1 i_2}(x_{i_1}, x_{i_2}) \;=\; & \int_{a_1}^{b_1} dx_1 W_1(x_1) ... \int_{a_{i_1-1}}^{b_{i_1-1}} dx_{i_1-1} W_{i_1-1}(x_{i_1-1}) \int_{a_{i_1+1}}^{b_{i_1+1}} dx_{i_1+1} W_{i_1+1}(x_{i_1+1}) ... \\ & \times \int_{a_{i_2-1}}^{b_{i_2-1}} dx_{i_2-1} W_{i_2-1}(x_{i_2-1}) \int_{a_{i_2+1}}^{b_{i_2+1}} dx_{i_2+1} W_{i_2+1}(x_{i_2+1}) ... \int_{a_N}^{b_N} dx_N W_N(x_N) \\ & \times \prod_{\substack{j=1 \\ j \neq i_1, i_2}}^{N} s_j(x_j) f(x_1, ..., x_N) - s_{i_1}(x_{i_1}) f_{i_1}(x_{i_1}) - s_{i_2}(x_{i_2}) f_{i_2}(x_{i_2}) \\ & - s_{i_1}(x_{i_1}) s_{i_2}(x_{i_2}) f_0 \end{aligned} \tag{6}$$

EMPR is like most of its kind based on divide–and–conquer philosophy. For a given N–variate function, there are 2^N EMPR undetermined components at the right side of the expansion. However in practise, the main purpose of this matter is not to evaluate all of them to lower the computational cost. Then, EMPR turns into an approximation method.

2 Tridiagonal Kernel Enhanced Multivariance Products Represantation (TKEMPR)

In this work, we specifically focus on the case of bivariate functions which are assumed to be square integrable over the interval $[\,a,b\,]^2$. These bivariate functions can be taken into the consideration as the kernel the univariate integral operators also.

By using bivariate EMPR, the kernel bivariate target function $K(x,y)$ can be rewritten with the following expansion

$$K(x,y) = \mathcal{K}_0 u(x)v(y) + \mathcal{K}_1(x)v(y) + u(x)\mathcal{K}_2(y) + \mathcal{K}_{1,2}(x,y) \tag{7}$$

where subindexed $\mathcal{K}$s are called constant, univariate, and bivariate EMPR components. $u(x)$ and $v(y)$ are the given support functions.

Predefined normalization and vanishing conditions enable us to evaluate the EMPR terms of the kernel $K(x,y)$ uniquely as

$$\mathcal{K}_0 = \int_{a_1}^{b_1} dx \int_{a_2}^{b_2} dy u(x)v(y)W_1(x)W_2(y)K(x,y), \tag{8}$$

$$\mathcal{K}_1(x) = \int_{a_2}^{b_2} dy v(y)W_2(y)K(x,y) - \mathcal{K}_0 u(x), \tag{9}$$

$$\mathcal{K}_2(y) = \int_{a_1}^{b_1} dx u(x)W_1(x)K(x,y) - \mathcal{K}_0 v(y), \tag{10}$$

and finally

$$\mathcal{K}_{1,2}(x,y) = K(x,y) - \mathcal{K}_0 u(x)v(y) - \mathcal{K}_1(x)v(y) - \mathcal{K}_2(y)u(x). \tag{11}$$

These four equations can also be rewritten in much more concise form by using the following integral operators

$$\mathcal{K}_1(x) = \left(\widehat{I}_x - \widehat{P}_u\right) \int_{a_2}^{b_2} dy v(y)W_2(y)K(x,y), \tag{12}$$

$$\mathcal{K}_2(y) = \left(\widehat{I}_y - \widehat{P}_v\right) \int_{a_1}^{b_1} dx u(x)W_1(x)K(x,y), \tag{13}$$

$$\mathcal{K}_{1,2}(x,y) = \left(\widehat{I}_x - \widehat{P}_u\right)\left(\widehat{I}_y - \widehat{P}_v\right) K(x,y) \tag{14}$$

 ISBN: 978-84-617-8694-7

where $\widehat{I}_x$ and $\widehat{I}_y$ are unit operators in the spaces of univariate functions depending on x and y respectively. $\widehat{P}$ and $\widehat{Q}$ are idempotent integral operators which project their operands into the one dimensional space spanned by the related $u(x)$ and $v(y)$ functions respectively. When we take x and y as the variable of interest, we can define these integral operators as the following form

$$\widehat{P}_u f(x) \equiv u(x) \int_{a_1}^{b_1} d\xi u(\xi) W_1(\xi) f(\xi), \qquad \widehat{P}_v g(y) \equiv v(y) \int_{a_2}^{b_2} d\eta v(\eta) W_2(\eta) g(\eta) \tag{15}$$

Herein, it is also possible to define the inner product through the integrals over the x and y dependent functions separately under the related weight functions as

$$(f_1, f_2)_x \equiv \int_{a_1}^{b_1} dx f_1(x) W_1(x) f_2(x), \qquad (g_1, g_2)_y \equiv \int_{a_2}^{b_2} dy g_1(y) W_2(y) g_2(y) \tag{16}$$

These definitions allow us to get the following inner product equalities as follows

$$(u, \mathcal{K}_1)_x = 0, \qquad (v, \mathcal{K}_2)_y = 0 \tag{17}$$

$$(u, \mathcal{K}_{1,2})_x = 0, \qquad \forall y \in [\, a_2, b_2 \,], \qquad (v, \mathcal{K}_{1,2})_y = 0, \qquad \forall x \in [\, a_1, b_1 \,] \tag{18}$$

The operators $\left(\widehat{I}_x - \widehat{P}\right)$ and $\left(\widehat{I}_y - \widehat{Q}\right)$ project to the subspaces orthogonal to the axes spanned by $u(x)$ and $v(y)$ functions respectively. To construct the recursive structure, we can rewrite the initial support functions for the target bivariate function with u_1 and v_1 separately. Then, we can create new $u_2(x)$ and $v_2(y)$ generated support functions to use them on bivariate $\mathcal{K}_{1,2}$ term which becomes as the target function to apply the recursive EMPR method for the next step.

$$u_1(x) \equiv u(x), \qquad u_2(x) \equiv \frac{1}{\beta_1} \mathcal{K}_1(x), \qquad \beta_1 \equiv (K_1, K_1)^{\frac{1}{2}} \tag{19}$$

$$v_1(y) \equiv v(y), \qquad v_2(y) \equiv \frac{1}{\gamma_1} \mathcal{K}_2(y), \qquad \gamma_1 \equiv (K_2, K_2)^{\frac{1}{2}} \tag{20}$$

Then, by using the first recursion step, the target bivariate $K(x, y)$ function can be given as the following expansion

$$K(x, y) = \alpha_1 u_1(x) v_1(y) + \beta_1 u_2(x) v_1(y) + \gamma_1 u_1(x) v_2(y) + K_{1,2}(x, y) \tag{21}$$

where $\alpha_1 \equiv K_0$. The target and obtained bivariate functions can be redefined for recursion as

$$K^{(1)}(x, y) \equiv K(x, y), \qquad K^{(2)}(x, y) \equiv K_{1,2}(x, y) \tag{22}$$

 ISBN: 978-84-617-8694-7

Then, for the given bivariate $K^{(1)}(x,y)$ kernel function, recursive EMPR expansion for the first step is

$$K^{(1)}(x,y) = \alpha_1 u_1(x)v_1(y) + \beta_1 u_2(x)v_1(y) + \gamma_1 u_1(x)v_2(y) + K^{(2)}(x,y) \tag{23}$$

where

$$\alpha_1 = \int_{a_1}^{b_1} dx \int_{a_2}^{b_2} dy u_1(x)v_1(y)W_1(x)W_2(y)K^{(1)}(x,y), \tag{24}$$

$$\beta_1 \equiv \left(\int_{a_1}^{b_1} dx K_x^{(1)}(x) W_1(x) \left[\widehat{I}_x - \widehat{P}_{u_1} \right] K_x^{(1)}(x) \right)^{\frac{1}{2}},$$

$$K_x^{(1)}(x) \equiv \int_{a_2}^{b_2} dy v_1(y) W_2(y) K^{(1)}(x,y), \tag{25}$$

and

$$\gamma_1 \equiv \left(\int_{a_2}^{b_2} dy K_y^{(1)}(y) W_2(y) \left[\widehat{I}_y - \widehat{P}_{v_1} \right] K_y^{(1)}(y) \right)^{\frac{1}{2}}$$

$$K_y^{(1)}(y) \equiv \int_{a_1}^{b_1} dx u_1(x) W_1(x) K^{(1)}(x,y), \tag{26}$$

The generated support functions which will be used for the next step can be written by using integral operators as follows

$$u_2(x) \equiv \frac{1}{\beta_1} \left(\widehat{I}_x - \widehat{P}_{u_1} \right) K_x^{(1)}(x), \qquad v_2(y) \equiv \frac{1}{\gamma_1} \left(\widehat{I}_y - \widehat{P}_{v_1} \right) K_y^{(1)}(y) \tag{27}$$

$K^{(2)}(x,y)$, the reminder bivariate term, which will be used as the new target function for the next step can be given as the following concise form

$$K^{(2)}(x,y) = \left(\widehat{I}_x - \widehat{P}_{u_1} \right) \left(\widehat{I}_y - \widehat{P}_{v_1} \right) K^{(1)}(x,y) \tag{28}$$

More generally, we can write this expansion for the jth step recursion

$$K^{(j)}(x,y) = \alpha_j u_j(x)v_j(y) + \beta_j u_{j+1}(x)v_j(y) + \gamma_j u_j(x)v_{j+1}(y) + K^{(j+1)}(x,y). \tag{29}$$

where

$$\alpha_j = \int_{a_1}^{b_1} dx \int_{a_2}^{b_2} dy u_j(x)v_j(y)W_1(x)W_2(y)K^{(j)}(x,y), \tag{30}$$

$$\beta_j \equiv \left(\int_{a_1}^{b_1} dx K_x^{(j)}(x) W_1(x) \left[\widehat{I}_x - \widehat{P}_{u_j} \right] K_x^{(j)}(x) \right)^{\frac{1}{2}}, \quad K_x^{(j)}(x) \equiv \int_{a_2}^{b_2} dy v_j(y) W_2(y) K^{(j)}(x,y) \tag{31}$$

 ISBN: 978-84-617-8694-7

$$\gamma_j \equiv \left(\int_{a_2}^{b_2} dy K_y^{(j)}(y) W_2(y) \left[\widehat{I}_y - \widehat{P}_{v_j}\right] K_y^{(j)}(y)\right)^{\frac{1}{2}}, \quad K_y^{(j)}(y) \equiv \int_{a_1}^{b_1} dx u_j(x) W_1(x) K^{(j)}(x,y) \tag{32}$$

$$u_{j+1}(x) \equiv \frac{1}{\beta_j}\left(\widehat{I}_x - \widehat{P}_{u_j}\right) K_x^{(j)}(x), \qquad v_{j+1}(y) \equiv \frac{1}{\gamma_j}\left(\widehat{I}_y - \widehat{P}_{v_j}\right) K_y^{(j)}(y), \tag{33}$$

The new target bivariate function given in (29) satisfies the following concise form

$$K^{(j+1)}(x,y) = \left(\widehat{I}_x - \widehat{P}_{u_j}\right)\left(\widehat{I}_y - \widehat{P}_{v_j}\right) K^{(j)}(x,y) \tag{34}$$

The expansion given in (23) can be established by all these recursions and define

$$\begin{aligned} K^{(1)}(x,y) &= \sum_{j=1}^{n} \left(\alpha_j u_j(x) v_j(y) + \beta_j u_{j+1}(x) v_j(y) + \gamma_j u_j(x) v_{j+1}(y)\right) \\ &+ K^{(n+1)}(x,y) \end{aligned} \tag{35}$$

where

$$\begin{aligned} K^{(n+1)}(x,y) &= \left[\prod_{i=1}^{n}\left(\widehat{I}_x - \widehat{P}_{u_i}\right)\right]\left[\prod_{i=1}^{n}\left(\widehat{I}_y - \widehat{P}_{v_i}\right)\right] K^{(1)}(x,y) \\ &= \left(\widehat{I}_x - \sum_{i=1}^{n}\widehat{P}_{u_i}\right)\left(\widehat{I}_y - \sum_{i=1}^{n}\widehat{P}_{v_i}\right) K(x,y). \end{aligned} \tag{36}$$

When n grows unboundedly, it becomes quite noticeable that $K^{(n+1)}(x,y)$ tends to vanish because of the idempotency and mutual annihilating properties of the projection operators over the $u(x)$ and $v(y)$ respectively. By this way, we have

$$K(x,y) = \sum_{j=1}^{\infty} \left(\alpha_j u_j(x) v_j(y) + \beta_j u_{j+1}(x) v_j(y) + \gamma_j u_j(x) v_{j+1}(y)\right). \tag{37}$$

which we call TKEMPR for the kernel function[4, 5]. This method also can be considered as the concise matrix format like three matrix product representation as follows

$$K(x,y) = \mathbf{u}(x)^T \mathbf{\Sigma} \mathbf{v}(y) \tag{38}$$

whose kernel $\mathbf{\Sigma}$ is tridiagonal denumerable infinite square matrix and $\mathbf{u}(x)$ and $\mathbf{v}(y)$ are denumerable infinite vectors. These vectors are composed of the elements $u_i(x)$ and $v_i(y)$ respectively. Kernel matrix $\mathbf{\Sigma}$ has αs, βs and γs as the downward ordered elements of the main diagonal, and, lower nearest neighbour of the main diagonal, and, upper nearest neighbour of the main diagonal respectively [6, 7, 8].

 ISBN: 978-84-617-8694-7

3 Continuous Singular Value Decomposition

The problem considered in this work is described as follows:

- For a given bivariate function which is also the kernel of the considered linear operator, a concise three matrix factor product decomposition[9, 10, 11] has been constructed by using recently developed decomposition, TKEMPR.
- The focused linear operator can be decomposed by using this square integrable kernel function's decomposition through Continuous Singular Value Decomposition.
- And as the final stage, we exhibit the main lines and relationships of these two decompositions.

For these reasons, let us now focus on the following linear operator decomposition

$$\widehat{\mathcal{I}}f(x) \equiv \int_a^b dy K(x,y) f(y) \tag{39}$$

where $f(x)$ belongs to the linear vector space of univariate functions which are square integrable over $[a,b]$ and $K(x,y)$ is the kernel function, assuming to be square integrable over $[a,b]^2$[13, 14]. For this work these functions are assumed to be real–valued to facilitate the analysis.

In the symmetric kernel case, the integral operator $\widehat{\mathcal{I}}$ given in (39) is self–adjoint. Therefore, there is no need to define its adjoint. Also, the left and right eigenfunctions are the same. In the nonsymmetric kernel we can focus on "Continouos Singular Value Decomposition" to protect the real–valued case for eigenvalues[13, 14, 15]. These lead us to write the following equations

$$\widehat{\mathcal{I}}v(x) = \sigma u(x), \qquad \widehat{\mathcal{I}}^{\dagger}u(x) = \sigma v(x) \tag{40}$$

Herein, we assume that there is nonsymmetric kernel case. By using the general definiton of adjoint operator, which can be found in scientific literature, we can get

$$\widehat{\mathcal{I}}^{\dagger}\widehat{\mathcal{I}}v(x) = \sigma^2 v(x), \qquad \widehat{\mathcal{I}}\widehat{\mathcal{I}}^{\dagger}u(x) = \sigma^2 u(x) \tag{41}$$

Here we can use the following notation

$$\widehat{\mathcal{I}}_L v(x) = \int_a^b dy K_L(x,y)\sigma^2 v(x), \qquad \widehat{\mathcal{I}}_R u(x) = \int_a^b dy K_R(x,y)\sigma^2 u(x) \tag{42}$$

such that

$$K_L(x,y) \equiv \int_a^b d\eta K(\eta,x)K(\eta,y), \qquad K_R(x,y) \equiv \int_a^b d\eta K(x,\eta)K(y,\eta) \tag{43}$$

 ISBN: 978-84-617-8694-7

The subscripts L and R symbolize the words "left" and "right" respectively. It is obvious that $K_L(x,y)$ and $K_R(x,y)$ are now symmetric kernels even if $K(x,y)$ is assumed to be nonsymmetric. And also, all σ^2 values are non–negative. This means, σ values which can be chosen as positive valued are defined as "Singular Values" of the operator $\widehat{\mathcal{I}}$ and $u(x)$s and $v(y)$s are called "the Left and Right Singular Functions" respectively. Then, the kernel function can be decomposed as the following form

$$K(x,y) = \sum_{i=1}^{\infty} \sigma_i u_i(x) v_i(y) \tag{44}$$

This expansion can also be given in the following concise form

$$K(x,y) = \mathbf{u}^T(x)\ \mathbf{\Sigma}\ \mathbf{v}(y) \tag{45}$$

where $\mathbf{u}(x)$ and $\mathbf{v}(y)$ are denumerable infinite vectors whose elements are $u_i(x)$s and $v_i(y)$s respectively while the denumerable infinite square matrix $\mathbf{\Sigma}$ is diagonal such that its main diagonal elements are singular values.

It is possible to combine the above mentioned form with the linear operator decomposition given in (39)

$$\widehat{\mathcal{I}} f(x) = \mathbf{u}^T(x)\ \mathbf{\Sigma}\ \int_a^b dy \mathbf{v}(y) f(y), \qquad \widehat{\mathcal{I}}^\dagger f(x) = \mathbf{v}^T(x)\ \mathbf{\Sigma}\ \int_a^b dy \mathbf{u}(y) f(y) \tag{46}$$

Then we can write the following spectral counterparts as

$$\widehat{\mathcal{I}}^\dagger \widehat{\mathcal{I}} f(x) = \mathbf{v}^T(x)\ \mathbf{\Sigma}^2\ \int_a^b dy \mathbf{v}(y) f(y) \tag{47}$$

$$\widehat{\mathcal{I}} \widehat{\mathcal{I}}^\dagger f(x) = \mathbf{u}^T(x)\ \mathbf{\Sigma}^2\ \int_a^b dy \mathbf{u}(y) f(y) \tag{48}$$

where we have used the symmetry in $\mathbf{\Sigma}$ and it leads us to

$$\int_a^b dx \mathbf{u}(x)\mathbf{u}(x)^T = \mathbf{I}_\infty, \qquad \int_a^b dx \mathbf{v}(x)\mathbf{v}(x)^T = \mathbf{I}_\infty \tag{49}$$

where $\mathbf{I}_\infty$ is the denumerable infinite identity matrix.

The basic aim of this work has been the decomposition of linear operator $\widehat{\mathcal{I}}$ which resulted with the iteratively structured eigenvalue problems. These problems can be taken into consideration as matrix diagonalization problems and increase computational cost. It is also possible to use TKEMPR procedures to decompose the linear operator as

$$\widehat{\mathcal{I}} = \sum_{i=1}^{\infty} \left(\alpha_i \widehat{P}_i + \beta_i \widehat{T}_{i+1,i} + \gamma_i \widehat{T}_{i,i+1} \right) \tag{50}$$

 ISBN: 978-84-617-8694-7

such that

$$\widehat{P}_i f(x) \equiv \int_a^b dy u_i(x) v_i(y) f(y), \quad \widehat{T}_{i,j} f(x) \equiv \int_a^b dx u_i(x) v_j(y) f(y), \quad i,j = 1,2,3,... \quad (51)$$

Herein, the resulting operations do not only turn into tridiagonalization instead of diagonalization but also they are recursive instead of iterative procedures [16].

4 Numerical Implementations

Let us begin our numerical experiments by using the below mentioned kernel function

$$K(x,y) = e^{(x+y)} + e^{(-x-y)} \quad (52)$$

which is a symmetric function over the interval $[0,1]$. For convenience in calculations we prefer to use symmetric function. But in the previous section we give the details of integral operator decomposition for nonsymmetric kernel functions. Therefore, the function given in (52) can be considered as being symmetrized function over the interval $[0,1]$. The exact solution of the spectral problem

$$\int_0^1 dy K(x,y)\phi(y) = \lambda\phi(y) \qquad 0 \leq x,y \leq 1 \quad (53)$$

can be given as

$$\lambda = 3.518549337, \qquad \phi(x) = 0.507153053e^x + 0.164328385e^{-x} \quad (54)$$

such that this eigenfunction is normalized over $[0,1]$. These results are taken from[17]. By keeping the greatest eigenvalue λ and corresponding normalized eigenfunction $\phi(x)$ given in (54), we can focus on our decomposition method by using TKEMPR method. In the three factor matrix product type representation of TKEMPR, the kernel matrix $\mathbf{\Sigma}$ is defined in general form as

$$\mathbf{\Sigma} = \begin{bmatrix} \alpha_1 & \gamma_1 & 0 & ... & 0 & ... & ... \\ \beta_1 & \alpha_2 & \gamma_2 & 0 & \ddots & ... & ... \\ 0 & \beta_2 & \alpha_3 & \ddots & 0 & \ddots & ... \\ \vdots & \ddots & \ddots & \ddots & \gamma_{m-1} & 0 & ... \\ 0 & ... & 0 & \beta_{m-1} & \alpha_m & 0 & ... \end{bmatrix} \quad (55)$$

where $\mathbf{\Sigma}$ is tridiagonal denumerable infinite square matrix. The implementation results will be given by using table including α_i values computing by TKEMPR steps.

 ISBN: 978-84-617-8694-7

	$u_1[x]=1,$ $v_1[y]=1$	$u_1[x]=ae^x,$ $v_1[y]=be^{-y}$	$u_1[x]=ae^x$ $v_1[y]=ae^y$	$u_1[x]=a(e^x+e^{-x})$ $v_1[y]=a(e^y+e^{-y})$	$u_1[x]=ae^x+be^{-x}$ $v_1[y]=ae^y+be^{-y}$
α_1	3.35207	3.08616	3.50757	3.49140	3.51839
α_2	0.27166	5.56393×10^{-11}	0.119297	0.13546	0.10847
α_3	0.00313	-2.38675×10^{-12}	8.71743×10^{-11}	-1.18143×10^{-15}	-3.56266×10^{-16}

In this table, a and b values are used for constant real valued coefficients which come from normalization of the relevant support functions. When we analyzed the table, we can suggest that in the first step of TKEMPR we obtain very close values to the greatest eigenvalue. It is given in the last column of the table that, TKEMPR three factor product decomposition method can develop a relationship between the methods solving eigenvalue problem. It is also possible to show the efficiency of this method with the following figure which includes the approximated function, shown with blue colour, obtained from 3×3 three factor product TKEMPR decomposition and the exact kernel function, shown with yellow colour. The norm value for this functions is 1.52656×10^{-32} with the working precision 16.

Abstract

Although count data often exhibit overdispersion, there are also count datasets with underdispersed behaviour. However, there are not many distributions that can account for underdispersion. The most well-known distributions that handle both over- and underdispersion are the Conway-Maxwell Poisson or CMP and the hyper Poisson or HP, among others. These distributions are flexible but have serious computational problems, since there are not explicit expressions for the normalizing constant nor the moments, which have to be computed numerically or by solving link equations. In this work we present a biparametric distribution for count data that can also cope with over- and underdispersion, but does not have the computational limitations of the aforementioned models. In fact, it is a particular case of the complex triparametric Pearson (CTP) distribution. Firstly, we show the main probabilistic properties of this new distribution; secondly, we compare it with the CMP and the HP through their probability mass function and finally, we include an application example that shows the versatility of this new model.

Key words: count data, CTP distribution, overdispersion, underdispersion
MSC 2000: 60E05

1 Introduction

It is often found that data exhibit overdispersion. In this case the negative binomial (NB) distribution is the preferred alternative model, although there are many other distributions for this kind of data, such as the generalized Poisson (GP), the univariate generalized Waring (UGW), the extended generalized Waring (EGW), the zero-inflated (ZI) models and so on (see, e.g. [3]). Underdispersion is also common, for instance, in counts obtained for rare

 ISBN: 978-84-617-8694-7

events but there are not so many distributions that handle with it. The most well-known are the weighted Poisson or WP [2], the CMP [8] and the HP [1], among others. These distributions are flexible but have the disadvantage of the absence of explicit expressions for the normalizing constant and the moments, so it is necessary to use approximations or link equations for computing them, which may be a serious problem.

The CTP distribution developed by [5] is also a count data model that can cope with over- and underdispersion and does have explicit expressions for its moments in terms of the parameters. Nevertheless it has three parameters: a, b and γ. In order to compare it with other biparametric models, in [4] the authors considered the particular case $a = 0$, called the complex biparametric Pearson (CBP) distribution. However, this model is always overdispersed and so has been compared with the NB, ZIP and GP (see [6]). Now, we develop another biparametric model that is also a particular case of the CTP but when $b = 0$. It keeps the property that it can account for both over- and underdispersion and so it competes with the CMP and HP.

Then the work is structured as follows. In Section 2 we introduce the new model and study its main properties. In Section 3 a comparison among this model, the CMP and the HP is carried out through the graphical representation of the pmf in function of the mean and the variance. Finally, Section 4 includes an example that illustrates the versatility and utility of this distribution.

2 The new distribution

The CTP distribution was developed by [5]. It is a triparametric discrete distribution of infinite range generated by the Gaussian hypergeometric function with complex parameters, so it belongs to the GHD family [3]. Specifically, its pmf has the expression:

$$f(x) = f_0 \frac{(a+ib)_x (a-ib)_x}{(\gamma)_x} \frac{1}{x!} = f_0 \prod_{j=1}^{x} \frac{(a+j-1)^2 + b^2}{(\gamma+j-1)j}, \quad x = 0, 1, \ldots \tag{1}$$

where i is the imaginary unit, $a \in \mathbb{R}$, $b \geq 0$ and $\gamma > 0$. $(\alpha)_r = \Gamma(\alpha + r)/\Gamma(\alpha)$ is the Pochhammer symbol and f_0 the normalizing constant given by

$$\frac{\Gamma(\gamma - a - ib)\Gamma(\gamma - a + ib)}{\Gamma(\gamma)\Gamma(\gamma - 2a)}.$$

This distribution arises as a solution of the next difference equation:

$$G(x) f_{x+1} - L(x) f_x = 0$$

where G and L are quadratic polynomials, $G(x) = (\gamma + x)(x + 1)$ and $L(x) = x^2 + \theta_1 x + \theta_2, \theta_1, \theta_2 \in \mathbb{R}$, the latter with complex roots $a \pm ib$.

 ISBN: 978-84-617-8694-7

One of the main properties of this distribution is that it can cope with over- and underdispersion. In fact, it is underdispersed if $a < -(\mu+1)/2$, equidispersed if $a = -(\mu+1)/2$ or overdispersed if $a > -(\mu+1)/2$. In particular, if $a \geq 0$ the CTP is always overdispersed.

In [4] the authors study the particular case $a = 0$ and they call it the complex biparametric Pearson (CBP) distribution. This model is always overdispersed and has been compared with other biparametric models (see [6]).

On this occasion, we consider the case $b = 0$ in such a way that we obtain another biparametric distribution which is a particular case of the CTP. We call this new model CBP type II or CBP_{II} with parameters a and γ. Actually, this model is generated by the Gaussian hypergeometric function ${}_2F_1(a, a; \gamma; 1)$, so it has no complex parameters. Regarding the polynomial $L(r)$, we are considering the case of a double root a.

Taking (1) into account, its pmf has the expression

$$f(x) = f_0 \frac{(a)_x^2}{(\gamma)_x} \frac{1}{x!} = f_0 \prod_{j=1}^{x} \frac{(a+j-1)^2}{(\gamma+j-1)j}, \quad x = 0, 1, \ldots \tag{2}$$

where $a \in \mathbb{R}, \gamma > 0$ and $f_0 = \frac{\Gamma(\gamma-a)^2}{\Gamma(\gamma)\Gamma(\gamma-2a)}$. So (2) can be rewritten as

$$f(x) = \frac{\Gamma(\gamma-a)^2}{\Gamma(\gamma-2a)\Gamma(a)^2} \frac{\Gamma(a+x)^2}{\Gamma(\gamma+x)\Gamma(x+1)}, \quad x = 0, 1, \ldots$$

Let us observe that the CBP_{II} has finite range when $a \in \mathbb{Z}$ since $f(x) = 0, x > -a$.

2.1 Properties

As the CBP_{II} distribution is a particular case of the CTP, the former inherits most of its properties:

1. There are explicit expressions for the mean and the variance in terms of the parameters of the model, that is,

$$\mu = \frac{a^2}{\gamma - 2a - 1}, \quad \sigma^2 = \frac{a^2(\gamma - a - 1)^2}{(\gamma - 2a - 1)^2(\gamma - 2a - 2)} = \mu \frac{\mu + \gamma - 1}{\gamma - 2a - 2}.$$

   To guarantee the existence of the mean and the variance it is clear that $\gamma > 2a + 1$ and $\gamma > 2a + 2$, respectively.

2. If $\frac{(a-1)^2}{\gamma-2a+1} \in \mathbb{Z}$, the distribution has two consecutive modes in this value and the previous one. Otherwise, the distribution is unimodal with mode in the integer part of that value. As a consequence, the pmf is $J-$shaped or bell-shaped. Moreover, it is a right skewed distribution.

 ISBN: 978-84-617-8694-7

3. It is underdispersed if $a < -(\mu+1)/2$, equidispersed if $a = -(\mu+1)/2$ or overdispersed if $a > -(\mu+1)/2$. Specifically, it can be shown that

   (a) a necessary condition to be underdispersed is $a < -0.5$. If $a \leq -1$, it is always underdispersed, but if $-1 < a < -0.5$ it is underdispersed when $\gamma > \frac{3a^2+4a-1}{2a+1}$.

   (b) a necessary condition to be equidispersed is $a < -0.5$. If $-1 < a < -0.5$ it is equidispersed when $\gamma = \frac{3a^2+4a+1}{2a+1}$.

   (c) a necessary condition to be overdispersed is $a > -1$. If $a \geq -1$, it is always overdispersed, but if $-1 < a < -0.5$ it is overdispersed when $\gamma > \frac{3a^2+4a-1}{2a+1}$.

   This property makes the CBP_{II} distribution more versatile to model a dataset.

4. A sufficient condition to be infinitely divisible (i.d.) is that $a > -0.5$ and $\gamma > a^2/(1+2a)$. So, if $a < -0.5$ the CBP_{II} distribution is not i.d. As a consequence, if the distribution is underdispersed it cannot be i.d.

5. It converges to the Poisson distribution when γ and $a^2 \to \infty$ with the same order of convergence and to the normal distribution when γ and $|a|$ have the same order of convergence.

Let us observe that when $a > 0$ the $CBP_{II}(a, \gamma)$ is a $UGW(a, a, \gamma - 2a)$, so the proposed model could be considered an underdispersed extension of a biparametric UGW.

3 Comparison with other distributions for count data

In order to find differences between the CBP_{II} and the CMP and HP distributions, we have compared their shapes, i.e., we have plotted their pmf for several values of the mean and the variance. So, we have obtained the expressions of the parameters of each model in terms of their mean and variance:

- for the $CBP_{II}(a, \gamma)$:

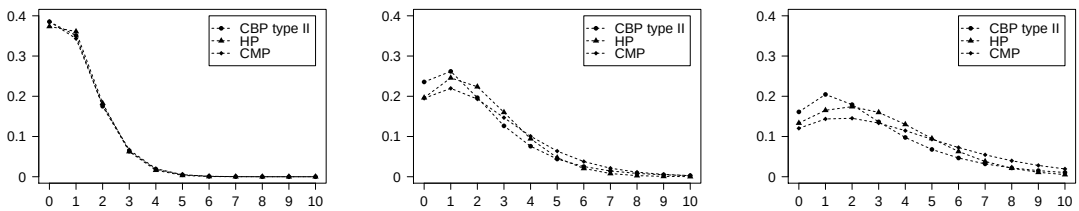
$$a = \frac{\mu^2 \pm \sqrt{\sigma^2 \mu \left[\sigma^2 + \mu\left(\mu - 1\right)\right]}}{\sigma^2 - \mu}, \quad \gamma = \frac{a^2}{\mu} + 2a + 1$$

  so, there are two solutions for each parameter. However, it can be shown that only one is possible for $\mu \geq 1$, which is the most usual case in count data.

- for the $HP(\gamma, \lambda)$ with $\gamma, \lambda > 0$ and pmf given by

$$P(X = x) = \frac{\Gamma(\gamma)}{{}_1F_1(1; \gamma; \lambda)} \frac{\lambda^x}{\Gamma(\gamma + x)}, \quad x = 0, 1, \ldots,$$

 ISBN: 978-84-617-8694-7



(a) $\mu = 1, \sigma^2 = 1.1$ (b) $\mu = 2, \sigma^2 = 4$ (c) $\mu = 3, \sigma^2 = 9$

Figure 1: Pmf of a CBP_{II}, HP and CMP for several values of the mean and the variance in an overdispersed scenario.

it is not possible to express the parameters in terms of μ and σ^2. [7] use the following link equations

$$\begin{aligned} \mu &= \lambda - (\gamma - 1)\left[1 - \frac{1}{{}_1F_1(1;\gamma;\lambda)}\right] \\ \sigma^2 &= \lambda + [\lambda - (\gamma - 1)]\,\mu - \mu^2. \end{aligned}$$

- for the $CMP(\lambda, v)$ with $\lambda > 0$, $v \geq 0$ and pmf

$$P(X = x) = \frac{\lambda^x}{(x!)^v}\frac{1}{Z(\lambda, v)}, \quad x = 0, 1, \ldots,$$

where $Z(\lambda, v) = \sum_{j=0}^{\infty} \frac{\lambda^j}{(j!)^v}$, we use the following approximate formulas (more details in [8])

$$\mu \approx \lambda^{1/v} - \frac{v-1}{2v}, \quad \sigma^2 \approx \frac{1}{v}\lambda^{\frac{1}{v}}.$$

These aproximations are specially good for $v \leq 1$ or $\lambda > 10^v$.

The comparison between the pmfs of the CBP_{II} and the CMP and HP is made in Figures 1 and 2 for overdispersed and underdispersed scenarios, respectively. Firstly, it is clear that the pmfs become $J-$shaped as the mean increases. It can be seen that the differences are more evident as the overdispersion or the underdispersion is more severe. Moreover, the CBP_{II} has higher probability in the modal value of the variable than the CMP and HP.

(a) $\mu = 1, \sigma^2 = 0.25$ (b) $\mu = 2, \sigma^2 = 1$ (c) $\mu = 3, \sigma^2 = 2.7$

Figure 2: Pmf of a CBP_{II}, HP and CMP for several values of the mean and the variance in an underdispersed scenario.

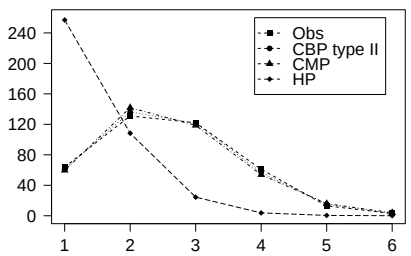

Figure 3: Observed and expected frequencies for data about the number of syllables of a Turkish poem.

4 Example

We consider data about the word length (in terms of number of syllables) in the turkish poem *Gidisat* by Ercüment Behzat Lâv available in [9]. Following these authors, the count for 1 is treated as a count for 0, and in general the count for y is treated as $y-1$, as though the data are generated by adding 1 to the distribution. These data exhibit underdispersion with a variance-mean ratio of 0.7372. Table 1 contains the parameter estimates, their standard errors (in parenthesis), observed and expected frequencies and the corresponding Pearson χ^2 test for the CMP, HP and CBP_{II} models. Observed and expected frequencies for each fit are represented in Figure 3. Although the CBP_{II} and CMP fits are very similar and really good, the former is slightly better and more accurate than the latter taking into account the AIC, the expected frequencies and the $p-$value.

Abstract

This paper is devoted to study the curvature of the Lagrange and PPH [1] reconstruction operators. We also compare the curvatures obtained in order to know which operator could be more suitable for some uses. Particularly we have considered the similarity with smoothing splines definition in order to develop an algorithm that propose nearly optimal weights in smoothing splines.
Key words: interpolation, curvature minimization, nonlinear, splines

MSC 2000: 41A05, 41A10, 65D17.

1 Introduction

Reconstruction operators are widely used in computer aided geometric design with interesting applications. They can be connected with subdivision schemes and in turn with fast algorithms for the generation of curves and surfaces.

Starting from a discrete set of data, the reconstruction operators aim at obtaining a piecewise function $p(x)$ which interpolates or approximates the data maintaining in many cases certain desirable properties. In particular, smoothing splines (see [6], [14]) in a given interval $[a, b]$ are based on polynomial reconstruction pieces which are connected with smooth joints at control knots and they minimize a functional of the type

$$J(p) := \int_a^b p''(x)^2 \, dx + \sum_j \mu_j (p(x_j) - f_j)^2, \tag{1}$$

 ISBN: 978-84-617-8694-7

which suppose a certain compromise, depending on the weights μ_j, between reducing the term approximating the curvature and keeping close to the initial set of data (x_j, f_j).

PPH reconstruction (see [1], [10]) is by construction a nonlinear interpolatory technique with several desirable properties. Among them, we would like to mention the following: each polynomial piece is builded with a fixed centered stencil, it is fourth order accurate on smooth convex regions, in the presence of singularities it reduces to second order but it does not lose all accuracy as it occurs in the linear case, moreover the reconstruction is free of Gibb's effects.

In this work we study the term of curvature of the above functional for Lagrange reconstruction and for PPH reconstruction given in [1] for the uniform case and in [13] for the non uniform case. We compare this term for both reconstruction operators and we deduce that PPH is an interesting candidate for minimization. On the other hand we calculate the weights that locally minimize the functional for the PPH reconstruction, and we use this result to relate this nonlinear reconstruction with splines theory, opening up doors to research about new nearly optimal weights in smoothing splines.

2 Curvature study on uniform grids

Let us consider the set of values $f_{j-1}, f_j, f_{j+1}, f_{j+2}$ corresponding to subsequent abcisas $x_{j-1}, x_j, x_{j+1}, x_{j+2}$ of a regular grid X of step h. The set of polynomials $p(x)$ which pass through the central points (x_j, f_j) and (x_{j+1}, f_{j+1}) can be written in terms of two free variables A and B as follows,

$$\begin{aligned} p(x) &:= \frac{x_{j+1}-x}{h} f_j + \frac{x-x_j}{h} f_{j+1} \\ &- \frac{1}{6}(x-x_j)(x_{j+1}-x)\left[A(1+\frac{x_{j+1}-x}{h}) + B(1+\frac{x-x_j}{h})\right]. \end{aligned} \tag{2}$$

At the boundary points x_{j-1}, x_{j+2} of the interval, the distance of each polynomial of the set to the initial data is given by

$$\begin{aligned} p(x_{j-1}) - f_{j-1} &= h^2(A - 2D_j), \\ p(x_{j+2}) - f_{j+2} &= h^2(B - 2D_{j+1}). \end{aligned} \tag{3}$$

where D_j and D_{j+1} are the following divided differences

$$\begin{aligned} D_j &= f[x_{j-1}, x_j, x_{j+1}] = \frac{f_{j-1} - 2f_j + f_{j+1}}{2h^2}, \\ D_{j+1} &= f[x_j, x_{j+1}, x_{j+2}] = \frac{f_j - 2f_{j+1} + f_{j+2}}{2h^2}, \end{aligned} \tag{4}$$

Introducing the second derivative of (2) in the curvature term in (1) we get

 ISBN: 978-84-617-8694-7

$$C(p) = \int_{x_j}^{x_{j+1}} p''(x)^2 \, dx = \frac{h}{3}(A^2 + AB + B^2). \tag{5}$$

For the sake of simplicity, from here in advance we particularize with the subscript L or P the parameters A, B or the curvature C associated to Lagrange or PPH polynomial.

Let be $PL(x)$ the Lagrange polynomial. It also interpolates the boundary points, i.e. it is the polynomial of set (2) that verifies

$$\begin{array}{l} p(x_{j-1}) = f_{j-1}, \\ p(x_{j+2}) = f_{j+2}. \end{array} \tag{6}$$

These conditions and equations (3) give us the parameters A and B associated to Lagrange polynomial,

$$\begin{array}{l} A_L = 2D_j, \\ B_L = 2D_{j+1}. \end{array} \tag{7}$$

The curvature term (5) in this case will be

$$C_L = \frac{h}{3}(D_j^2 + D_j D_{j+1} + D_{j+1}^2). \tag{8}$$

When $p(x)$ is the PPH polynomial (see [1] for more details) there are two possible cases depending on the absolute values of the divided differences D_j, D_{j+1}.

Case 1. $|D_j| \leq |D_{j+1}|$, i.e, the possible singularity is at $[x_{j+1}, x_{j+2}]$,

$$\begin{array}{l} p(x_{j-1}) = f_{j-1}, \\ p(x_{j+2}) = \widetilde{f}_{j+2}. \end{array} \tag{9}$$

where $\widetilde{f}_{j+2}$ and $\widetilde{D}$ are given by

$$\widetilde{f}_{j+2} = f_{j+2} - 4h^2 \left(\frac{D_j + D_{j+1}}{2} - \widetilde{D} \right). \tag{10}$$

$$\widetilde{D} = \begin{cases} \frac{2D_j D_{j+1}}{D_j + D_{j+1}} & \text{if } \; D_j D_{j+1} > 0, \\ 0 & otherwise. \end{cases} \tag{11}$$

From conditions (9) and equations (9) result

 ISBN: 978-84-617-8694-7

$$\begin{aligned} A_P &= 2D_j, \\ B_P &= 4\widetilde{D} - 2D_j. \end{aligned} \tag{12}$$

Therefore the coefficient B_P and the curvature term C_P will depend on the sign of the product D_jD_{j+1}.

Case 1.1. $D_jD_{j+1} > 0$.

$$B_P = \frac{2D_j(3D_{j+1} - D_j)}{D_j + D_{j+1}} \tag{13}$$

$$C_P = \frac{4hD_j^2(D_j^2 - 2D_jD_{j+1} + 13D_{j+1}^2)}{3(D_j + D_{j+1})^2}. \tag{14}$$

Comparing curvature terms associated to Lagrange interpolation (8) and to PPH reconstruction (14) we can see that

$$C_L - C_P = \frac{4hD_{j+1}(D_{j+1} - D_j)^2(5D_j + D_{j+1})}{3(D_j + D_{j+1})^2} \geq 0. \tag{15}$$

Case 1.2. $D_jD_{j+1} \leq 0$.

$$B_P = -2D_j, \tag{16}$$

$$C_P = \frac{4hD_j^2}{3}. \tag{17}$$

And the difference $C_L - C_P$ becomes

$$C_L - C_P = \frac{4hD_{j+1}(D_j + D_{j+1})}{3} \geq 0. \tag{18}$$

Case 2. $|D_j| > |D_{j+1}|$, i.e, the possible singularity lies at $[x_{j-1}, x_j]$

$$\begin{aligned} p(x_{j-1}) &= \widetilde{f}_{j-1}, \\ p(x_{j+2}) &= f_{j+2}. \end{aligned} \tag{19}$$

where [1]

$$\widetilde{f}_{j-1} = f_{j-1} - 4h^2\left(\frac{D_j + D_{j+1}}{2} - \widetilde{D}\right). \tag{20}$$

Working in a similar way as in case 1 we obtain

 ISBN: 978-84-617-8694-7

$$\begin{aligned} A_P &= 4\widetilde{D} - 2D_{j+1}, \\ B_P &= 2D_{j+1}, \end{aligned} \tag{21}$$

and depending on the sign of the product D_jD_{j+1} results

Case 2.1. $D_jD_{j+1} > 0$.

$$A_P = \tfrac{2D_{j+1}(3D_j - D_{j+1})}{D_j + D_{j+1}}, \tag{22}$$

$$C_P = \frac{4hD_{j+1}^2(13D_j^2 - 2D_jD_{j+1} + D_{j+1}^2)}{3(D_j + D_{j+1})^2}. \tag{23}$$

$$C_L - C_P = \frac{4hD_j(D_j - D_{j+1})^2(D_j + 5D_{j+1})}{3(D_j + D_{j+1})^2} \geq 0. \tag{24}$$

Case 2.2. $D_jD_{j+1} \leq 0$.

$$A_P = -2D_{j+1}, \tag{25}$$

$$C_P = \frac{4hD_{j+1}^2}{3}. \tag{26}$$

$$C_L - C_P = \frac{4hD_j(D_j + D_{j+1})}{3} \geq 0. \tag{27}$$

We have just seen that when data are in a regular grid the curvature term in equation (1) associated to PPH reconstruction operator is smaller than the one associated to the Lagrange operator. Let us remark that a similar study can be carried out with non uniform grids. This result is the motivation and the central idea to carry out a nonlinear definition of the weights in (1) which aims at improving the performance of smoothing splines according to the initial data.

Abstract

The reduction of the dimensionality is of great interest in the context of big data processing. Multidimensional scaling methods, or MDS, are techniques for dimensionality reduction, where data from a high-dimensional space are mapped into a lower-dimensional space. They consume relevant computational resources and an intensive research has been developed to accelerate them. In this work, several MDS methods are revised and accelerated on modern MultiGPU clusters.

Key words: Dimensionality Reduction; Multidimensional Scaling; High Performance Computing; GPU computing

1 Background

Real-world data, such as speech signals, images, biomedical, financial, telecommunication and other data usually have a high dimensionality. Each data instance (point) is characterized by some features. The dimensionality of such data, as well as the amount of processed data, is constantly increasing but the requirement of processing these data within a reasonable time frame still remains an open problem. Recent development in graphics hardware allows performing generic parallel computations on powerful hardware and provides an opportunity to solve many time-consuming problems.

 ISBN: 978-84-617-8694-7

Multidimensional Scaling (MDS) is one of the most popular dimensionality reduction method [1, 3]. MDS aims at finding points $Y_1, Y_2, \ldots, Y_m$ in the low-dimensional space $\mathbb{R}^s$, $s < n$, such that the distances between them are as close as possible to the distances between the original points $X_1, X_2, \ldots, X_m$ in the multidimensional space $\mathbb{R}^n$. This is achieved by minimizing the stress function

$$E_{MDS} = \sum_{i<j} \Big(d(X_i, X_j) - d(Y_i, Y_j) \Big)^2. \quad (1)$$

Here $d(\cdot, \cdot)$ is the distance between two points in the corresponding space. MDS is widely-used in different fields [6, 8, 9, 11].

Recently, power of GPU has been employed to speedup MDS algorithms. Fester et al. [5] proposed a CUDA implementation of MDS algorithm based on the high throughput multidimensional scaling (HiT-MDS). In [13], authors suggested a new efficient parallel algorithm for MDS based on virtual particle dynamics (VPD-MDS) [4] and explored this algorithm on GPU. In [7], the multi-level MDS Glimmer algorithm was developed for GPU, by dividing the input data into hierarchical levels and executing the algorithm recursively. The method is based on a stochastic approach [2]. Another CUDA-based technique to get MDS approximation is CFMDS [11]. It implements both single-level and multi-level approaches: if the data can fit the memory of the GPU entirely, a classical algorithm is executed; otherwise, the input data are divided into smaller portions that fit the global memory. In [10], authors proposed a correlation clustering framework which uses MDS for layout and GPU-acceleration to speedup Visual feedback. In [12], the fast sampling-based multidimensional scaling (SBMDS) on a multi-core GPU architecture was proposed to improve content-based image retrieval (CBIR) systems. Although the research on this field is being carried out actively, it remains relevant as the new GPU architecture and heterogeneous platforms constantly appear that should be effectively exploited for solving dimensionality reduction problems of different complexities.

2 MultiGPU implementation of MDS methods

In this work the main focus is the acceleration of MDS methods on modern GPU architectures. According to this idea our contributions are:

1. Update the CUDA MDS versions on the modern GPUs. For example, MDS is dominated by the reduction operations to compute the distances among data. On modern GPU the reduction among the local data of different threads can be optimized by the use of shuffled operations avoiding the use of the shared memory. These operations are only available from the Kepler GPU architecture.

2. Explore what is the best GPU-threads organization according to the particular number of data dimensions and items of every instance of the problem.

 ISBN: 978-84-617-8694-7

3. Develop a parallel MDS version on MultiGPU clusters.

4. Provide multicore and GPU versions and define an approach to identify the best option between both, according to the particular characteristics of every application example.

Our proposal is evaluated on a set of test applications which are well-known as examples where the MDS approaches are used.

emails: ozaki@sic.shibaura-it.ac.jp, ogita@lab.twcu.ac.jp

Abstract

This paper considers test matrices for numerical linear algebra. The proposed method generates real symmetric or unsymmetric matrices whose singular values are known exactly. This is useful for checking the accuracy of numerically computed results. The computational cost of the proposed method is significantly less than that of matrix multiplication, and the strategy can be straightforwardly extended to a real symmetric matrix with exact eigenvalues.

Key words: test matrix, floating-point arithmetic, numerical linear algebra,
MSC 2000: 15A18, 65F15,

1 Introduction

This paper considers test matrices for numerical linear algebra. Test matrices have been well summarised in the literature [1, Section 28]. Here we denote two orthogonal matrices as $U \in \mathbb{R}^{m\times m}$ and $V \in \mathbb{R}^{n\times n}$. A matrix $\Sigma \in \mathbb{R}^{m\times n}$ is a diagonal matrix of singular values. Then, test matrices are sometimes generated by the following singular value decomposition form:

$$A := U\Sigma V^T. \tag{1}$$

This can be used by 'gallery' functions with the 'randsvd' option in MATLAB [2]. Let $\mathbb{F}$ be a set of floating-point numbers as defined by IEEE 754 [3]. If we use floating-point numbers and floating-point arithmetic, there are problems when obtaining a matrix with exact singular values based on (1).

 ISBN: 978-84-617-8694-7

Problem 1 Although both U and V are orthogonal matrices, their elements may not be representable by floating-point numbers ($\mathbb{F} \not\ni u_{ij}, v_{ij} \in \mathbb{R}$). One could obtain U and V by QR decomposition from a non-singular matrix. However, the exact orthogonal matrix is difficult to obtain due to accumulation of rounding errors.

Problem 2 Even if U, Σ and V are represented by floating-point numbers ($U \in \mathbb{F}^{m\times m}, \Sigma \in \mathbb{F}^{m\times n}$ and $V \in \mathbb{F}^{n\times n}$), rounding errors may occur in the evaluation of matrix multiplications $U\Sigma V^T$. Then, the singular values of a computed result are not σ_{ii}.

We propose a method that produces a matrix with exact singular values using a Hadamard matrix. With the proposed method, the user inputs Σ to obtain diagonal matrix Σ' ($\approx \Sigma$), where σ'_{ii} is the exact singular value of $U\Sigma' V^T \in \mathbb{F}^{m\times n}$.

2 Floating-point Arithmetic and Hadamard Matrix

The function $\texttt{diag}(x, m, n)$, $x \in \mathbb{F}^{\min(m,n)}$ generates an m-by-n diagonal matrix D with $d_{ii} = x_i$. $\texttt{fl}(\cdot)$ and $\texttt{fl}_\triangle(\cdot)$ indicate computed results obtained by floating-point arithmetic with rounding to the nearest mode (roundTiesToEven) and a rounding upward mode (roundTowardPositive), respectively. Assume that neither overflow nor underflow occurs in $\texttt{fl}(\cdot)$. Here, let $\texttt{u}$ and $\texttt{u}_S$ be a roundoff unit and the smallest positive number in $\mathbb{F}$, e.g., $\texttt{u} = 2^{-53}$ and $\texttt{u}_S = 2^{-1074}$ for binary64 in IEEE 754, respectively. A constant $\texttt{realmax}$ is the largest floating-point number in $\mathbb{F}$. The function $\texttt{ufp}(\cdot)$, i.e. the unit in the first place, is defined as follows

$$\texttt{ufp}(a) = 2^{\lfloor \log_2 |a| \rfloor} \text{ (for } a \neq 0), \quad \texttt{ufp}(a) = 0 \text{ (for } a = 0), \quad a \in \mathbb{R}.$$

Here, we introduce several lemmas used to prove the proposed method.

Lemma 1 (well-known)**.** *For $a \in \mathbb{F}$, $a \in 2\texttt{u} \cdot \texttt{ufp}(a)\mathbb{Z}$ holds.*

Lemma 2 (well-known)**.** *For $a \in \mathbb{R}$ ($\texttt{u}_S\mathbb{Z} \ni |a| \leq \texttt{realmax}$), $k = 2^w, w \in \mathbb{Z}$, if $\texttt{u}k\mathbb{Z} \ni |a| \leq k$, then $a \in \mathbb{F}$.*

Lemma 3 ([4])**.** *For $a, b \in \mathbb{F}$, $a + b = \texttt{fl}(a + b) + \delta$, $|\delta| \leq \texttt{u} \cdot \texttt{ufp}(a + b)$ is satisfied.*

Lemma 4 ([4])**.** *For $a, b \in \mathbb{F}$ ($|a| \geq |b|$), $c = \texttt{fl}(a + b)$, $\texttt{fl}(c - a) = c - a$ is satisfied.*

A Hadamard matrix H is a matrix whose entries are either +1 or -1, such that $H^T H = HH^T = nI$. For $n = 2^k, k \in \mathbb{N}_0$, we can generate a $2n$-by-$2n$ Hadamard matrix as follows [5]:

$$\begin{pmatrix} H & H \\ H & -H \end{pmatrix}, \tag{2}$$

 ISBN: 978-84-617-8694-7

where $H = 1$ for $n = 1$. Let $H^{(n)}$ be an n-by-n Hadamard matrix generated by (2). Note that this matrix is symmetric. Assume that $\sqrt{mn} \in \mathbb{N}$. A matrix A can be obtained by $A := H^{(m)}\Sigma H^{(n)}/\sqrt{mn}$. All elements in $H^{(m)}$ and $H^{(n)}$ can be represented exactly using floating-point numbers. No rounding error occurs in the division, because $\sqrt{mn}$ is a power of two. Therefore, Problem 1 (Section 1) is solved. We explain how to avoid rounding errors in matrix multiplication in the following.

3 Proposed Method

Assume that a user gives a vector $\sigma \in \mathbb{F}^{\min(m,n)}$. We produce a vector σ' $(\approx \sigma) \in \mathbb{F}^{\min(m,n)}$ to satisfy $\mathtt{fl}(H^{(m)}\Sigma' H^{(n)}/\sqrt{mn}) = H^{(m)}\Sigma' H^{(n)}/\sqrt{mn}$, where $\Sigma' = \mathtt{diag}(\sigma', m, n)$. Here, let $t \in \mathbb{F}$ be the following:

$$t := 1.5\mathtt{ufp}\left(\mathtt{fl}_{\triangle}\left(2\sum_{i=1}^{n}\sigma_i\right)\right). \tag{3}$$

We compute

$$\sigma'_i = \mathtt{fl}((t + \sigma_i) - t) \tag{4}$$

for all i. Then, no rounding error occurs in $\mathtt{fl}(H^{(m)}\Sigma' H^{(n)})$. Therefore, the singular values of $\mathtt{fl}(H^{(m)}\Sigma' H^{(n)}/\sqrt{mn})$ are σ'_i.

Theorem 1. *$H^{(m)}$ and $H^{(n)}$ are generated by (2). Assume that $2\min(m,n)\mathtt{u} \le 1$ and vector $\sigma' \in \mathbb{F}^n$ is obtained by (4). Let $\Sigma' = \mathtt{diag}(\sigma', m, n)$. Then,*

$$B := \begin{cases} H^{(m)}\Sigma' H^{(n)} = \mathtt{fl}(H^{(m)}(\Sigma' H^{(n)})) & (m \le n) \\ H^{(m)}\Sigma' H^{(n)} = \mathtt{fl}((H^{(m)}\Sigma')H^{(n)}) & (otherwise) \end{cases}$$

holds.

Proof. Here, we provide a proof for $H^{(m)}\Sigma' H^{(n)} = \mathtt{fl}(H^{(m)}(\Sigma' H^{(n)}))$ for $m \le n$, because $H^{(m)}\Sigma' H^{(n)} = \mathtt{fl}((H^{(m)}\Sigma')H^{(n)})$ for $m > n$ can be proved similarly. First, $\Sigma' H^{(n)} = \mathtt{fl}(\Sigma' H^{(n)})$ trivially holds. Then, b_{ij} becomes the following:

$$b_{ij} = \sum_{k=1}^{m} h_{ik}^{(m)} \sigma'_k h_{kj}^{(n)}.$$

The definition of t in (3) yields $\mathtt{ufp}(t) \le \mathtt{ufp}(t + \sigma_i)$ for all i. From Lemma 1, we obtain the following:

$$\sigma'_i \in 2\mathtt{u} \cdot \mathtt{ufp}(t). \tag{5}$$

 ISBN: 978-84-617-8694-7

From Lemma 4 and 3, we obtain

$$\sigma_i' = \mathtt{fl}((t+\sigma_i)-t) = \mathtt{fl}(t+\sigma_i) - t = \sigma_i + \delta_i, \quad |\delta_i| \le \mathtt{u}\cdot\mathtt{ufp}(t+\sigma_i) \le 2\mathtt{u}\cdot\mathtt{ufp}(t),$$

which derives the following:

$$|\sigma_i'| \le \sigma_i + 2\mathtt{u}\cdot\mathtt{ufp}(t). \tag{6}$$

From the assumption for n, the definition of t in (3), (5) and (6), we obtain the following:

$$2\mathtt{u}\cdot\mathtt{ufp}(t) \ni \sum_{k=1}^{m} h_{ik}^{(m)}\sigma_k' h_{kj}^{(n)} \le \sum_{k=1}^{m}|\sigma_k'| \le \sum_{k=1}^{m}(\sigma_k + 2\mathtt{u}\cdot\mathtt{ufp}(t)) \le \mathtt{ufp}(t) + 2m\mathtt{u}\cdot\mathtt{ufp}(t) \le 2\mathtt{ufp}(t).$$

Therefore, from Lemma 2, $H^{(m)}\Sigma' H^{(n)} = \mathtt{fl}(H^{(m)}(\Sigma' H^{(n)}))$ holds. □

Note that we do not need to compute full matrix multiplication for $\mathtt{fl}(H^{(m)}(\Sigma' H^{(n)}))$ using recursive approaches. We assume that both m and n are powers of two. Otherwise, the following matrix

$$\begin{pmatrix} H & O \\ O & P \end{pmatrix} \tag{7}$$

can be used rather than a Hadamard matrix and similar discussion is possible, where $P \in \mathbb{F}^{(n-\mathtt{ufp}(n))\times(n-\mathtt{ufp}(n))}$ and O are a permutation matrix and the zero matrix, respectively.

Note that $\sigma_i = \sigma_j \Rightarrow \sigma_i' = \sigma_j'$ holds, i.e., multiple singular values can be set. However, if $\sigma_i \neq \sigma_j$ but σ_i is very close to σ_j, then σ_i' may be equal to σ_j'. Therefore, the proposed method fails to produce clustered singular values.

Abstract

In this paper, we use the popular splitting strategy to design a fast iterative algorithm for image restoration. We divide the algorithm into three steps via fast method, called fast iterative shrinkage/thresholding algorithm with backtracking to reduce image noise. we also give the convergence analysis for the proposed method. Numerical results demonstrate the efficiency and viability of the proposed algorithm, applied to l_1 regularization model and total-variation (TV) regularization model.

1 Introduction

In the field of engineering, many application problems including image processing, compressed sensing are aiming to recover underlying image or signal from a degraded version. A degraded image or signal g can be modeled as

$$g = Ax + b, \tag{1}$$

where $x \in \mathbb{R}^n$ is the image or signal to be reconstructed, A is a $m \times n$ matrix that models the measurement process, and $b \in \mathbb{R}^m$ is an additive noise. In linear inverse problem (1), the goal is to recover image x when g and A are given. For different choices of A, recovering x becomes different application problems. For instance, it becomes the deblurring problem if A represents a blurring matrix; it becomes the inpainting problem if A represents a projection of an image onto some known pixels domain. If A is the identity matrix, it reduces to the denoising problem. But linear inverse problem (1) is usually ill-posed in image processing. For instance, in image deblurring, linear inverse problem (1) is ill-posed in the sense that the blurring matrix A is ill-conditioned and solution could be sensitive to the additive noise. The linear inverse problem (1) has infinite number of solutions.

2 Preliminaries

Definition 2.1. *[8] An operator $P : \mathbb{R}^n \to \mathbb{R}^n$ is called nonexpansive if, for any $u, v \in \mathbb{R}^n$, we have*

$$\|P(u) - P(v)\|_2 \leq \|u - v\|_2. \tag{2}$$

If there exist a number $\beta \in (0, 1)$ and a nonexpansive operator $T : \mathbb{R}^n \to \mathbb{R}^n$ such that $P = (1 - \beta)I + \beta T$ is nonexpansive, then P is called β-averaged. In particular, when $\beta = 1/2$, P is called a firmly nonexpansive operator.

Remark 2.2. *[9] The firmly nonexpansive operator is defined as*

$$\|P(u) - P(v)\|_2^2 \leq (P(u) - P(v))^T(u - v). \tag{3}$$

Lemma 2.3. *[10] Let α be a positive number and $\mathcal{R}$ be a convex and semicontinuous function. Suppose*

$$x^* = argmin_x \|u - x\|_2^2 + \alpha\mathcal{R}(x) \tag{4}$$

and define $S : \mathbb{R}^n \to \mathbb{R}^n$ such that $x = S(u)$. Then S is firmly nonexpansive.

Lemma 2.4. *[11] Let P_1 and P_2 be β_1-averaged nonexpansive operators ($\beta_1, \beta_2 \in (0, 1)$), respectively. Then P_1P_2 is the $(\beta_1 + \beta_2 - \beta_1\beta_2)$-averaged nonexpansive.*

Theorem 2.5. *[12] Let $P : \mathbb{R}^n \to \mathbb{R}^n$ be a β-averaged nonexpansive operator. If the set of fixed points of P is nonempty, then for any u_0, the sequence $\{u_k\}$, where $u_k = P(u_{k-1})$ for $k = 1, 2, 3, \ldots$, converges to a fixed point in $\mathbb{R}^n$.*

 ISBN: 978-84-617-8694-7

3 An iteration algorithm and the convergence analysis

3.1 A modified split fast iterative shrinkage/thresholding algorithm

In this section, we propose a modified split fast iterative shrinkage/thresholding algorithm to solve (1). Our method is based on the decoupling model of deblurring and denoising which is proposed in [6]. Then (1) could be rewritten as (an initial guess x_0 is used)

$$\begin{cases} \widehat{x}_k = \text{argmin}_x \|Ax - g\|_2^2 + \alpha_1 \|x - x_{k-1}\|_2^2 \\ \widetilde{x}_k = \text{argmin}_x \|x - \widehat{x}_k\|_2^2 + \alpha_2 \mathcal{R}_1(x) \\ x_k = \text{argmin}_x \|x - \widetilde{x}_k\|_2^2 + \alpha_3 \mathcal{R}_2(x), \end{cases} \tag{5}$$

where α_1 is a positive parameters for deblurring, α_2, α_3 are the positive parameters for denoising and for both $\mathcal{R}(x) = \|x\|_1$ or $\mathcal{R}(x) = \|x\|_{TV}$.

Theorem 3.1. *Let $S_c S_b S_a : \mathbb{R}^n \to \mathbb{R}^n$. If the set of fixed points of $S_c S_b S_a$ is nonempty, then algorithm* (5) *converges to a fixed point.*

Proof. By applying Theorem 2.5, we have algorithm (5) converges to a fixed point. □

Remark 3.2. *When A is full rank, i.e., the smallest eigenvalue of $A^T A$ is larger than 0, algorithm* (5) *converges to a unique fixed point for any initial vector x_0.*

Lattice Sums (Lennard-Jones Ingham Coefficients) for Cubic and Hexagonal Lattices

Elke Pahl[1], Antony Burrows[1] and Peter Schwerdtfeger[1]

[1] *Centre for Theoretical Chemistry and Physics, Institute for Natural and Mathematical Sciences (INMS) and The New Zealand Institute for Advanced Study (NZIAS), Massey University Albany, Private Bag 102904, Auckland 0745, New Zealand*

emails: e.pahl@massey.ac.nz, , p.a.schwerdtfeger@massey.ac.nz

Abstract

The main contribution to the cohesive (binding) energy of a solid is the two-body part containing all dimer interactions of the extended system. Using an extended Lennard-Jones functional form, $\sum_{n>3} c_n x^{-n}$, for the description of the dimer interactions one can find the following analytical expression for the two-body cohesive energy per atom [1]:

$$E_{\mathrm{ELJ}}^{\mathrm{coh}} = \frac{1}{2} \sum_{n>3} c_n L_n r_s^{-n} \tag{1}$$

This formula has the beauty of being only dependent on the potential parameters, c_n, the next-nearest neighbor distance in the crystal, r_s, and the so-called Lennard-Jones Ingham coefficients, L_n. The availability of an analytical form also allow us to derive analytical expression for other solid-state properties like pressure, bulk modulus and even zero-point energy.

The Lennard-Jones coefficients are lattice sums which only depend on the underlying symmetry of the lattice and as thus, have to be calculated only once for every lattice symmetry. Nevertheless, an accurate computation is difficult because these three-dimensional lattice sums present very slowly converging series connected to the well-known number-theoretical problem of finding the number of representations of a sum of N squares. Fast-converging formulae can be found when the lattice sums can be written in form of homogeneous quadratic equations ([2] and references therein). While such formulae already exist for cubic lattices, the only know formula by Kane and Goeppert-Mayer [3] is plagued by inhomogeneities.

Here, we will illustrate the origin of and connection between different cubic lattice sums by visulazing the underlying 3D structures. For the hexagonal lattice we derive

a new lattice formula only consisting of sums over homogeneous quadratic forms which makes a fast and accurate evaluation accessible.

Yinyang K-means clustering for hyperspectral image analysis

Mercedes Eugenia Paoletti[1], Juan Mario Haut[1], Javier Plaza[1] and Antonio Plaza[1]

[1] *Department of Technology of Computers and Communications, University of Extremadura, Escuela Politecnica, Avda. de la Universidad s/n*

emails: mpaolett@alumnos.unex.es, juanmariohaut@unex.es, jplaza@unex.es, aplaza@unex.es

Abstract

Hyperspectral images are widely used in remote sensing applications due to their wealth of information in the spectral domain, that allows for very detailed scene classification. Clustering is one of the most used unsupervised techniques for the analysis of these scenes. Popular clustering techniques such as K-means are computationally expensive, particularly when applied to hyperspectral images characterized by their large dimensionality. An efficient implementation of K-means is the so-called *Yinyang K-means*, which outperforms K-means algorithms by clustering the centers in the initial stage, and leveraging efficiently maintained lower and upper bounds between each point and the cluster centers. In this work, we have adapted an efficient implementation of this algorithm using graphics processing units (GPUs) for hyperspectral image analysis. We have carried out a comparison of this technique with other existing implementations with the aim of demonstrating its usefulness in hyperspectral imaging. Our obtained results suggest that this technique is ideal for working with big hyperspectral data repositories.

Key words: Hyperspectral imaging, k-means clustering, YinYang K-means, GPUs.

1 INTRODUCTION

Current Earth observation (EO) sensors acquire and produce high-dimensional data cubes with hundreds of spectral channels and millions of pixels. For instance, NASA's Jet Propulsion Laboratory's Airbone Visible/Infrared Imaging Spectrometer (AVIRIS) [1] measures the solar reflected spectrum from 400nm to 2500nm at intervals of 10nm. The

 ISBN: 978-84-617-8694-7

EO-1 Hyperion imaging spectrometer collects bands in the range of 400nm to 2500nm too [2, 3]. The resulting hyperspectral datasets [4] provide information corresponding to large observation areas on the surface of the Earth, using hundreds of contiguous spectral bands. As a result, these instruments can produce three-dimensional data cubes with size significantly larger than traditional images. These images can be exploited in many practical applications, such as monitoring and management of the environment and agriculture, urban and regional planning, detection of relevant geological zones (e.g. mineral detection) or defense and intelligence issues (e.g. target detection or mine detection).

However, hyperspectral images present many challenges in terms of storage and processing due to their large dimensionality. In addition, modern sensors are producing an almost continuous stream of data [3]. For example, AVIRIS has a data collection rate of 2.5 MB/s and Hyperion collects almost 71.9 GB/hour. On the other hand, most of the satellite missions that will be soon in operation, such as the environmental mapping and analysis program (EnMAP http://www.enmap.org/) present similar data collection ratios. This creates the need for scalable and efficient processing techniques for hyperspectral data in the context of different applications [3].

Many techniques (supervised and unsupervised) have been developed to address the aforementioned challenges. One of the most widely used unsupervised methods is clustering, which aims to organize the data so that pixels with similar spectral content are clustered together in the same class [5]. In this case, there is no need for labeled samples which are common in supervised techniques [6]. Although clustering offers an unsupervised alternative that has been widely used in various fields, it is also a very challenging task due to the large spectral variability and complex spatial structures present in hyperspectral images. The most popular and widely used family of clustering algorithms is represented by centroid-based clustering methods such as K-means [7].

K-means assumes that similar pixels always form clusters in feature space. By applying this method to hyperspectral images we can obtain satisfactory results, but K-means is hampered by its computational complexity. There are a handful of studies which aim to address this issue, either adapting the algorithm to parallel processing structures such as field-programmable gate array (FPGAs) [5, 8]or cloud computing architectures [9]. Other works aim at developing improved implementations such as K-means++ [10, 11], the $AFKMC^2$ [12], the K-means projective clustering [13] or the filtered K-means [7]. The *Yinyang* K-means [14] is a recent improvement of K-means. This method features a space-conscious elastic design that adaptively uses the upper and lower bound based filters while maintaining various space constraints. The upper and lower bound based filters are continuously and carefully maintained, and provide an efficient evolvement and interplay mechanism.

Our main goal in this paper is to adapt the *Yinyang* K-means to hyperspectral image processing. The implementation that we have adopted is optimized for GPUs using

 ISBN: 978-84-617-8694-7

NVIDIA Compute Device Unified Architecture (CUDA). To test the effectiveness of the implementation, we have compared it with other existing k-means implementations and made an exhaustive analysis of the pros and cons of all the implementations used.

The remainder of the paper is organized as follows. Section 2 will delve into the K-means method and the improvements provided by the *Yinyang* K-means version, presenting its theoretical foundations. Section 3 validates the *Yinyang* K-means algorithm by comparing it with other implementations in terms of execution times. Finally, section 4 concludes with some remarks and hints at plausible future research lines.

2 K-means method: an overview

2.1 The K-means clustering algorithm

K-means is one of the easiest unsupervised learning algorithms and most widely used method to group data in a specified number of clusters. Suppose a set of n observations $X = (x_1, x_2, ..., x_n)$, where each observation is $x_i \in \mathbb{R}^d$, i.e. $x_i = [x_{i_1}, x_{i_2}, ..., x_{i_d}]$ (where d is the number of spectral channels). The goal is to group each observation into a number of *clusters* k fixed a priori ($k <= n$). Iteratively, K-means calculates the centers of the k groups, optimizing the error of each group as $\min \sum_{j=1}^{k} \sum_{i=1}^{n_k} \parallel x_i^j - c_j, \parallel^2$ where $\parallel x_i^j - C_j \parallel^2$ is the euclidean distance between a data point x_i^j of the cluster j (n_k is the observations within each cluster) and the cluster center c_j, which if it is the point that minimizes the equation also called *centroid of cluster j*.

K-means algorithm successfully performs the task of obtaining useful information from the dataset, such as the best distance metric for the data [15]. However, the results can vary greatly due to a small change in parameters and in the choice of the initial centers. So, a proper initialization will result in a final best solution. In order to obtain a set of good initial cluster centers, several methods have been proposed, as K-means++ [10, 11]. This algorithm obtains a set of k initial centers which are generally very close to the final solution.

2.2 *Yinyang* K-means method

The main problem with the traditional K-means implementation is that it performs a lot of redundant work when recalculating distances corresponding to samples which are not going to change the cluster. With this in mind, *Yinyang* K-means optimizes two important points in the K-means algorithm: the assignment steps and the update steps. In order to do that, it implements two filters and a new center update method.

In the standard K-means, the assignment step computes the distances between every point x_i and every cluster center c_j in order to find out the closest center to each point.

 ISBN: 978-84-617-8694-7

The *Yinyang* K-means instead uses two filters to detect which distance calculations are unnecessary and avoids computing them. These filters are based on the triangle inequality:

- Group filtering groups the k clusters into t groups $G = g_1, g_2, ..., g_t$, where each $g_i \in G$ is a set of the clusters and t must no be greater than $k/10$. t provides a design knob for controlling the space overhead and redundant distance elimination. For each group, it calculates:

  1. Upper bound: for each point x in cluster j ($j = j(x)$) it sets the upper bound to $uj(x) = d(x, j(x))$, i.e. the distance between x and cluster. The upper bound is updated as $uj'(x) = uj(x) + \delta(j)$, where $\delta(j)$ is the distance of the cluster j.
  2. Lower bound: for each point x in cluster j ($j = j(x)$) it sets the lower bound $lj(x, g_i)$ as the shortest distance between x and all centers in g_i excluding $j(x)$. The lower bound is updated as $lj'(x, g_i) = lj(x, g_i) - max_{c \in g_i}\delta(c)$, $\delta(c) = d(c, c')$ is the shift of cluster center due to the center update.

  If the updated lower bound is major than the updated upper bound, $lj'(x, g_i) > uj'(x)$, no reassignment is needed for point x and all the group-level comparisons can be avoided.

- Local filtering is used for get the new centroid of a cluster, avoiding unnecessary distance operations. A new center $c' \in g'_i$ cannot be the closest center to a point x if there is another center $p' \neq c'$ such that $d(x, p') < lj(x, g_i) - \delta(c)$

On the other hand, in the updating step, K-means computes the new center for each cluster. In *Yinyang* K-means new centers are computed as $c' = \frac{c \cdot |V| - \left(\sum_{y \in V - OV} y\right) + \sum_{y' \in V' - OV} y'}{|V'|}$ where V' and V denote a cluster in the current and previous iteration, OV is $V \cap V'$, c is the old center and c' is the new center.

2.3 Parallel GPU *Yinyang* K-means

The parallel implementation of *Yinyang* K-means that we have adopted is available in a library. It has been optimized for low memory consumption and use of a large number of clusters, bearing in mind the limitations of the K-means algorithm related to the calculation of the centroids that requires having all the data be available in the same place. In the context of the CUDA-based GPU implementation, if the data occupies a large amount of storage, it is impossible to store them in the memory of a single GPU, so it is necessary to cut the samples into as many intervals as GPUs are available. As a result, in our adopted implementation each GPU will work with its own interval, calculating the distances and the local centroids, writing the local assignments and broadcasting its results to other GPUs.

The parameters used by our adopted implementation are the number of clusters, k, the number of cluster groups (t), and the value for *tolerance*, which will be used by the algorithm

 ISBN: 978-84-617-8694-7

to stop its execution (if the number of reassignments drop below the tolerance value). The parallel *Yinyang* K-means execution is initialized with random centroids (or it can also be initialized by intelligently produced centroids such as those produced by K-means++) and calculates the Euclidean distance (L2) to perform the centroid selection calculations as $d_2(\overrightarrow{x}, \overrightarrow{y}) = \sqrt[2]{\sum_i (x_i - y_i)^2}$.

The output of the method is a vector of centroids and a vector with the cluster index for each sample (numerical labels for each pixel).

3 Experiments and results

3.1 Experimental Configuration

In order to evaluate the performance of the adopted *Yinyang* K-means implementation, we use a hardware environment composed by a 6th Generation Intel® Core™i7-6700K processor with 8M of Cache and up to 4.20GHz (4 cores/8 way multitask processing), 32GB of DDR4 RAM with a serial speed of 2400MHz, a GPU NVIDIA GeForce GTX 1080 with 8GB GDDR5X of video memory and 10Gbps of memory frequency, a Toshiba DT01ACA HDD with 7200RPM and 2TB of capacity, and an ASUS Z170 pro-gaming motherboard. On the other hand, the software environment is composed by Ubuntu 16.04.4 x64 as operating system, CUDA 8 and Python.

3.2 Hyperspectral data sets

In our experiments, we use four different hyperspectral images. The first one was collected by AVIRIS [1] in 1992 over a set of agricultural fields with regular geometry and with a multiple crops and irregular patches of forest in Northwestern Indiana. This scene, Indian Pines, has 145x145 pixels with 224 spectral bands in the range from 400 to 2500nm, with 10nm of spectral resolution, 20nm moderate spatial resolution and 16 bits radiometric resolution. 4 zero bands plus 20 bands with lower signal-to-noise ratio (SNR) have been removed, retaining 200 spectral channels. Dataset has 16 ground-truth classes(Fig. 1).

Also, we use a larger version of the Indian Pines scene. This one has a much larger size of 2678×614 pixels. It was collected over the same area that small Indian Pines, but spanning a much larger extent. It contains 220 spectral bands in the range from 400 to 2500 nm, with spectral resolution of 10 nm, moderate spatial resolution of 20 nm and 16 bits of radiometric resolution. The total number of classes is 58. (Fig. 4).

The third dataset was collected by AVIRIS over Salinas Valley, California (Fig. 3). The area covered has 512×217 samples and the spatial resolution is 3.7 m per pixel. 204 out of the 224 bands are kept after 20 water absorption bands are removed. Dataset has 16 land-cover classes.

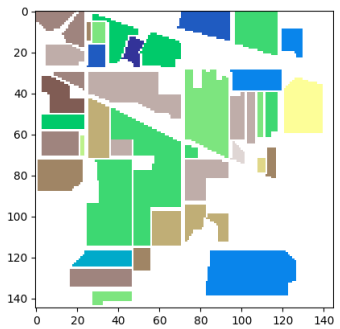

Figure 1: Ground-truth of small Indian Pines scene.

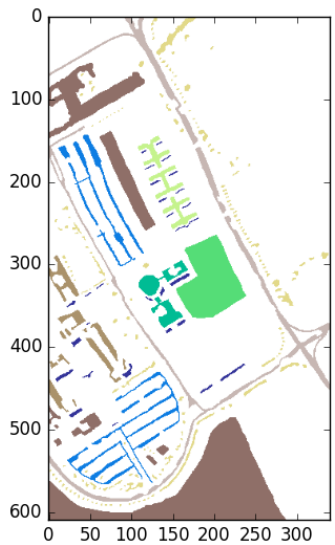

Figure 2: Ground-truth of University of Pavia.

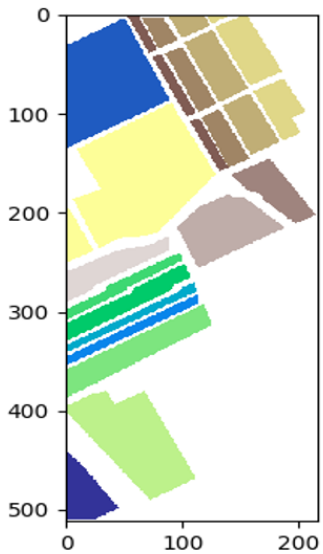

Figure 3: Ground-truth of Salinas scene.

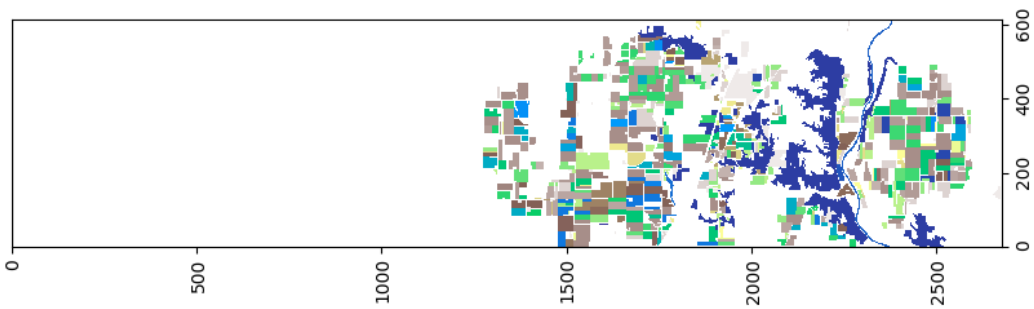

Figure 4: Ground-truth of big Indian Pines scene.

The fourth hyperspectral dataset was collected by the Reflective Optics System Imaging Spectrometer (ROSIS) sensor [16] during a flight campaign over Pavia, northern Italy. The dataset covers an urban environment, with various solid structures, natural objects and shadows (9 classes in total). The scene (see Fig. 2) contains 103 spectral bands of 610×340 pixels in the spectral range from 0.43 to 0.86μm, with spatial resolution of 1.3m/pixel.

3.3 Performance evaluation

In order to evaluate the performance of parallel *Yinyang* K-means, several experiments have been executed. The first one is a comparison between the GPU version of *Yinyang*

 ISBN: 978-84-617-8694-7

K-means and other iterative and parallel GPU implementations of the original (Lloyd) K-means algorithm setting the maximum number of centroids to the number of classes. The tolerance value was set to 0.001. To complete the experiment, we have tested two initiations of centroids: 1) completely random and 2) K-means++ method. Each version has been executed 10 times and the average times are reported for statistical significance. The obtained results are reported in Table 1.

Initialization	**Lloyd Iterative**		**Lloyd CUDA**		**Yinyan CUDA**

random	37.217 (2.960)	1	69.518 (6.057)	0.535	56.321 (11.650)	0.661

Table 1: Average time executions (standard deviation) and speed-up for each implementation of K-means initialized with random centroids and K-means++.

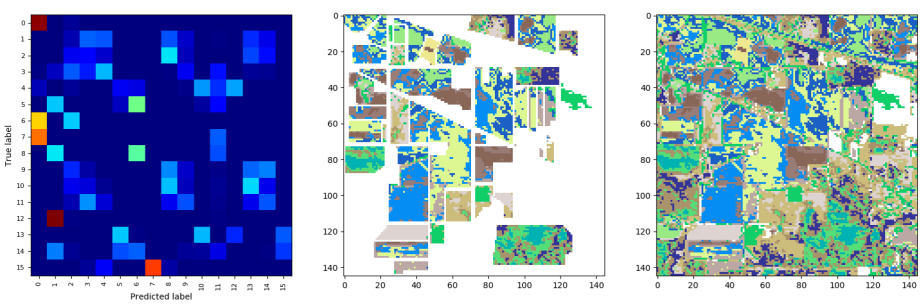

Figure 5: Small Indian Pines *Yinyang* K-means classification results: the confusion matrix and the classification maps without background and with background.

For small Indian Pines image, the fastest K-mean implementation is the original Lloyd

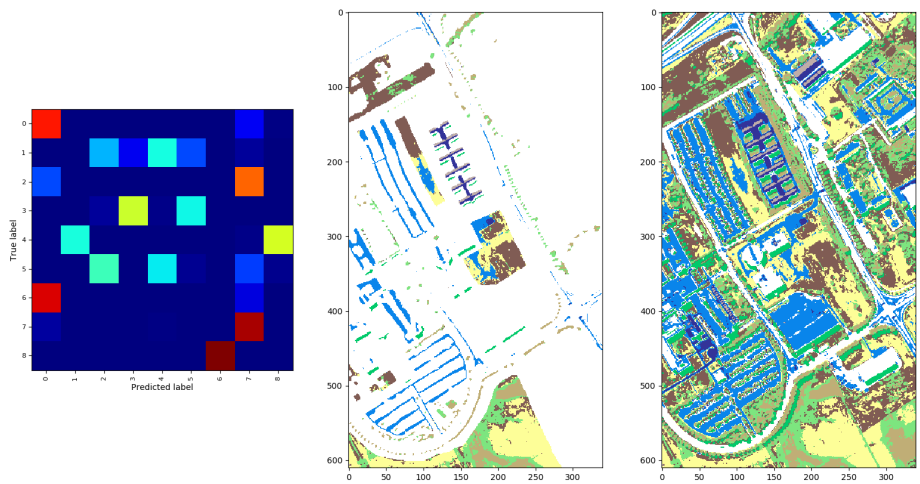

Figure 6: Pavia University *Yinyang* K-means classification results: the confusion matrix and the classification maps without background and with background.

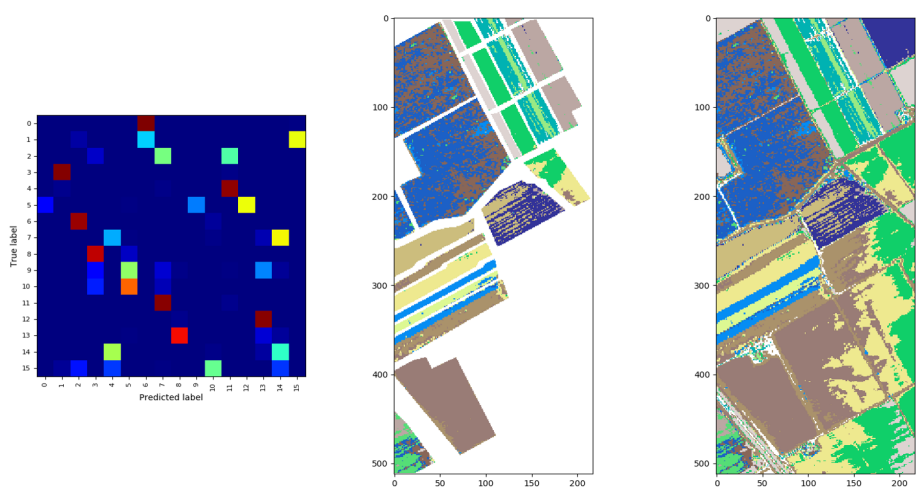

Figure 7: Salinas *Yinyang* K-means classification results: the confusion matrix and the classification maps without background and with background.

iterative version with K-means++ initialization. It is 2.41 times faster than the *Yinyang* cuda implementation with K-means++ initialization and 2.79 times faster than the same algorithm with random initialization. This is due to the small size of the image (only 145×145 pixels in only 16 groups), which is not enough to get the most out of GPU versions. In Fig. 5 we can see the classification results of *Yinyang* K-means. The confusion

matrix is a typical mechanism to evaluate unsupervised clustering methods, where in our representation warm colors indicate a high value and warm colors indicate a low value. The two classification maps show the clustering result without and with background pixels. As we can observe, the obtained result is reasonable for a K-means method, despite some noise at the borders of the classes.

For Pavia University dataset, the fastest implementation is also the iterative version and, among the two parallel GPU versions, the original LLoyd algorithm is faster than *Yinyang*. In this case we have more data than Indian Pines, but still enough complexity (only 9 centroids). In Fig. 6 we can observe the confusion matrix of the classification with *Yinyang*, whose results are better than in the Small Indian Pines. The classification maps reveal less noise at the borders.

For Salinas we have similar results: although we have a lot of data, the complexity is not enough (only 16 centroids). So, the iterative version is still the fastest. But we can see that *Yinyang* with K-means++ initialization is better than the original Lloyd algorithm parallelized in GPU: the differences between GPU versions are already starting to appear. In Fig. 7 we can see that the classification results with *Yinyang* are better than in the small Indian Pines and Pavia University images. Specifically, border pixels are better identified.

Finally, for big Indian Pines the fastest implementation is the iterative Lloyd algorithm (2678×614 with 58 centroids), but if we compare the two GPU versions, the *YinYang* is faster than the parallel GPU Lloyd. Since the classification results are similar to the ones already reported for the small Indian Pines image, we do not include these results for space considerations.

In summary, our results indicate that *YinYang* K-means works better than the CUDA version of Lloyd algorithm when more data needs to be processed, but higher complexity appears to be needed in order to improve the iterative version. So, we repeated the first experiment increasing the number of centroids to be calculated in a second experiment, which compares the parallel GPU implementation of *Yinyang* K-means with the same implementations of the original K-means algorithm, using a maximum number of centroids set to one hundred times the number of classes in each scene (i.e. 1600, 900, 1600 and 5800 centroids, respectively). Again, this is intended to increase the analysis complexity. The tolerance value is 0.001 in all cases. Again,we tested with random and K-means++ [10, 11] initializations. The obtained results are reported in Table 2.

For small Indian Pines dataset the fastest implementation is the *Yinyang* K-means with random initialization. It reaches a speed up of 7.071 over the iterative version. In the first experiment, with 16 classes the execution times were 0.441 and 0.511, at this time with 1600 centroids to calculate the execution times of *Yinyang* increase in just one second. However for iterative version, it needed 0.183-0.185 seconds and now it needs 6 seconds more. Also, for Pavia University scene *Yinyang* K-means is the fastest implementation, with K-means++ initialization. With the same number of pixels and 900 centroids, *Yinyang*

random	2022.694 (260.634)	1	463.165 (16.392)	5.132	113.459 (3.653)	20.952

Table 2: Average time executions (standard deviation) and speed-up for each implementation of K-means initialized with random centroids and K-means++.

K-means needs only two more seconds. The iterative version needs 12 or 14 seconds more, from the first experiment where it needed 0.23-0.22 seconds. For Salinas dataset we observe the same behavior: with 1600 centroids to calculate, the fastest one is *Yinyang* in GPU reaching a speedup of 7.678. For the big Indian Pines image, *Yinyang* K-means reaches a significant speedup: a 20.95. These results show that, the more the complexity of the analysis, the better the performance of the *Yinyang* GPU which is intended for big data problems involving not only massive data repositories but also complex analysis scenarios.

4 Conclusions and Future Lines

In this paper, we have proved a recent variant of K-means, the *Yinyang* K-means algorithm, to hyperspectral image analysis, in particular a parallel GPU implementation, which has been shown to obtain good processing results in hyperspectral image analysis when compared with other popular K-means implementations. Specifically, our experimental results show the effectiveness of the parallel GPU implementation of *Yinyang* K-means using four different hyperspectral scenes. The algorithm performs particularly effectively when we need to process big data and calculate a large set of centroids. The method not only improves as more data become available, but also with the increase of the complexity of the clusterization. On the other hand, the ranking results are in line with those obtained by any K-means algorithm. As future work, we are planning on using the *Yinyang* K-means in

 ISBN: 978-84-617-8694-7

conjunction with other techniques for hyperspectral image classification (e.g. supervised and semi-supervised techniques) with the aim of improving the obtained classification results.

Abstract

Security threats affecting electronics communications in the current world make necessary the encryption and authentication of every transaction. The increasing levels of security required are leading to an overload of transactions servers due to cryptographic tasks. In this paper a hardware-implemented co-processor for Elliptic Curve Cryptography operations for accelerating secure services is presented. The proposed co-processor can be implemented in last generations of FPGAs allowing to have in the same chip the secure web/database server and the cryptographic co-processor.

Key words: High-Performance cryptographic servers, security, FPGAs, hardware-software co-design.

1 Introduction

The number of electronic transactions is increasing every day in all aspects of daily life: financial, on-line shopping, domotics, automotive, an so on. Security of these transactions constitutes a challenge requiring more and more computing resources because of the number of devices connected, and the proliferation of cyber-criminals. In fact, the interchange of information trough computing networks must be secured by means of public-key cryptography combined with symmetric cryptosystems and secure hash functions. Some of the

ISBN: 978-84-617-8694-7

algorithms involved have high computing requirements, specially those related to public-key cryptography. Moreover, every year attackers have available more powerful computing systems, making some of these algorithms obsolete and/or insecure like the recent case of SHA1 [1]. In this context, servers with heavy loads of secure electronics transactions require high computing resources leading to high power consumption. Hardware accelerators [2, 3, 4] can be a solution for freeing the server from cryptographic computations, but they must be carefully designed for achieving an optimal trade-off between computation resources and area requirements. In fact, a powerful Elliptic Curve cryptographic co-processor can perform scalar-point operations in a microseconds, but probably the CPU of the server can not generate requests at those rates, thus maintaining the crypto-processor in idle state the majority of the time. Consequently, it would be more efficient to use more compact crypto-processors requiring less area, but implemented in smaller devices (and with less power consumption). In the other hand, new generations of Field Programmable Devices, such as Zynq from Xilinx [5] or Stratix 10 from Altera [6] include powerful microprocessors enabling the possibility of having a complete software server together with hardware-implemented co-processors in the same chip. Taking advantage of the co-design possibilities enabled by these devices, in this paper, three different implementations of an ECC (Elliptic Curve Cryptography) hardware co-processor co-existing with a CPU in the same Programmable Device are presented and compared in terms of performance an area requirements.

2 Background

Secure Sockets Layer (SSL) and Transport Layer Security (TLS) [7, 8] are the standard protocols widely used for exchanging securely information trough insecure channels such as the Internet. Within the algorithms included in the cipher-suites [8] of these protocols, those related to public-key exchange (RSA, ECDH) and authentication (RSA,DSA, ECDHA) are the most resources consuming. Hardware implementation of these algorithms would free the main server of being busy with heavy cryptographic operations and thus would allow better attending and managing the queues of clients asking for transactions. Among the algorithms dedicated to public-key exchange and authentication, those based on ECC are the most suitable for being implemented in hardware [9]. Moreover, ECC presents some other advantages with respect to RSA related to the key size [10, 11, 12, 13] (1024-bit RSA is equivalent to 163-bit ECC), thus minimizing communications between the main CPU and the cryptographic co-processor. Therefore, in this paper we propose using ECC defined over binary fields for implementing hardware co-processors for helping servers to attend massive secure transactions over computer networks.

 ISBN: 978-84-617-8694-7

2.1 Elliptic Curve Cryptography

An elliptic curve E defined over a finite field $GF(q)$ consists on a set of points $P = (x_p, y_p)$ where x_p and y_p are elements of $GF(q)$ satisfying the Weirstrass equation [15], together with the point at infinite, O. The curves are defined by means of two coefficients $a \in GF(q)$ and $b \in GF(q)$, named the coefficients of E. IF q is a power of 2, must be $b \neq 0$ in $GF(2^m)$, and the points $P = (x_p, y_p)$ over E (except O), satisfy the equation:

$$y_p{}^3 + x_p y_p = x_p{}^3 + a x_p{}^2 + b \tag{1}$$

If $q = 2^m$, the field elements can be represented using polynomial bases, by choosing an irreducible polynomial $f(t)$. In this case, an element a of the field is represented using the bit string:

$$a = (a_{m-1}...a_2 a_1 a_0) \tag{2}$$

corresponding to the polynomial

$$a(t) = a_{m-1}t^{m-1} + ...a_2 t^2 + a_1 t + a_0 \tag{3}$$

where a_i are elements of $GF(2)$. One of the characteristics enabling the use of elliptic curves in cryptography is the possibility of defining an internal operation into the curve, named elliptic addition. Geometrically, the sum of two points P, Q is given by a point $R = P + Q$ with the property that P, Q, and $-R$ lies on the same straight line. From the full elliptic addition, the scalar product of a point P of the curve E and a natural n is defined as:

$$nP = P + .^n. + P \tag{4}$$

This operation, that is the additive equivalent to the exponentiation in multiplicative abelian groups, constitutes the base of the cryptography using elliptic curves [10].

Given a curve E defined over a field $GF(q)$, r a positive prime integer dividing the number of points on E, $\#E$, and a curve point G of order r (generator of a subgroup of order r), an EC key pair can be defined. Specifically, taking $s \in [1, r-1]$ as an EC private key, and $W = sG$ as the associated EC public key, a public key cryptosystem for interchanging a secret value can be established. In fact, if two communicants A and B generate their corresponding EC key pairs $(s_A, W_A), (s_B, W_B)$, party A can compute the secret value $P = s_A \cdot W_B$ using the public key of B. Then, B can recover the secret value from the public key of A, making $P = s_B \cdot W_A$ because:

$$P = s_A \cdot W_B = s_A \cdot s_B \cdot G = s_B \cdot s_A \cdot G = s_B \cdot W_A \tag{5}$$

This is the basic principle for public key cryptography using EC, and the conditions to be met by the parameters involved and the details of the different primitives can be found in [10, 14, 15, 16].

 ISBN: 978-84-617-8694-7

2.2 Selection of the cipher-suite and ECC curves

As SSL is considered obsolete and insecure [17], we have selected the following cipher-suites defined in TLS 1.2 [8] and based in ECC[18]:

- TLS_ECDH_ECDSA_WITH_NULL_SHA
- TLS_ECDH_ECDSA_WITH_RC4_128_SHA
- TLS_ECDH_ECDSA_WITH_3DES_EDE_CBC_SHA
- TLS_ECDH_ECDSA_WITH_AES_128_CBC_SHA
- TLS_ECDH_ECDSA_WITH_AES_256_CBC_SHA
- TLS_ECDHE_ECDSA_WITH_NULL_SHA
- TLS_ECDHE_ECDSA_WITH_RC4_128_SHA
- TLS_ECDHE_ECDSA_WITH_3DES_EDE_CBC_SHA
- TLS_ECDHE_ECDSA_WITH_AES_128_CBC_SHA
- TLS_ECDHE_ECDSA_WITH_AES_256_CBC_SHA

When using these cipher-suites, public-key exchange is performed using ECDH (ECC Diffie-Hellman) or ECDHE (Ephemeral ECDH) [19], and digital signature is performed by means of ECDSA [20, 21]. In both cases, ECC scalar-point operations are required. Statistically, the two most used curves in TLS 1.2 [19] are:

- secp256r1 (NIST P-256)
- sect233r1 (NIST B-233)

The first one is defined over a $GF(p)$ field, while sect233r1 is defined over a binary field ($GF(2^{233})$), thus being more affordable in terms of resources and performance for a hardware implementation. Therefore, it will be the standard curve used in our design.

2.3 ECC domain parameters

As pointed out in previous subsection, the NIST B-233 [21] curve has been selected for the hardware implementation of the ECC co-processor. Thus, the EC domain parameters will be the following:

- $m = 233$

 ISBN: 978-84-617-8694-7

- $f = t^{233} + t^{74} + 1$
  (reduction polynomial for the field)
- $a = 1$
- b= 066 647EDE6C 332C7F8C 0923BB58 213B333B 20E9CE42 81FE115F 7D8F90AD
- r = 6901746346790563787434755862277025555839812737345013555379383634485463
  (number of elements of the subgroup)
- $h = 2$ (cofactor)
- G_x= 0FA C9DFCBAC 8313BB21 39F1BB75 5FEF65BC 391F8B36 F8F8EB73 71FD558B
- G_y= 100 6A08A419 03350678 E58528BE BF8A0BEF F867A7CA 36716F7E 01F81052
  (base point)

3 Co-processor design

The processor design depends on the algorithm used for computing the scalar-point operation. Montgomery-Ladder algorithm [14], presents some advantages for hardware (and software) implementations because it avoids inversion field operation in the main loop when projective or mixed coordinates are used. In this case, inversion only is required for coordinates conversion, and the recovering of the y coordinate (the algorithm operates only over the x coordinate) [14].

If binary representation of scalar k is $k = k_{m-1}2^{m-1} + ...k_2 2^2 + k_1 2 + k_0$, Algorithm 1 provides the scalar-point product kP in projective coordinates:

Algorithm 1 Montgomery ladder over projective coordinates

Require: k, P
Ensure: kP
1: $P_1 \leftarrow P$ *and* $P_2 \leftarrow 2P$
2: **for** $i = m - 2$ **downto** 0 **do**
3: **if** $k_i = 0$ **then**
4: $P_1 \leftarrow 2P_1$ *and* $P_2 \leftarrow P_1 + P_2$
5: **else**
6: $P_1 \leftarrow P_1 + P_2$ *and* $P_2 \leftarrow 2P_1$
7: **end if**
8: **end for**
9: **return** P_1

 ISBN: 978-84-617-8694-7

Operations required in *Algorithm 1* are point addition and doubling. When using projective coordinates [14], these operations results in field multiplications, additions and squarings. Field addition and squarings are combinational operations, and inversion is only required in coordinates conversion, resulting an execution time of [22]:

$$T \approx 6 \times m \times T_{mul} + 3 \times T_{inv} + 2 \times T_{mul} \tag{6}$$

Therefore, the execution time mainly depends of T_{mul}, the time required for completing the field-multiplication operation. In the next subsection, implementation of field-multiplier is analyzed.

3.1 Field multiplication

As pointed out in equation (6), the design of the multiplier determines the total execution time of the ECC scalar-point operation. There are several options for field-multiplier implementation, that can be grouped into two main sets:

- **Combinational multipliers**. These are multipliers based on Karatsuba-Ofman algorithm [23], and allow completing the field multiplication in only one clock cycle. As a drawback, these multipliers have high area requirements.
- **Sequential multipliers**. These are based on Digit Serial (DS) operations [22], with lower area needs, but requiring more number of clock cycles for completing the operation.

Performance of DS multipliers is based on operating at high clock frequencies, but this generates high power consumption. In the other hand, area requirements of Karatsuba-Ofman (KOA) multipliers are immoderate. In this work, we propose a mixed solution by means of introducing registers into an improvement of the KOA multiplier, named NOKOA (Non-Overlapping KOA) multiplier [24]. KOA and NOKOA multipliers are defined recursively: at step j the multiplier of 2^j inputs is built using three 2^{j-1} inputs multipliers. This structure allows saving area with respect to classical school multipliers, but generate higher delays. In order to improve delay, in the first stages (low values of j), classical school multipliers can be used, resulting the known as hybrid-KOA [25] (and hybrid-NOKOA) multipliers. It is possible to improve area figures of NOKOA multipliers reusing one multiplier at the last stage by means of registering the partial results. In this way, NOKOA3C multiplier is obtained allowing area savings around 50% with respect to NOKOA, at expenses of requiring 3 clock cycles for completing multiplication. If this process is repeated in the second stage of recursion, the NOKOA9C multiplier is obtained, requiring 9 clock cycles, with a 75% of area reduction.

Table 1 shows the implementation results for DS (Digit-Serial) multipliers with 1-bit, 8-bit, 24-bit and 39-bit digits from [22, 26] and NOKOA, NOKOA3C, and NOKOA9C

 ISBN: 978-84-617-8694-7

multipliers over the binary field $GF(2^{233})$ on a Virtex-5 device (xc5vlx110-3ff1760). This device has been selected for comparison purposes with DS multipliers proposed in [26], and all implementations were performed by using ISE 14.2.

Results shown in Table 1 have been obtained at four different operating frequencies: 25MHz, 50MHz, 100MHz, and the maximum operating frequency supported by the design. As can be observed, multipliers based on NOKOA algorithm are, in general, more efficient than DS multipliers. In fact, if we compare similar-size multipliers like DS_g24 and NOKOA9C (although NOKOA9C has around 30% less area than DS_g24), NOKOA9C achieves the final result in less time than DS_g24. Only when operating at the maximum operation frequency, DS_g24 presents better results (27ns) than NOKOA9C (42ns). However, if we take into account that dynamic power consumption is proportional to the clock frequency, DS_g24 requires more energy for completing the field multiplication than NOKOA9C.

In the case of NOKOA3C and DS_g39, (they have similar area), NOKOA3C always presents better results. Regarding NOKOA, it presents the best results at expenses on more area requirements. Therefore, the best trade-off taking into account area requirements, performance and total time for completing the field operation, is shown by NOKOA3C.

3.2 Field inversion/division

Field inversion is the most costly operation in binary finite fields, and the different proposals for their implementation are based on two mathematical results

1. Extended Euclides Algorithm (EEA). There exist efficient implementations like [27, 28], allowing the inversion in m clock cycles, or digit-serial implementations like [22], reducing the number of clock cycles at expenses of a higher area requirements.

2. Little Fermat Theorem (LTF). The Little Fermat Theorem establishes that the multiplicative inverse in a finite field can be obtained from:

$$p^{-1} = p^{2^m-2} = (p^{2^{m-1}-1})^2 \tag{7}$$

   and the standard [10] proposes an algorithm applying successive squarings, completing the inversion in m clock cycles. Another possibility is the use of the Itoh-Tsujii Algorithm (ITA) [29], optimizing the number of steps for the exponentiation calculus. In [30], ITA implementations minimizing the number of clock cycles are presented.

As Montogomery ladder algorithm requires inversion only when converting coordinates (see equation 6), we will use DS division with 1-bit digit size [22] for saving area resources.

3.3 Design of the ECC scalar-point Unit

Using the blocks described in previous subsections for field operations, Figure 1 shows the block diagram corresponding to the proposed ECC scalar-point unit.

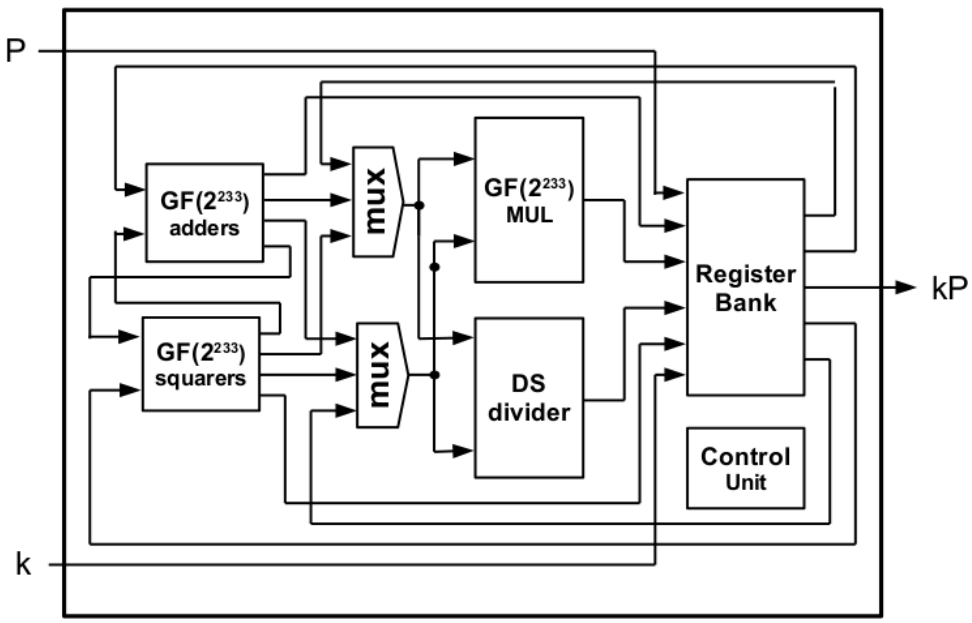

Figure 1: ECC Scalar-point Unit for B-233 curve

Table 2 shows implementation results corresponding to the three proposed co-processors, called ECC_B-233_NOKOA, ECC_B-233_NOKOA3C, and ECC_B-233_NOKOA9C. They have been implemented using Vivado 2016.4 over a Zynq [5] ZC102 device (Xc7z020clg484-1), with a target operating frequency of 50MHz for a contained power consumption.

The target device has around 53200 LUTs, thus it is possible to implement several

Table 2: ECC_B-233 implementation results using NOKOA, NOKOA3C and NOKOA9C multipliers

Design	# LUTS	#cycles	Freq. (MHz)	Total time
ECC_B-233_NOKOA	16320	2813	50	56.26 us
ECC_B-233_NOKOA3C	4891	5612	50	112.24 us
ECC_B-233_NOKOA9C	2366	14013	50	280.26 us

 ISBN: 978-84-617-8694-7

co-processors in the same device and take advantage or parallelism to achieve higher performance, if required. The selection of the co-processor to use will depend on the performance needed, the area available for implementing the co-processor (it could be necessary to include other hardware accelerators), and power consumption restrictions. Also, higher operating frequencies can be used for improving performance at expenses of increasing power consumption.

4 Conclusion

An ECC hardware-implemented co-processor has been presented. The co-processor has been implemented over a Zynq device, which includes an ARM Cortex A9 micro-processor, together with 53200 LUTs for hardware implementations. The designed co-processor, which shows contained area requirements, fits into the device, thus allowing to implement a complete high-performance cryptographic server together with web/database services into an unique chip.

Abstract

Indicators such as the arithmetic mean and the variance have a construction based on the additive character of the real numbers field. Here we explore the analogues of some measures of central tendency and dispersion of data, but in the context of the real positive field, the base framework of the multiplicative (bigeometric) calculus.

Key words: statistics, geometric mean, bigeometric calculus
MSC 2000: 92B05

1 Introduction

In statistics the most known central tendency for a set of numerical data is the arithmetic mean, as we know, is constructed by adding the products of these data by certain weights. Therefore, such data is in a structure in which addition and multiplication operations exist and also have certain minimum properties (eg, an ordered and complete field), so a minimal context is necessary. In this work, we will use the fact that the real numbers set has, in its interior, an isomorphic image of itselves to derive a series of statistical indicators. Mainly, to asociate those with aritmethic origin with the geometric ones.

Let us begin by pointing out that: **the arithmetic mean and the geometric mean are isomorphic measures of central tendency**. That is to say, these can be thought like ways to measure the same, except that in equivalent contexts.

Indeed, the exponential function $\exp :]-\infty, +\infty[\to]0, +\infty[$ establishes an isomorphism between the complete ordered field of the real numbers $(\Re, +, \cdot)$ and its image the positive

 ISBN: 978-84-617-8694-7

reales numbers $(\Re^+, \cdot, *)$, where $\Re^+ =]0, \infty[$ and $*$ defines the operation $a * b = a^{\ln(b)}$, for any a, $b \in \Re^+$. Regarding the implications (theoretical and application) associated with the construction of the proportional calculation from the positive real field, see [1, 2, 3]. The main intention of the present work is to introduce some basic elements that allow to pass from an additive vision of the statistic to one of multiplicative type or, that we could also call, of proportional type.

This small work is organized as follows: In section 2 the arithmetic and geometric mean is linked. In section 3, the geometric version of a measure of data dispersion is constructed from its arithmetic analogue. Finally, section 4 formalizes and generalizes a series of types of averages (isomorphic to each other) within the real field.

2 Geometric mean

Notice that, given $a, b \in \Re^+$, obviously we have

$$a \cdot b = \exp\{\ln(a) + \ln(b)\},$$

and then

$$\sqrt{a \cdot b} = \exp\left\{\frac{\ln(a) + \ln(b)}{2}\right\}$$

In other words, the isomorphism $\exp : (\Re, +, \cdot) \to (\Re^+, \cdot, +)$ translates the mean (*arithmetic*) M_A with respect to the first operation (the addition) of the framework $(\Re, +, \cdot)$, in the mean (*geometric*) M_G with respect to the first operation (multiplication) of the framework $(\Re^+, \cdot, *)$, by the identity:

$$M_G(a, b) = \exp\{M_A(\ln(a), \ln(b))\}.$$

In a reverse reading, the function $\ln :]0, +\infty[\to]-\infty, +\infty[$, transposes the geometric mean of $(\Re^+, \cdot, *)$, in the arithmetic mean of $(\Re, +, \cdot)$, by the formula:

$$M_A(a, b) = \frac{a + b}{2} = \ln\{\sqrt{\exp(a) \cdot \exp(b)}\} = \ln\{M_G(e^a, e^b)\}.$$

In spite of the equivalence of these measures, as the isomorphism is inward, that is, towards the field of real positive, a part of the totality of the real numbers, there is also a gain. This allows us to see the arithmetic mean and the geometric mean as measures based on the first and second operation del campo respectively.

Moreover, since the weighted arithmetic average for a set of $\{x_1, \cdots, x_n\}$ of real numbers and $\{\alpha_1, \cdots, \alpha_n\}$, $0 \leq \alpha_i \leq 1$, $\alpha_1 + \cdots + \alpha_n = 1$, as weights is given by

$$M_A^*(\{x_i\}, \{\alpha_i\}) = \alpha_1 x_1 + \cdots + \alpha_n x_n,$$

ISBN: 978-84-617-8694-7

using isomorphism the corresponding weighted geometric mean for a set of positive real number $\{y_1, \cdots, y_n\}$ is given by:

$$M_G^*(\{y_i\}, \{\beta_i\}) = \exp(M_A^*(\{\ln(y_i)\}, \{\ln(\beta_i)\})),$$

Expression that is equal to $\exp\{\ln(\beta_1)\ln(y_1) + \cdots + \ln(\beta_n)\ln(y_n)\}$ and which can also be written as

$$y_1^{\ln(\beta_1)} \cdots y_n^{\ln(\beta_n)}.$$

Finally, we have

$$M_G^*(\{y_i\}, \{\beta_i\}) = (\beta_1 * y_1) \cdots (\beta_n * y_n) = y_1^{\alpha_1} \cdots y_n^{\alpha_n},$$

where the set of $\{\beta_i\}$, $\alpha_i = \beta_i$, are subject to the following conditions: $1 \leq \beta_i \leq e$ and $\beta_1 \cdots \beta_n = e$.

3 Geometric dispersion

Recall that if $\{x_1, \cdots, x_n\}$ is a certain set of data, then the average arithmetic deviation that the data moves away from a value y is given by the expression:

$$V_A(y, \{x_i\}) = \frac{1}{n}\sum_{i=1}^{n} |y - x_i|.$$

The absolute value function $|\cdot| : \Re \to \Re^+$ allows us to convert the field $(\Re, +, \cdot)$ in a metric space. Note that, the isomorphic field $(\Re^+, \cdot, *)$ is a *relative metric space* now performed by the so-called *relative value* defined by $[\,\cdot\,] : \Re^+ \to]1, \infty[$ with

$$[a] = \begin{cases} a & \text{if} \quad a \leq 1, \\ a^{-1} & \text{if} \quad a < 1. \end{cases}$$

The analogous *geometric deviation* $V_G(\cdot, \cdot)$ should be given by:

$$V_G(y, x_i) = \exp\{V_A(\ln(y), \{\ln(x_i)\})\}.$$

This is,

$$V_G(y, \{x_i\}) = \exp\left\{\frac{1}{n}\sum_{i=1}^{n} |\ln(y) - \ln(x_i)|\right\} = \exp\sum_{i=1}^{n}\left|\ln\{(y/x_i)^{1/n}\}\right|,$$

since $|\ln(u)| = \ln([u])$, we have

$$V_G(y, \{x_i\}) = \exp\left\{\sum_{i=1}^{n} \ln[(y/x_i)^{1/n}]\right\} = \left\{\prod_{i=1}^{n}\left[\frac{y}{x_i}\right]\right\}^{1/n}.$$

With no further effort we have reciprocally:

$$V_A(y, \{x_i\}) = \ln\{V_G(e^y, \{e^{x_i}\})\}.$$

 ISBN: 978-84-617-8694-7

4 Generalization and formalism

Inductively we introduce the sequence:

$$e_{k+1} = \exp\{e_k\}, \quad \text{with} \quad e_0 = 0.$$

Notice that, for each $k \geq 1$, e_k is the neutral element of the operation $\oplus_k$ defined on the interval $I_k =]e_{k-1}, \infty[$ recursively by

$$a \oplus_{k+1} b = \exp\{\ln(a) \oplus_k \ln(b)\},$$

where $\oplus_0$ is the usual sum.

With this operation the family of structures $\{(I_k, \oplus_k, \oplus_{k+1})\}_{k\geq 1}$ is a sequence of ordered and complete fields, therefore, all isomorphic to each other, *i.e.* isomorphic to $(\Re, +, \cdot)$, by means of the exponential function.

The interesting thing is that, as I_k is a subset of $\Re$, $k \geq 0$, with $e_{-1} = -\infty$, all the concepts derived by isomorphism in any of these fields have a reading in the basal field $(\Re, +, \cdot)$, which also, from now on we can denote by $(I_0, \oplus_0, \oplus_1)$.

Definition: The *k-th average*, $k \geq 0$, among the numbers $x_1, \cdots, x_n$ of I_k, is defined by:

$$M_k(x_i) = (x_1 \oplus_k \cdots \oplus_k x_n) \ominus_{k+1} (e_{k+1} \oplus_k \cdots \oplus_k e_{k+1}), \tag{1}$$

where $\ominus_j$ is the inverse operation of $\oplus_j$, which is also defined recursively by means of $a \ominus_{k+1} b$ equals to $\exp\{\ln(a) \ominus_k \ln(b)\}$, $\ominus_0$ the usual subtraction.

Remark: Some examples to illustrate, using only two elements, are :

- $M_0(a, b) = (a \oplus_0 b) \ominus_1 (e_1 \oplus_0 e_1) = (a + b)/(1 + 1) = M_A(a, b)$.
- $M_1(a, b) = (a \oplus_1 b) \ominus_2 (e_2 \oplus_1 e_2) = (a \cdot b) \ominus_2 (e \cdot e)$. Then, continuing with the calculations $M_1(a, b) = \exp\{\ln(ab) \ominus_1 \ln(e^2)\}$, which is equal to $\exp\{\ln(ab)/2\}$, this is, a $(ab)^{1/2}$, *i.e.*, $M_G(a, b)$.

Theorem: *Given a set* $\{x_i\} \subset I_{k+1}$, *some* $k \geq 0$, *then*

- $M_{k+1}(\{x_i\})) = \exp(M_k(\{\ln(x)\}))$, *and*
- $M_{k+1}(\{x_i\})) \leq M_k(\{x_i\})$.

Stabilization of switched systems with state-dependent switching noise

C. Pérez[1], F. Benítez[1] and J. B. García-Gutiérrez[1]

[1] *Department of Mathematics, University of Cádiz*

emails: carmen.perez@uca.es, quico.benitez@uca.es,
juanbosco.garciagutierrez@alum.uca.es

Abstract

This paper studies the stabilization of second-order switched linear systems with state-dependent switching noise. Based on the method of stabilization known for this kind of switched systems without noise, we define some regions in the plane where the noise can be produced and the stabilization is also assured. Moreover, we give a procedure for determining completely these regions. Finally, in order to illustrate the results, several numerical examples are presented.

Key words: switched systems, switching noise, robust stabilization, time-delay, Lyapunov function

1 Introduction

A switched system is a kind of hybrid system that consists of several subsystems and a switching law determining at any time instant which subsystem is active. In recent years, the study of switched systems has received growing attention in Control Theory and its applications ([8], [9], [14]). They have been studied from several points of view such as the controllability ([17]), reachability ([14], [18], or stability ([15], [10]).

The problem of stability has been studied from several viewpoints ([8], [10]). One of these viewpoints is the problem of constructing a switching law that makes the switched system asymptotically stable. It is important to note that in this problem the only control action is the switching law. In the literature, there are several two approaches to stabilization for switched systems. In papers such as [7], [16] or [4] Lyapunov theory is employed to construct switching laws for a class of switched systems totally composed of unstable subsystems.

 ISBN: 978-84-617-8694-7

Another approach to this problem is based on detailed analysis of the vector field. For second-order systems, some necessary and sufficient conditions for stability/stabilizability have been obtained in [12] and [19] through analysis on the structure of the vector field. In [19] the problem of stabilizing two second-order linear systems is solved; i.e., a method to define switching laws that decide when a switched system is stabilizable is given. Also, recently, Cong [3] characterises the stability of these switched linear systems by classifying the switching laws into only two types.

A common assumption in the above results is that the detection of the switching signal is instant. However, in many real switched systems, the switchings cannot be instant, i.e., the changing of the switching law cannot be detected instantly, but only after a time period. For this reason, it is important to study the situation when switching noise is produced.

Based on the method of stabilization in [19] where the switchings are produced in rays, we define some regions in the plane where the switchings can be produced and the stabilization is also assured. With these results, we study the problem of stabilization with state-dependent switching noise. Related to this problem, in [5] and [6] the authors present definitions and results of these stochastic systems.

The remainder of this paper is organized as follows. In Section 2 some definitions and some results are included. In Section 3 we present the results that assure the regions of stability. In Section 4 we present the main result of this work. Several numerical examples are given in Section 4 in order to illustrate the results. Finally, the conclusions are provided in Section 5.

2 Preliminaries

Consider a switched linear system

$$\dot{x}(t) = A_{\sigma(t)}x(t), \tag{1}$$

where A_i is a 2×2 matrix, for $i = 1, 2$, $x \in \mathbb{R}^2$, and $\sigma : [0, \infty) \longrightarrow \{1, 2\}$ is a piecewise constant function called *switching law*. Such a function σ has a finite number of discontinuities, which we call *switching times*, on every bounded time interval and takes a constant value on every interval between two consecutive switching times. The role of σ is to indicate the active subsystem at each time instant t.

Before presenting the method of stabilization we need this definition:

Definition 1 *Let r_1 and r_2 be two rays starting from the origin. The set given by*

$$\{x \in \mathbb{R}^2 : x = \mu z_1 + (1 - \mu)z_2,\ z_1 \in r_1,\ z_2 \in r_2,\ 0 \leq \mu \leq 1\}$$

will be called the cone delimited by r_1 and r_2 and denoted by $\mathrm{C}(0, r_1, r_2)$.

 ISBN: 978-84-617-8694-7

In [19] the stabilizing switching law is given in the following form:

$$\sigma(t) = \delta(x(t)) \tag{2}$$

where $\delta : \mathbb{R}^2 \to \{1, 2\}$. Moreover, the switchings are produced in two rays r_1 and r_2, i.e., when the trajectory intersects these rays, we switch. These rays are always given by the equation $\det(A_1x, A_2x) = 0$.

By the results in [19] and [3], in [13] only two kinds of switching laws are used to study the stabilization: type I or type II. Under switching laws of type I, the solution rotates around the origin clockwise or counterclockwise direction (spinning switching in [3]). On the contrary, under switching laws of type II, the trajectories of each subsystem are of opposite directions, thus, the solution remains in a cone (chattering switching in [3]).

The switching laws of type I are defined as follows:

- $\sigma(t) = 1$ (resp. $\sigma(t) = 2$) when $x(t) \in \{x \in \mathbb{R}^2 : \det(A_1x, A_2x) > 0\}$ and each subsystem at $x(t)$ is of the clockwise (resp. counterclockwise) direction.

- $\sigma(t) = 2$ (resp. $\sigma(t) = 1$) when $x(t) \in \{x \in \mathbb{R}^2 : \det(A_1x, A_2x) < 0\}$ and each subsystem at $x(t)$ is of the clockwise (resp. counterclockwise) direction.

For switching laws of type II, we need to suppose that there exists a cone where the subsystems are of opposite directions and the set $\{x \in \mathbb{R}^2 : \det(A_1x, A_2x) > 0\}$ or $\{x \in \mathbb{R}^2 : \det(A_1x, A_2x) < 0\}$ is contained in this cone. Hence, if S_1 is a cone where A_1 is of clockwise (resp. counterclockwise) direction, A_2 is of counterclockwise (resp. clockwise) direction and $\{x \in \mathbb{R}^2 : \det(A_1x, A_2x) > 0\}$ (resp. $\{x \in \mathbb{R}^2 : \det(A_1x, A_2x) < 0\}$) is contained in this set, the switchings under a switching law of type II are produced when the solution intersects the rays $\det(A_1x, A_2x) = 0$.

In both cases (type I or II), the switchings are produced in rays. The problem of this is that the stabilization is not assured if the switchings are not produced in these rays. In [13], the problem of time-delay in detection of switching law is studied. From this study it is deduced the following result:

Theorem 1 *[13] Let A_1 and A_2 be two unstable 2×2 matrices. Suppose that for the switched system (1) the switching laws of type I (resp. II) are stabilizing. Then there exists $T_0 \in (0, \overline{T})$ such that the switched system under the switching law of type I (resp. II) and with time-delay equal to T is*

- *stable if $T \in [0, T_0)$.*

- *non stable if $T \in (T_0, \overline{T}]$.*

 ISBN: 978-84-617-8694-7

From the proof of this result, it is deduced that for time-delay T_0, a periodic solution is obtained. Moreover, we obtain two rays, denoted by s_1 and s_2, where the switchings for this time-delay are produced.

Under this notation, we prove in the following section that when the switchings from A_1 to A_2 are produced in $\mathrm{C}(0, r_1, s_1)$ and the switchings from A_2 to A_1 are produced in $\mathrm{C}(0, r_2, s_2)$, the switched system remains stable.

In order to prove this, we need to introduce a concept studied in [11]. This concept will be employed in the next section.

Definition 2 *[11] A function $H_A : \mathbb{R}^2 \to \mathbb{R}^+$ is a generalized first integral of $\dot{x} = Ax$ if $H_A(x)$ is not constant on any open subset of $\mathbb{R}^2$, $H_A(x(t))$ is piecewise constant along the trajectories of $\dot{x} = Ax$, and attains a finite set of values for all $t \in [0, T]$ (T finite).*

For a system $\dot{x} = Ax$ with A a 2×2 real matrix, a generalized first integral is constructed in [11] by considering two cases. In the first, the eigenvalue of A are complex and in the second, they are real.

The relation between the system $\dot{x} = Ax$ and its generalized first integral is the following $H(x(t)) = H(x(0))$ along the trajectories of $\dot{x} = Ax$, i.e., $x(t)$ coincides with the contour $H_A(x(t)) = H_A(x_0)$ if x is the solution of $\dot{x} = Ax$ with $x(0) = x_0$ (see [11] for more details). Therefore, when H is differentiable, $\frac{dH(x(t))}{dt} = \nabla H(x(t))Ax(t) = 0$.

3 Existence of the regions of stabilization

In this section we present the results under which the existence of the regions of stabilization is assured.

Theorem 2 *Let A_1 and A_2 be two unstable 2×2 matrices. Suppose that for the switched system (1) the switching laws of type I (resp. II) are stabilizing. Then there exists two cones C_1 and C_2 such that the switched system is stable under a switching law σ if we switch from A_1 to A_2 when $x(t) \in \mathrm{C}_1$ and we switch from A_2 to A_1 when $x(t) \in \mathrm{C}_2$.*

PROOF. Firstly, we suppose that the switching law of type I is stabilizing and the solution under this switching law rotates around the origin in clockwise direction. Under the nota-tion in the previous section, we define $\mathrm{C}_1 = \mathrm{C}(0, r_1, s_1)$ and $\mathrm{C}_2 = \mathrm{C}(0, r_2, s_2)$ (see Figure 1).

Now, if σ is a switching law under which the switchings from A_1 to A_2 are produced in C_1 and the switchings from A_2 to A_1 are produced in C_2, we have to prove that the switched system for σ is stable. In order to do that, we define a Lyapunov function for this system.

 ISBN: 978-84-617-8694-7

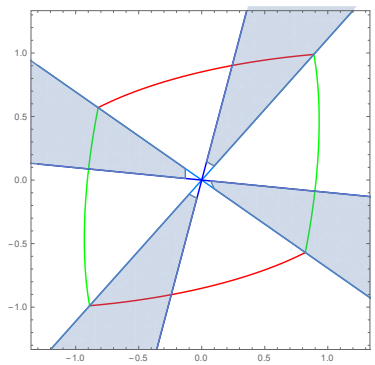

Figure 1: The cones $\mathrm{C}_1 = \mathrm{C}(0, r_1, s_1)$ and $\mathrm{C}_2 = \mathrm{C}(0, r_2, s_2)$ and the periodic solution for T_0.

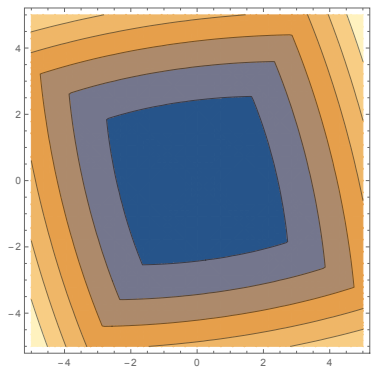

Figure 2: The level curves of V defined for a system with switching law of type I.

The Lyapunov function is defined as follows:

$$V(x) = \begin{cases} H_1(x) & \text{if} \quad x^T P x \leq 0 \\ kH_2(x) & \text{if} \quad x^T P x < 0 \end{cases}$$

where H_i is the first integral of A_i for $i = 1, 2$, P is the matrix that defines the quadratic form given by s_1 and s_2, and k is a positive constant defined in order to V be continuous (see Figure 2 V tipoI).

It is easy to prove that $V(x) \geq 0$ for any $x \in \mathbb{R}^2$ and, from definition, V is continuous. However, V is non differentiable at x with $x^T P x = 0$. For this reason, in order to prove the stability, we use the upper right Dini derivative for V, that is,

$$D^+ V(x(t)) = \limsup_{\tau \to 0^+} \frac{V(x(t+\tau)) - V(x(t))}{\tau}$$

 ISBN: 978-84-617-8694-7

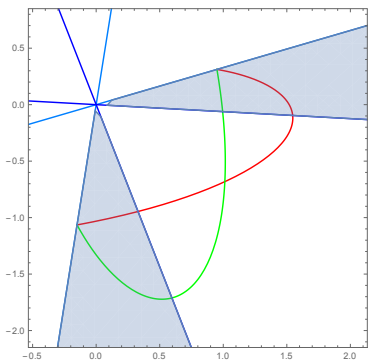

Figure 3: The cones $\mathrm{C}_2 = \mathrm{C}(0, s_1, r_1)$ and $\mathrm{C}_1 = \mathrm{C}(0, r_2, s_2)$ and the periodic solution for T_0.

It is proved (see [1] or [2] for more details) that if x is the solution of (1) under the switching law σ and $D^+V(x(t)) \leq 0$ for each $t \geq 0$, the system is stable.

Therefore, we only have to prove that $D^+V(x(t)) \leq 0$ for each $t \geq 0$. Let consider several cases for $x(t)$. If $x(t) \in \mathrm{C}(0, s_1, r_2) \cup r_2$, then, by the definition of σ, the solution of the system is given by A_1. Therefore, as $x(t)^T P x(t) > 0$, $D^+V(x(t)) = \nabla V(x(t))\dot{x}(t) = \nabla H_1(x(t))A_1 x(t) = 0$ by the definition of H_1. Analogously, it is proved that if $x(t) \in \mathrm{C}(0, s_2, r_1) \cup r_1$, then, $D^+V(x(t)) = 0$.

If $x(t) \in \mathrm{C}(0, r_2, s_2)$, then, by the definition of σ, the solution of the system can be given by A_1 or A_2. If the system is given by A_1, as $x(t)^T P x(t) > 0$, $D^+V(x(t)) = \nabla V(x(t))\dot{x}(t) = \nabla H_1(x(t))A_1 x(t) = 0$. If, on the contrary, the system is given by A_2, as $x(t)^T P x(t) > 0$, $D^+V(x(t)) = \nabla V(x(t))\dot{x}(t) = \nabla H_1(x(t))A_2 x(t)$. But, we know that, in this region, $\det(A_1 x(t), A_2 x(t)) > 0$, thus, $D^+V(x(t)) = \nabla H_1(x(t))A_2 x(t) < 0$. Now, if $x(t) \in \mathrm{C}(0, r_1, s_1)$, it can be proved that $D^+V(x(t)) < 0$.

If $x(t) \in s_2$, by the definition of σ, the solution of the system is given by A_2 and, $D^+V(x(t)) = \nabla H_2(x(t))A_2 x(t) = 0$. Similarly, if $x(t) \in s_1$, it is proved that $D^+V(x(t)) = \nabla H_1(x(t))A_1 x(t) = 0$. And the result is proved for switching laws of type I.

Now, we suppose that the switching law of type II is stabilizing. And we define $\mathrm{C}_2 = \mathrm{C}(0, s_1, r_1)$ and $\mathrm{C}_1 = \mathrm{C}(0, r_2, s_2)$ (see Figure 3). In this case, given a swiching law σ such that the switchings from A_1 to A_2 are produced in C_1 and the switchings from A_2 to A_1 are produced in C_2, we have to prove that (1) under this switching law is stable.

Again, we define a function V and we show that is a Lyapunov function for this system.

$$V(x) = \begin{cases} H_1(x) & \text{if} \quad x \in \mathrm{C}(0, r_1, r_2) \\ kH_2(x) & \text{if} \quad x \in \mathrm{C}(0, s_1, r_1) \cup r_1 \\ lH_2(x) & \text{if} \quad x \in \mathrm{C}(0, r_2, s_2) \cup r_2 \end{cases}$$

 ISBN: 978-84-617-8694-7

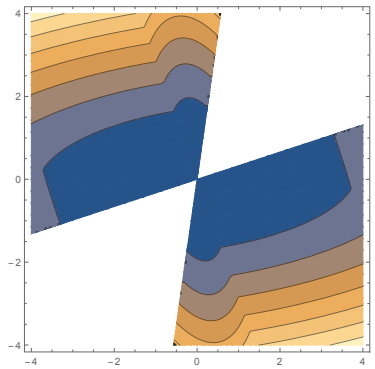

Figure 4: The level curves of V defined for a system with switching law of type II.

where H_i is the first integral of A_i for $i = 1, 2$ and k and l are positive constants defined in order to V be continuous.

It is important to note that V, in this case, is only defined in the region $\mathrm{C}(0, s_1, s_2)$ but, by definition of σ, the solution of the system is contained in this region. (see Figure 4).

Moreover, in this case, V is differentiable because at $x \in r_1$ or $x \in r_2$, A_1x and A_2x are parallel. Thus, we can consider the derivative of $V(x(t))$. If we prove that is non positive, we obtain that the system is stable.

If $x(t) \in \mathrm{C}(0, r_1, r_2) \cup r_1 \cup r_2$, then, by the definition of σ, the solution of the system can be given by A_1 or A_2. If the system is given by A_1, $\frac{dV(x(t))}{dt} = \nabla V(x(t))\dot{x}(t) = \nabla H_1(x(t))A_1x(t) = 0$. If, on the contrary, the system is given by A_2, $\frac{dV(x(t))}{dt} = \nabla V(x(t))\dot{x}(t) = \nabla H_1(x(t))A_2x(t)$. But, we know that, in this region, $\det(A_1x(t), A_2x(t)) > 0$, thus, $\frac{dV(x(t))}{dt} < 0$.

If $x(t) \in \mathrm{C}(0, s_1, r_1)$, then, by the definition of σ, the solution of the system can be given by A_1 or A_2. If the system is given by A_2, $\frac{dV(x(t))}{dt} = \nabla V(x(t))\dot{x}(t) = \nabla H_2(x(t))A_2x(t) = 0$. If, on the contrary, the system is given by A_1, $\frac{dV(x(t))}{dt} = \nabla V(x(t))\dot{x}(t) = \nabla H_2(x(t))A_1x(t)$. But, we know that, in this region, $\det(A_1x(t), A_2x(t)) > 0$, thus, $\frac{dV(x(t))}{dt} < 0$. Analogously, we can prove that if $x(t) \in \mathrm{C}(0, r_2, s_2)$, then $\frac{dV(x(t))}{dt} \leq 0$.

□

4 Stabilization with state-dependent switching noise

Now, we consider a stochastic switched linear system

$$\dot{x}(t) = A_{\sigma(x(t))}x(t), \tag{3}$$

 ISBN: 978-84-617-8694-7

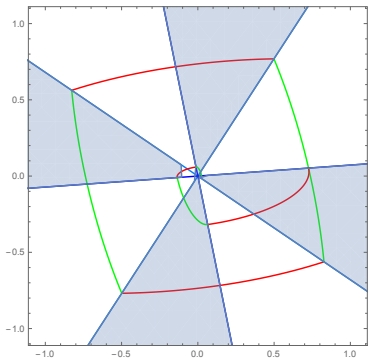

Figure 5: Stable solution and periodic solution for Example 1

where A_i is a 2×2 matrix, for $i = 1, 2$, $x \in \mathbb{R}^2$, and now $\{\sigma(x(t)); t \geq 0\}$ is a stochastic process taking values in $\{1, 2\}$. This stochastic process determines the switchings between the subsystems by the intensity function h.

By using the results in the previous section, we obtain the following result:

Theorem 3 *Let A_1 and A_2 be two unstable 2×2 matrices. Suppose that for the switched system (1) the switching laws of type I (resp. II) are stabilizing. Then there exists $\epsilon > 0$ and a intensity function $h : [-\epsilon, \epsilon] \to (0, \infty)$ such that the switched system (3) is stable with probability 1.*

5 Numerical examples

Now, in order to illustrate these results, three numerical examples are presented.

Example 1 *Consider a switched linear system given by (1) where the matrices are the following:*

$$A_1 = \begin{pmatrix} -2 & 52 \\ -8 & 6 \end{pmatrix} \qquad A_2 = \begin{pmatrix} 11 & 10 \\ -50 & -9 \end{pmatrix}$$

By applying the method in [19], we obtain that the switching law of type I is stabilizing and the solution rotates around the origin in clockwise direction (see Figure 5).

Moreover, applying Theorem 1, a periodic solution is obtained and two rays s_1 and s_2 (see Figure 5). Finally, by Theorem 3, we have that if we switch in the cones C_1 and C_2, the solution is stable .

 ISBN: 978-84-617-8694-7

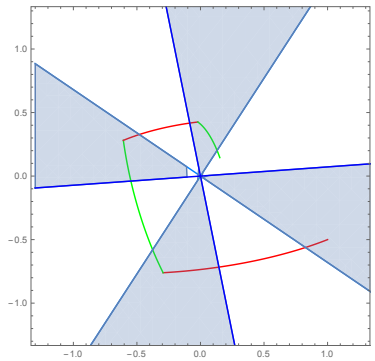

Figure 6: Stable solution for initial condition $x_0 = (1, -0.5)$ and cones where the switchings are produced for Example 1

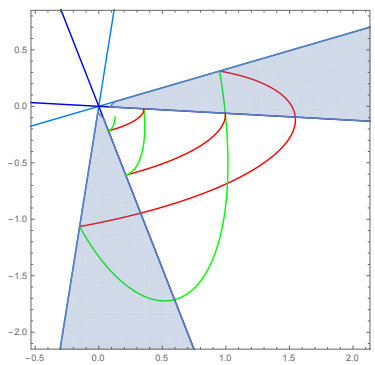

Figure 7: Stable solution and periodic solution for Example 2

Example 2 *Consider a switched linear system given by (1) where the matrices are the following:*

$$A_1 = \begin{pmatrix} 1 & 13 \\ -2 & 3 \end{pmatrix} \qquad A_2 = \begin{pmatrix} -1 & -2 \\ 10 & 3 \end{pmatrix}$$

By applying the method in [19], we obtain that the switching law of type II is stabilizing and the solution remains in a region where the trajectory of A_1 is of clockwise direction and the trajectory of A_2 is of counterclockwise direction (see Figure 7).

Moreover, applying Theorem 1, a periodic solution is obtained and two rays s_1 and s_2 (see Figure 7). Finally, by Theorem 3, we have that if we switch in the cones C_1 and C_2, the solution is stable (see Figure 8).

 ISBN: 978-84-617-8694-7

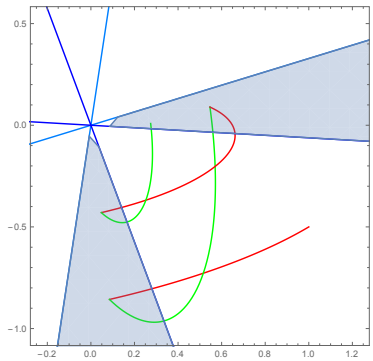

Figure 8: Stable solution for initial condition $x_0 = (1, -0.5)$ and cones where the switchings are produced.

6 Conclusions

In this work the stabilization of second-order switched linear system with state-dependent switching noise has been studied. Based on the method of stabilization of [19] and [3], we have presented a result that assures the existence of regions of stabilization where although the switchings are produced and the system is also stability. A method of finding these regions have been given.

By using these regions, we have presented a result that assures the stability when the switchings are given by a stochastic process.

As future work, it can be studied more regions where the switchings can be produced. The objective can be obtain necessary and sufficient conditions for stabilization.

emails: mariano.perez@uv.es, silvia.rueda@uv.es, juan.orduna@uv.es

Abstract

Curved monitors are getting more and more popular nowadays, due to the immersive sensation they provide to users in front of planar monitors. The display in curved monitors are cylindrical surfaces with significant curvatures, which must be taken into account for a correct projection of the rendered scene.

In this paper, we propose new equations for non-linear image projection over cylindrical surfaces (adapted to the geometry of the curved monitor displays) instead of the planar projection. These equations enable the implementation of a Fish Tank Virtual Reality system based on curved monitors. In each frame, and once the position of the observer eyes has been detected, this system computes the correct stereographic projection of the scene, in order to achieve a realistic representation with a high degree of immersion. This Fish Tank Virtual Reality system including curved monitors significantly improves the user immersive sensation.

Key words: FishTank VR, Curved Monitors, Non-Planar Projections, View-Dependent Stereoscopy

1 Introduction

Fish Tank Virtual Reality (FTVR) systems render the stereoscopic image of a 3D scene on a monitor by using a perspective projection coupled to the position of the observer eyes [1]. These systems were proposed for the first time to explore the effect that would have in the user experience the tracking of the user head in the exploring of 3D virtual environments [2]. In that work, the system was composed of three main elements: a pair of stereoscopic glasses, a high-frequency planar monitor, and a mechanical device for the head tracking.

 ISBN: 978-84-617-8694-7

Stereoscopic glasses provide different images to left and right eyes, significantly improving the depth perception and the immersive sensation. Typically, there are two kind of glasses, passive, or active ones. The former ones can be based on either color filters (anaglyph glasses) or polarization filters (polarized glasses). The latter ones use switching shutters (LC shutter glasses) [4]. The technology behind these devices has become stable, and it has hardly evolved in the last five years. However, the technology for the head tracking has significantly changed since its original proposal, allowing the replacement of the mechanical devices by a simple web camera [3]. This improvement has reduced costs and has made the process much more comfortable for the user. Finally, computer monitors technology has suffered an incredible evolution, changing even their geometry and appearing curved instead of planar monitors. However, in spite of this evolution the current implementation of existing FTVR systems still use a planar monitor as physical displays. As a consequence, the graphical software still produces a planar perspective projection.

In this paper, we propose a Fish Tank Virtual Reality system for curved monitors. This system uses a non-linear projection over cylindrical surfaces (adapted to the geometry of the curved monitor) instead of the typical planar projection. In each frame, and once the position of the observer eyes has been detected, this system computes the correct stereographic projection of the scene, in order to achieve a realistic representation. This system enables the use of curved monitors in FTVR systems, increasing the user immersive sensation.

The rest of the paper is organized as follows: Section 2 introduces some preliminary concepts about FTVR systems required for understanding the rest of the paper. Section 3 describes the non-planar projection carried out on curved monitors. Next, section 4 shows the results obtained with the proposed implementation. Finally, section 5 shows some concluding remarks.

2 Background

Curved monitors are becoming increasingly popular because they yield a better user experience than planar monitors, even though the experienced improvement depends on then monitor width, the shape of the monitor curve, and the distance to the user eyes. Unlike the case of curved TVs, this distance is usually small. One of the reasons for the extended use of curved monitors is the fact that they improve the user immersion. They slightly curve the image forward, yielding a wider field of view for the same width, as shown in figure 1.

Other reason for the increasing use of curved monitors is the superior image quality. On one hand, curved monitors focus the light coming from the monitor directly to the user eyes, increasing the light contrast in a factor ranging between 1.5x and 1.8x in regard to the one achieved with a planar monitor. On other hand, curved monitors yield a more uniform image quality between the central and peripheral pixels. This is due to the fact that current technologies like IPS or OLED require that the user view is as perpendicular

 ISBN: 978-84-617-8694-7

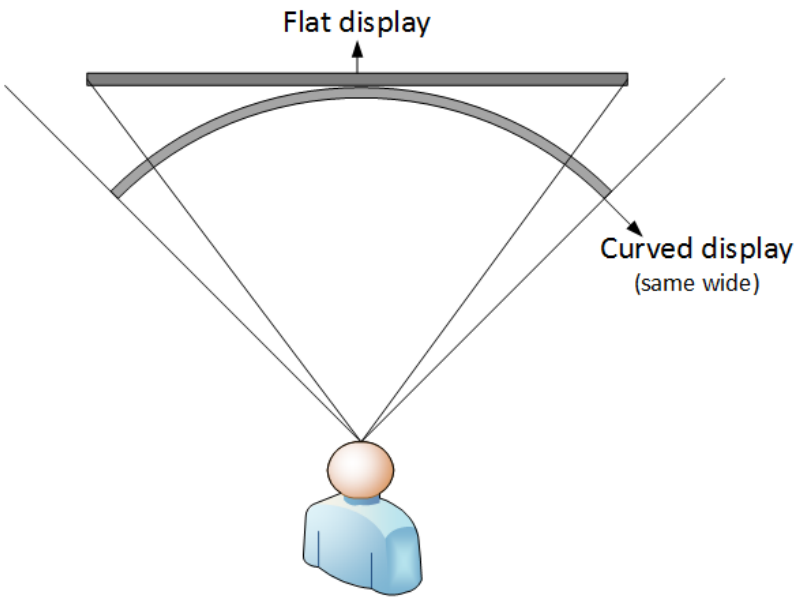

Figure 1: A curved monitor yields a wider field of view than a planar monitor of the same width.

as possible to the display surface. In the case of a large monitor with a user located close to the monitor surface (a common situation), the peripheral pixels are not display with a high quality because there is a small angle between the user view and the surface. However, in a curved monitor ideally all the pixels are located at the same distance and forming the same angle with the user view, as illustrated in figure 2.

A monitor in a FTVR system acts as a window through which the user can explore the virtual world. The graphics pipeline used for rendering the scene should project the scene on the display geometry of the monitor in order to produce credible effects. Traditionally, planar monitors have been used, so the graphics software and hardware (rasterization algorithms and the graphic pipeline in graphic cards) are optimized for planar projections. When a curved monitor is used, a non-planar projection adjusted to the display geometry must be used to map the 3D virtual scene on the final viewport. This task cannot be directly carried out with the current graphic hardware, and it may imply a high difficulty, specially if an asymmetric view frustum is used (the projection center is not located on the perpendicular line passing through the center of the projection plane, but on any other point, and changing in function of the relative position of the user in regard to the monitor).

Traditionally, there have been two different kinds of non-planar projections: image-based or geometry-based rendering methods [5]. Image-based implementations carry out

 ISBN: 978-84-617-8694-7

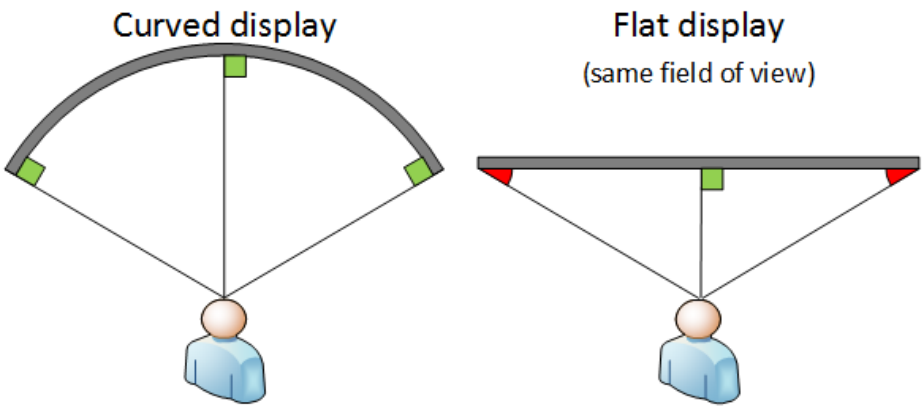

Figure 2: The apparent size and vision angle is the same for both central and peripheral pixels in the case of a curved monitor.

two steps: first, they render the 3D scene onto a texture using planar projections, and the second step renders the final view by applying the texture with the desired non-planar projection equations. The main potential weaknesses of this method are the appearance of sampling artifacts and the incompatibility with the antialiasing filtering hardware [8]. In its turn, the geometry-based rendering methods can be split into two groups: the first one splits the viewport into several narrow, rectangular slices, and then it uses planar perspective projections on each of them [6, 7]. These implementations usually yield a good performance with a reduced number of slices, but the performance decreases with the number of slices. Also, an additional drawback is the difficulty for implementing this method on current graphic architectures. The second group of geometry-based rendering methods directly compute the equation of the non-planar projection on mesh vertices, and they render the final image using the usual linear rasterization method implemented in the graphic pipeline. This method is conceptually simple and it can be easily implemented in the vertex shader (thus it could work even in early programmable GPUs), and even using instructions of the old non-programmable graphic libraries [9]. However, the main drawback of this approach is that the vertices are transformed using non-linear equations, but the inner fragments of the primitives are linearly interpolated using the rasterization process of the graphic pipeline. This problem becomes specially serious when coarse geometry is rendered, although it can be reduced by splitting the primitives through the use of geometry shaders [5] or tessellation shaders[10].

Currently, the implementations of non-planar projections described in the literature are restricted to the particular case where the view volume corresponds to a symmetric view frustum (that is, the line connecting the Center of Projection (COP) with the center of the display is perpendicular to the display surface, as shown on the left part if figure 3). Also,

 ISBN: 978-84-617-8694-7

in the case of spheric or cylindric projections the COP is located always at the center of the sphere or cylinder. This limitation represents an additional problem if the user is not located exactly at that position or when stereo is used (since each user eye must be the COP, the surface of the sphere/cylinder is different for each eye, the physical display cannot be the projection surface for both eyes simultaneously), because the projection rendered on the display provides the user with a wrong perspective from his/her point of view. Precisely, this is the typical situation in a FTVR system, since in these systems the display is located on a fixed position, the user can freely move, and the projection must be adapted on each moment to the position of the user eyes (once they have been detected through any tracking system). This is the problem motivating this work, which is aimed to develop a non-planar projection suitable for the use of curved monitors in FTVR systems.

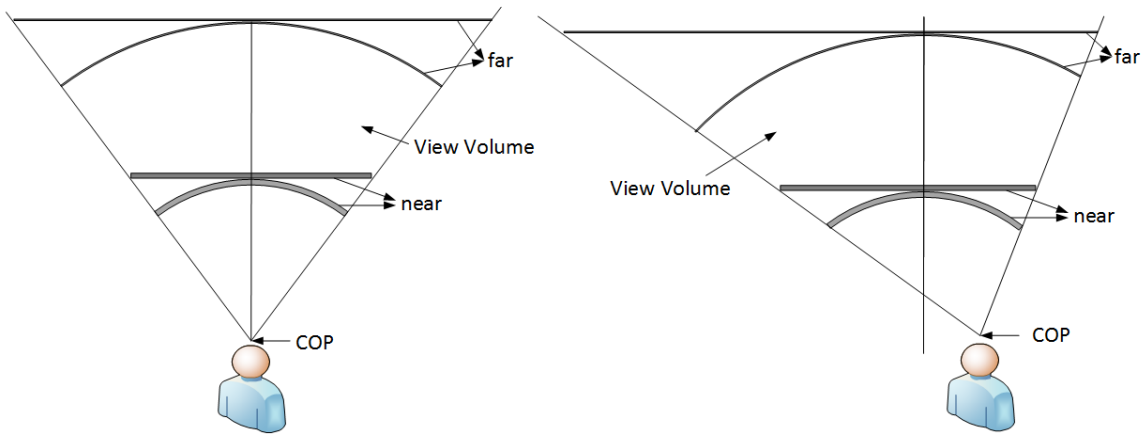

Figure 3: Planar and non-planar projection with symmetric view frustum (left), and asymmetric view frustum (right).

3 A Rendering Method for Asymmetric view frustum Rendered on Curved Displays

This method assumes a FTVR using a curved monitor as the physical display where the scene included in the view volume is projected. Since each eye COP is located at the position of the user eyes, and the user head can be located at any relative position in regard to the monitor (located at a fixed position), the view frustum corresponding to each eye must be necessarily asymmetric.

The geometry of curved monitor displays corresponds to a cylinder portion, and therefore the projection must be cylindrical. Figure 4 shows a scheme of the starting situation. In this figure, R y θ_{max} are physical parameters of the curved monitor, representing the display

curvature and the maximum angle obtained from the center of the cylinder, respectively. The center of that cylinder is taken as the origin of the world coordinates system.

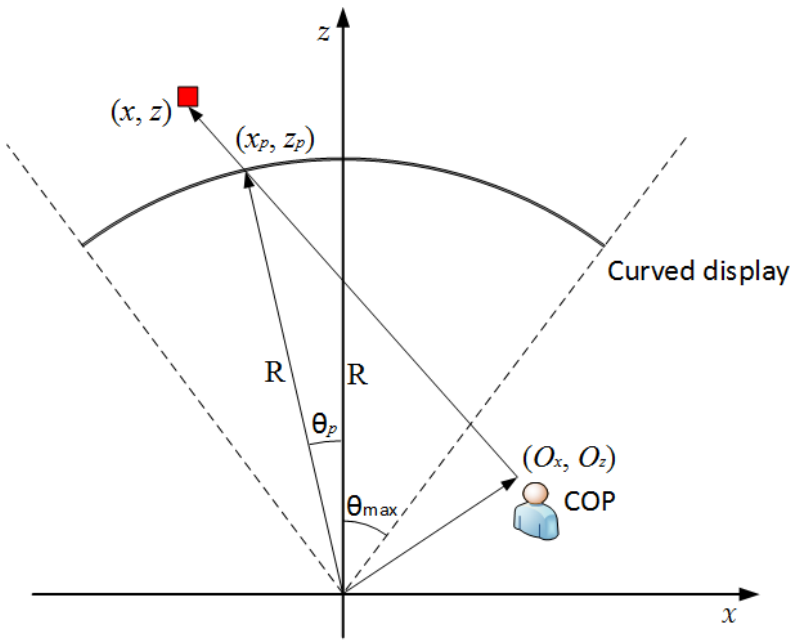

Figure 4: Cylindrical projection scheme

Figure 4 shows a case where the COP is not located at the coordinates origin, but on a different position (O_x, O_y). Following the straight line connecting the position (x, z) of any point of an scene object to the COP, this point is projected onto the cylinder surface point (x_p, z_p), which in polar coordinates corresponds to (R, θ_p). The transformation from Cartesian to polar coordinates is carried out using the following equations:

$$(x_p, z_p) = (R \sin \theta_p, R \cos \theta_p) \tag{1}$$

In order to obtain the projection of a given point, we compute the intersection point of the straight line passing through points (x, z) and (O_x, O_z), whose slope is $m = (x - O_x)/(z - O_z)$, and the circumference of the cylinder $x_p^2 + z_p^2 = R^2$. Combining these equations, we obtain the following equation:

$$z_p^2(1 + m^2) + z_p(2mO_x - 2m^2O_z) + (m^2O_z^2 + O_x^2 - 2mO_zO_x - R^2) = 0 \tag{2}$$

Equation 2 is a second order equation. While the COP is located inside the cylinder (the usual situation) this equation has two solutions: one of them corresponds to the first

 ISBN: 978-84-617-8694-7

intersection of the straight with the circumference (the point we are looking for) and the other one corresponds to the intersection point behind the COP. However, the latter point can be ignored because it will not be visible from this point of view. If we call $a = 1 + m^2$, $b = 2mO_x - 2m^2O_z$ y $c = m^2O_z^2 + O_x^2 - 2mO_zO_x - R^2$, since a is a positive value, the coordinates of the searched intersection point are obtained from the following equations:

$$z_p = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \tag{3}$$

$$x_p = m(z_p - O_z) + O_x \tag{4}$$

However, these equations are incomplete, since we have not considered the height component y, which is the main cylinder axis. Taking as origin the center of the display, the component y_p is obtained in a similar way of that of x_p, from the straight line connecting points (y, z) and (O_y, O_z), and whose slope is $m' = (y - O_y)/(z - O_z)$:

$$y_p = m'(z_p - O_z) + O_y \tag{5}$$

3.1 Implementation

We propose a geometry-based solution which applies the cylindrical projection equations directly to the position of the mesh vertices. The transformations are applied in the vertex shader, and they transform all the vertices included within the view volume to vertices included within the typical canonical clipping volume: a cube whose edges length is 2 coordinate units, centered at the coordinates origin, whose points have coordinates $x_c, y_c, z_c \in [-1, 1]$. The primitives which are totally or partially included within the cube follow from that point the usual stages of the graphic pipeline.

The starting view volume, which corresponds to an asymmetric view frustum, is truncated on both the top and bottom part by two cylindrical surfaces of radio R_{far} y R_{near} centered on the coordinates origin. Since the *near* surface corresponds to the surface of the curve monitor, it should be taken $R_{near} = R$, being R the curvature radius of the curved monitor. R_{far} can be taken as any value greater than R_{near}. The other two parameters defining the display geometry are the angle θ_{max} shown in figure 4 and the monitor display height h. Starting from these parameters, we transform this non-linear volume into a regular volume (a cube) by using these equations:

$$x_c = \frac{\theta_p}{\theta_{max}} \tag{6}$$

$$y_c = \frac{2y_p}{h} \tag{7}$$

$$z_c = \frac{2\sqrt{x^2 + z^2}}{R_{far} - R_{near}} - \frac{R_{far} + R_{near}}{R_{far} - R_{near}} \tag{8}$$

 ISBN: 978-84-617-8694-7

Where θ_p is the angular component of the intersection point polar coordinates, which is obtained from coordinate x_p by applying the inverse transformation of equation 1. y_p is the value obtained from equation 5, and x and z are the coordinates of the vertex included in the view volume for which the transformation is done.

As commented above, a drawback of this approach is that it only transforms in a non-linear way the vertices, but not the inner fragments of the triangles corresponding to these vertices (which are linearly interpolated using the rasterization process of the graphic pipeline). This problem can be visually perceptible in the edges of a relatively large triangle (a triangle including a significant number of pixels once projected on the display) as the fact that the sides appear as straight lines instead of appearing as curve lines, as id could be expected in a cylindrical projection. In order to minimize this problem, we include tessellation shaders in the graphic pipeline. These shaders take as input primitives each of the triangles included in the view volume, using the vertices coming from the output of the vertex shader as input control points. By applying the the viewport transformation on the triangles we obtain their coordinates in the window space (in pixels), and we can determine the apparent size of each triangle in the display, as well as decide if it should be split it into more triangles. When triangles are subdivided, the same transformations made in the vertex shader (equations 6, 7 and 8) are applied to each of the new generated vertices in the tessellation shaders.

4 Results

In this section, we analyze the results obtained when the proposed transformations are applied, compared to the results obtained with the linear projection transformations. We have implemented a FTVR based on a personal computer with an Intel Core i7-4790 processor, 12 GB memory and an NVIDIA GeForce GTX 650 GPU; a Logitech C170 webcam for the tracking of user head and eyes; some pairs of anaglyph 3D glasses for obtaining an stereoscopic vision; one planar and one curved monitor, both with a 21 inch display, for comparing the obtained results. Both display dimensions are 67 cm. wide and 28 cm. high.

The rendered scene for performance evaluation purposes is a quite simple scene, composed of a matrix of 5x3x3 cubes, with a 2D wood texture of 512x512 pixels mapped on every cube face. The number of vertices in the cubes is variable, and we have changed it in order to study how it affects to system performance.

Figures 5 and 6 show the visual effects obtained with both kinds of projections: planar (left figures) and cylindrical (right figures). The first figure shows a scene using symmetric view frustum, while the second one shows the same scene using asymmetric view frustum, that is, changing the position of the user head (the COP has been moved 25 cm. right and 10 cm. up with respect to the monitor center).

Both figures show significant differences between the shape of the pictures on the left

 ISBN: 978-84-617-8694-7

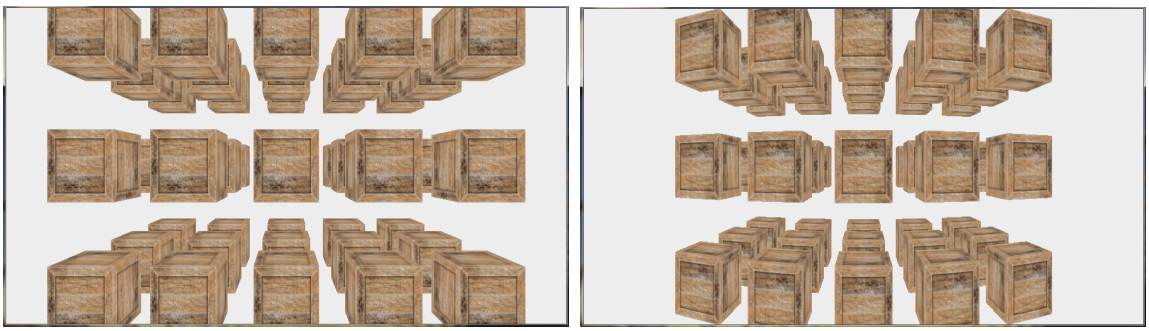

Figure 5: Scene rendered using symmetric view frustum with linear (left) and cylindrical (right) projections.

Figure 6: Scene rendered using asymmetric view frustum with linear (left) and cylindrical (right) projections.

and the right sides. Moreover, the right picture in figure 6 shows how the proposed transformation allow the correct rendering on a curved monitor even when the user is not located at the COP. These results show that the proposed transformations efficiently adapt the rendered image to the curved monitor geometry, achieving a more realistic effect regardless of the head user position.

Next, figure 7 corresponds to the same scene, but in this case using anaglyph images for achieving stereoscopic 3D effect. That is, this figure shows the same scene ready to be seen by users wearing anaglyph glasses. Nevertheless, since the image is ready for curved monitors, the reader can experience the result achieved on a curved monitor by printing the image on a paper and curving the paper. By moving the head right and up with respect to the line running through the center of the image, the reader will obtain the correct view of the image. Again, this figure shows that the proposed transformation provides the user

 ISBN: 978-84-617-8694-7

with realistic effects in the case of 3D images.

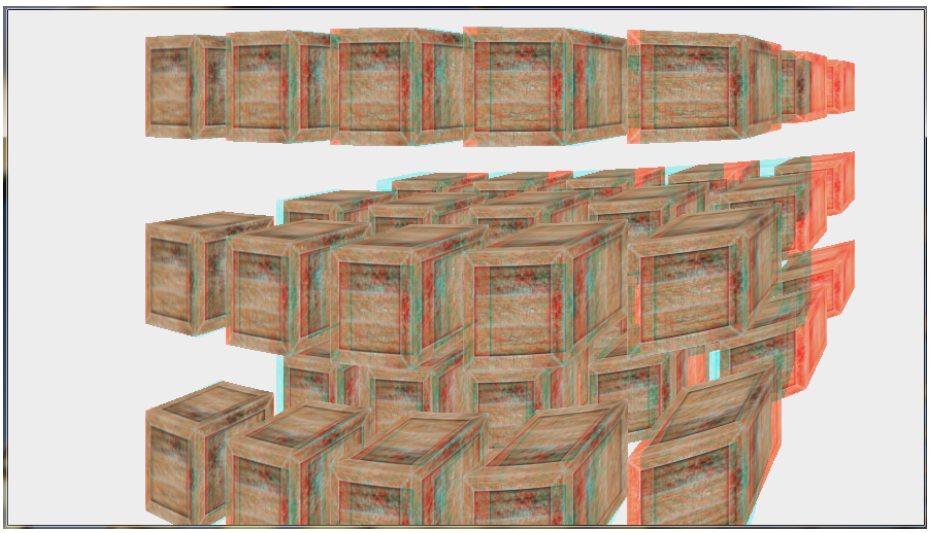

Figure 7: Stereoscopic rendering (red-cyan anaglyph) of the same scene using asymmetric view frustum with cylindrical projection.

On other hand, we have evaluated the quantitative effects of the proposed transformations. Table 1 shows comparative results, in terms of the frames per second rate achieved by the FTVR system, when both the proposed transformations and the typical planar projection transformations are applied. We have considered different number of vertices over which the transformations are applied, ranging from a few thousands to 400 million vertices.

	Num. of Vertices								
	6.5K	25K	100K	400K	1.5M	6.5M	25M	100M	400M
Linear Proj.	1430	1425	1420	1417	625	187	51	12.9	3.3
Cylind. Proj.	1427	1423	1420	1415	620	186	50	12.8	3.2

Table 1: Frames per second rendered as a function of the number of vertices in the scene.

Table 1 shows that the use of the proposed transformation does not significantly affect the system performance, since the frames per second achieved with both transformations are very similar even when the number of the triangles in the scene is huge (even bigger than the number of rendered pixels). These results prove that the proposed transformations do not add any overhead to the graphic system.

 ISBN: 978-84-617-8694-7

5 Conclusions

In this paper, we have proposed new transformations that enable the implementation of a FishTank VR system by using curved monitors instead of the planar ones, in order to increase the user immersive sensation. We have reformulated the projection equations in the literature not only to adapt them to the cylindrical geometry of curved monitor displays, but also to take into account the used head location at every moment, which may be not centered in regard to the position of the monitor. Also, we have implemented the new equations in the vertex and the tessellation shaders, using cylindrical projections with asymmetric view frustum. We have evaluated that implementation in a FTVR system with a curved monitor. The performance evaluation results show that the user perceives a correct perspective of the rendered scene at every moment, regardless of his/her head relative position to the monitor. Also, the quantitative results show that the proposed equations have no significant effects on the graphic system performance, achieving the same frame rates than when using the linear equations in the literature. These results prove that the proposed transformations enable the use of curved monitors in FTVR systems, improving the user immersive sensation.

Abstract

In this paper, we introduce the notion of (β_M, ψ, ξ) fuzzy contractive mappings and investigate the existence of fuzzy fixed points for such mappings. We also give illustrative example to show that our result is more general than the results in literatures.

Key words: Admissible mapping; β_M-admissible mapping; Fuzzy mapping; Fuzzy fixed point.
MSC 2000: 46T99, 47H10, 47H09, 54H25.

1 Introduction

Fuzzy concepts play the one importance role in real world problems which were used to modeled mathematically for the purpose of automation, like regulation, production control and many others. The study of fuzzy concepts for contractive mappings was instigated by Heilpern [2]. He introduced fuzzy contractive mappings and proved the existence of fuzzy fixed point theorem which is a generalization of Nadler's [3]. Afterward, there are mathematicians generalized and proved a fuzzy fixed point theorems for fuzzy contractive mappings in metric spaces and other spaces (see [4–12]).

The notion of β_*–admissible for multivalued mapping was introduced by Asl *et al.* [13]. Mohammadi *et al.* [14] introduced the concept of β-admissible for multivalued mappings

 ISBN: 978-84-617-8694-7

which is different from the notion of β_*–admissible. In 2014, Phiangsungnoen *et al.* [10] introduced the notion of β_M admissible for fuzzy mappings in the sense of Mohammadi *et al.* [14]. In the same year, Ali *et al.* [16]introduced and proved the notion of (β, ψ, ξ)-contractive multivalued mappings to generalized and extended the notion of contractive mappings to closed valued multifunctions via β_*–admissible.

In this paper, by using the notion of β_M admissible of Phiangsungnoen *et al.* [10]. We introduce the concept of (β_M, ψ, ξ) fuzzy contractive mappings and investigate the existence of fuzzy fixed points for such mappings. We also give illustrative example to show that our result is more general than the results in literatures.

2 Preliminaries

In this section, we recall some basic definitions and preliminaries that will be needed in this paper.

Let X be a space of points with generic elements of X denoted by x and $I = [0, 1]$. A fuzzy subset of X is characterized by a membership function such that each element in X is associated with a real number in the interval I.

Let (X, d) be a metric space and A be a fuzzy set in X. If X is endowed with topology, for $\alpha \in [0, 1]$, the α-level set of A, denoted by $[A]_\alpha$, is defined as $[A]_\alpha = \{x : A(x) \geq \alpha\}$, where $\alpha \in (0, 1]$ and for $\alpha = 0$ we have $[A]_0 = \overline{\{x : A(x) > 0\}}$, where $\overline{B}$ denotes the closure of the non-fuzzy set B.

Let X be a nonempty set. For $x \in X$, we write $\{x\}$ the characteristic function of the ordinary subset $\{x\}$ of X. For $\alpha \in (0, 1]$, the fuzzy point x_α of X is the fuzzy set of X given by

$$x_\alpha(y) = \begin{cases} \alpha & ; \quad x = y \\ 0 & ; \quad x \neq y \end{cases} .$$

In the sequel, $I = [0, 1]$, (X, d) and I^X denote the metric space and the collection of all fuzzy subsets of X. For $A, B \in I^X$, a fuzzy set A is said to be more accurate than a fuzzy set B (denoted by $A \subset B$) if and only if $Ax \leq Bx$ for each x in X, where $A(x)$ and $B(x)$ denote the membership function of A and B, respectively. For $x \in X$, $S \subset X$, $A, B \in I^X$ and $\alpha \in [0, 1]$, we define $d(x, S) = \inf\{d(x, a); a \in S\}$,

$$p_\alpha(x, A) = \inf\{d(x, a); a \in [A]_\alpha\},$$

$$p_\alpha(A, B) = \inf\{d(a, b); a \in [A]_\alpha, b \in [B]_\alpha\},$$

$$p(A, B) = \sup_\alpha p_\alpha(A, B),$$

 ISBN: 978-84-617-8694-7

$$D_\alpha(A,B) = H\big([A]_\alpha,[B]_\alpha\big) = \max\Big\{\sup_{a\in[A]_\alpha} d(a,[B]_\alpha), \sup_{b\in[B]_\alpha} d(b,[A]_\alpha)\Big\},$$

$$d_\infty(A,B) = \sup_\alpha D_\alpha(A,B).$$

and

$$\mathcal{W}_\alpha(X) = \{C \in I^X : [C]_\alpha \text{ is nonempty and compact }\}.$$

It is easy to see that H is the Hausdorff metric on $\mathcal{W}_\alpha(X)$ induced by the metric d.

Definition 2.1 ([4]) *Let (X,d) be a metric space. $Q : X \to I^X$ and $\alpha \in [0,1]$. A fuzzy point x_α in X is called fuzzy fixed point of Q if $x_\alpha \subset Qx$. If $\{x\} \subset Qx$, then x is called fixed point of Q.*

Lemma 2.2 ([2]) *Let (X,d) be a metric space, $x \in X$ and $A \in I^X$. For $\alpha \in [0,1]$, if $p_\alpha(x,A) = 0$ and $[A]_\alpha$ is closed subset of X, then $x_\alpha \subset A$.*

Definition 2.3 ([13]) *Let X be a nonempty set, $Q : X \to 2^X$, where 2^X is a collection of nonempty subsets of X and $\beta : X \times X \to [0,\infty)$. We say that Q is β_*-admissible if for $x,y \in X$ with $\beta(x,y) \geq 1$we have$\beta_*(Qx,Qy) \geq 1$, where $\beta_*(Qx,Qy) := \inf\{\beta(a,b) : a \in Qx$ and $b \in Qy\}$.*

Definition 2.4 ([14]) *Let X be a nonempty set, $Q : X \to 2^X$, where 2^X is a collection of nonempty subsets of X and $\beta : X \times X \to [0,\infty)$. We say that Q is β-admissible whenever for each $x \in X$ and $y \in Qx$ with $\beta(x,y) \geq 1$, we have $\beta(y,z) \geq 1$ for all $z \in Qy$.*

Remark 2.5 *If Q is β_*-admissible mapping, then Q is also β-admissible mapping.*

Definition 2.6 ([10]) *Let (X,d) be a metric space, $\beta : X \times X \to [0,\infty)$, $\alpha \in [0,1]$ and $Q : X \to W_\alpha(X)$. A mapping Q is said to be β_M-admissible if for each $x \in X$ and $y \in [Qx]_\alpha$, with $\beta(x,y) \geq 1$, we have $\beta(y,z) \geq 1$ for all $z \in [Qy]_\alpha$.*

In this results we let Ψ be the family of nondecreasing $\psi : [0,\infty) \to [0,\infty)$ such that $\sum_{n=1}^{\infty} \psi^n(t) < \infty$ for each $t > 0$ and ψ is continuous function. It easy to see that for $\psi \in \Psi$, $\psi(t) < t$ for all $t > 0$ and $\psi(0) = 0$. Moreover, we let Ξ be the family of functions $\xi : [0,\infty) \to [0,\infty)$ such that ξ is continuous, nondecreasing on $[0,\infty)$, $\xi(0) = 0$ and $\xi(t) > 0$ for all $t \in (0,\infty)$ and ξ is subadditive function. The example of ξ function showed in Example 2.1 [16].

Lemma 2.7 *Let (X,d) is a metric space and let $\xi \in \Xi$. Then $(X, \xi \circ d)$ is a metric space.*

 ISBN: 978-84-617-8694-7

3 Fuzzy fixed point theorems for (β_M, ψ, ξ) fuzzy contractive mappings

Theorem 3.1 *Let (X, d) be a complete metric space, $\alpha \in [0, 1]$ and Q be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$. Suppose that there exist $\psi \in \Psi$, $\xi \in \Xi$ and $\beta : X \times X \to [0, \infty)$ such that*

$$\beta(x, y) \geq 1 \Rightarrow \xi(D_\alpha(Qx, Qy)) \leq \psi(\xi(J(x, y) + lK(x, y))), \tag{3.1}$$

for all $x, y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x, y) &= \max\Big\{d(x, y), p_\alpha(x, Qx), p_\alpha(y, Qy), \frac{p_\alpha(x, Qy) + p_\alpha(y, Qx)}{2}\Big\}, \\ K(x, y) &= \min\big\{p_\alpha(x, Qx), p_\alpha(y, Qy), p_\alpha(x, Qy), p_\alpha(y, Qx)\big\}. \end{aligned}$$

If the following condition holds :

(i) Q is β_M-admissible,

(ii) there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ such that $\beta(x_0, x_1) \geq 1$,

(iii) if $\{x_n\}$ is sequence in X such that $\beta(x_n, x_{n+1}) \geq 1$ and $x_n \to x$ as $n \to \infty$, then $\beta(x_n, x) \geq 1$,

then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

Proof 1 *By hypothesis, there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ in condition (ii), we get $\beta(x_0, x_1) \geq 1$. If $x_0 = x_1$, then we have nothing to prove. Let $x_0 \neq x_1$. If $x_1 \in [Qx_1]_\alpha$, then x_1 is fuzzy fixed point of Q. Let $x_1 \notin [Qx_1]_\alpha$. Since $[Qx_1]_\alpha$ is nonempty compact subset of X, there exists $x_2 \in [Qx_1]_\alpha$, such that*

$$0 < \xi(d(x_1, x_2)) = \xi(p_\alpha(x_1, Qx_1)) \leq \xi(D_\alpha(Qx_0, Qx_1)). \tag{3.2}$$

From (3.2) and the fact that $\beta(x_0, x_1) \geq 1$, we have

$$\begin{aligned} 0 < \xi(d(x_1, x_2)) &\leq \xi(D_\alpha(Qx_0, Qx_1)) \\ &\leq \psi(\xi(J(x_0, x_1) + lK(x_0, x_1))) \end{aligned} \tag{3.3}$$

where

$$\begin{aligned} J(x_0, x_1) &= \max\Big\{d(x_0, x_1), p_\alpha(x_0, Qx_0), p_\alpha(x_1, Qx_1), \frac{p_\alpha(x_0, Qx_1) + p_\alpha(x_1, Qx_0)}{2}\Big\} \\ &= \max\Big\{d(x_0, x_1), p_\alpha(x_1, Qx_1)\Big\}, \end{aligned}$$

 ISBN: 978-84-617-8694-7

and

$$\begin{aligned} K(x_0,x_1) &= \min\{p_\alpha(x_0,Qx_0),p_\alpha(x_1,Qx_1),p_\alpha(x_0,Qx_1),p_\alpha(x_1,Qx_0)\} \\ &= \min\{p_\alpha(x_0,x_1),p_\alpha(x_1,x_2),p_\alpha(x_0,x_2),0\}. \end{aligned}$$

Assume that $\max\{d(x_0,x_1),p_\alpha(x_1,Qx_1)\} = p_\alpha(x_1,Qx_1)$. *Then from equation (3.3), we have*

$$\begin{aligned} 0<\xi(d(x_1,x_2)) &\leq \xi(D_\alpha(Qx_0,Qx_1)) \\ &\leq \psi(\xi(J(x_0,x_1)+lK(x_0,x_1))) \\ &\leq \psi(\xi(\max\{d(x_0,x_1),p_\alpha(x_1,Qx_1)\}+0)) \\ &= \psi(\xi(p_\alpha(x_1,Qx_1))) \\ &\leq \psi(\xi(d(x_1,x_2))) < \xi(d(x_1,x_2)) \end{aligned}$$

which is a contradiction. Hence, $\max\{d(x_0,x_1),p_\alpha(x_1,Qx_1)\} = d(x_0,x_1)$. *Then from equation (3.3), we have*

$$0<\xi(d(x_1,x_2)) \leq \xi(D_\alpha(Qx_0,Qx_1)) \leq \psi(\xi(d(x_0,x_1))).$$

By the same argument, for $x_2 \in X$, *we have* $[Qx_2]_\alpha$ *is a nonempty compact subset of* X *and then there exists* $x_3 \in [Qx_2]_\alpha$ *such that*

$$\xi(d(x_2,x_3)) = \xi(p_\alpha(x_2,Qx_2)) \leq \xi(D_\alpha(Qx_1,Qx_2)). \tag{3.4}$$

For $x_0 \in X$ *and* $x_1 \in [Qx_0]_\alpha$ *with* $\beta(x_0,x_1) \geq 1$, *by definition of* β_M*-admissible, we get*

$$\beta(x_1,x_2) \geq 1. \tag{3.5}$$

From (3.1), (3.4) and (3.5), we have

$$\begin{aligned} \xi(d(x_2,x_3)) &\leq \xi(D_\alpha(Qx_1,Qx_2)) \\ &\leq \psi(\xi(J(x_1,x_2)+lK(x_1,x_2))) \end{aligned} \tag{3.6}$$

where

$$\begin{aligned} J(x_1,x_2) &= \max\left\{d(x_1,x_2),p_\alpha(x_1,Qx_1),p_\alpha(x_2,Qx_2),\frac{p_\alpha(x_1,Qx_2)+p_\alpha(x_2,Qx_1)}{2}\right\} \\ &= \max\{d(x_1,x_2),p_\alpha(x_2,Qx_2)\}, \end{aligned}$$

and

$$\begin{aligned} K(x_1,x_2) &= \min\{p_\alpha(x_1,Qx_1),p_\alpha(x_2,Qx_2),p_\alpha(x_1,Qx_2),p_\alpha(x_2,Qx_1)\} \\ &= \min\{p_\alpha(x_1,x_2),p_\alpha(x_2,x_3),p_\alpha(x_1,x_3),0\}. \end{aligned}$$

 ISBN: 978-84-617-8694-7

Assume that $\max\{d(x_1,x_2), p_\alpha(x_2,Qx_2)\} = p_\alpha(x_2,Qx_2)$. *Then from equation (3.6), we have*

$$\begin{aligned} 0 < \xi(d(x_2,x_3)) &\leq \xi(D_\alpha(Qx_1,Qx_2)) \\ &\leq \psi(\xi(J(x_1,x_2)+lK(x_1,x_2))) \\ &\leq \psi(\xi(\max\{d(x_1,x_2),p_\alpha(x_2,Qx_2)\}+0)) \\ &= \psi(\xi(p_\alpha(x_2,Qx_2))) \\ &\leq \psi(\xi(d(x_2,x_3))) < \xi(d(x_2,x_3)) \end{aligned}$$

which is a contradiction. Hence, $\max\{d(x_1,x_2), p_\alpha(x_2,Qx_2)\} = d(x_1,x_2)$. *Then from equation (3.6), we have*

$$0 < \xi(d(x_2,x_3)) \leq \xi(D_\alpha(Qx_1,Qx_2)) \leq \psi(\xi(d(x_1,x_2))) = \psi^2(\xi(d(x_0,x_1))).$$

By induction, we can construct a sequence $\{x_n\}$ *in* X *such that, for each* $n \in \mathbb{N}$, $x_n \in [Qx_{n-1}]_\alpha$ *with* $\beta(x_{n-1},x_n) \geq 1$ *and*

$$0 < \xi(d(x_n,x_{n+1})) \leq \xi(D_\alpha(Qx_{n-1},Qx_n)) \leq \psi(\xi(J(x_{n-1},x_n)+lK(x_{n-1},x_n)))$$

where

$$\begin{aligned} J(x_{n-1},x_n) &= \max\left\{d(x_{n-1},x_n), p_\alpha(x_{n-1},Qx_{n-1}), p_\alpha(x_n,Qx_n), \frac{p_\alpha(x_{n-1},Qx_n)+p_\alpha(x_n,Qx_{n-1})}{2}\right\} \\ &= \max\{d(x_{n-1},x_n), p_\alpha(x_n,x_{n+1})\}, \end{aligned}$$

and

$$\begin{aligned} K(x_{n-1},x_n) &= \min\left\{p_\alpha(x_{n-1},Qx_{n-1}), p_\alpha(x_n,Qx_n), p_\alpha(x_{n-1},Qx_n), p_\alpha(x_n,Qx_{n-1})\right\} \\ &= \min\left\{p_\alpha(x_{n-1},x_n), p_\alpha(x_n,x_{n+1}), p_\alpha(x_{n-1},x_{n+1}), 0\right\}. \end{aligned}$$

Hence

$$\xi(d(x_n,x_{n+1})) \leq \psi(\xi(\max\{d(x_{n-1},x_n), p_\alpha(x_n,x_{n+1})\})) \tag{3.7}$$

for all $n \in \mathbb{N}$. *If there exists* $n^* \in \mathbb{N}$ *which* $p_\alpha(x_{n^*},Qx_{n^*}) = 0$, *then from Lemma 2.2, we have* $(x_{n^*})_\alpha \subset Qx_{n^*}$, *that is* $(x_{n^*})_\alpha$ *is a fuzzy fixed point of* Q. *Therefore, we suppose that for each* $n \in \mathbb{N}$, $p_\alpha(x_n,Qx_n) > 0$ *and thus* $d(x_{n-1},x_n) > 0$ *for all* $n \in \mathbb{N}$. *So, if* $d(x_n,x_{n+1}) > d(x_{n-1},x_n)$ *for some* $n \in \mathbb{N}$, *then from (3.7) and* $\psi(t) < t$ *for* $t \in (0,\infty)$, *we have*

$$\xi(d(x_n,x_{n+1})) \leq \psi(\xi(d(x_n,x_{n+1}))) < \xi(d(x_n,x_{n+1}))$$

 ISBN: 978-84-617-8694-7

which is a contradiction to our assumption. Therefore, we have

$$\begin{aligned}\xi(d(x_n,x_{n+1})) &\leq \psi\big(\xi(d(x_{n-1},x_n))\big)\\ &\leq \psi\big(\psi\big(\xi(d(x_{n-2},x_{n-1}))\big)\big)\\ &\vdots\\ &\leq \psi^n\big(\xi(d(x_0,x_1))\big). \end{aligned} \tag{3.8}$$

Next, we will show that $\{x_n\}$ is a Cauchy sequence in X. Since function ψ is belong to Ψ, there exist $\nabla > 0$ and positive integer $g = g(\nabla)$ such that

$$\sum_{n\geq h}\psi^n(\xi(d(x_0,x_1))) < \nabla.$$

Let $m > n > g$. Using the triangular inequality, previous relation and (3.8), we have

$$\xi(d(x_n,x_m)) \leq \sum_{i=n}^{m-1}\xi(d(x_i,x_{i+1})) \leq \sum_{i=n}^{m-1}\psi^i(\xi(d(x_0,x_1))) \leq \sum_{n\geq g}\psi^n(\xi(d(x_0,x_1))) < \nabla.$$

This implies that $\lim_{n,m\to\infty} d(x_m,x_n) = 0$. Hence $\{x_n\}$ is a Cauchy sequence in (X,d). By completeness of (X,d), there exists $z \in X$ such that $x_n \to z$ as $n \to \infty$. Next, we claim that $p_\alpha(z,Qz) = 0$ for each $\alpha \in [0,1]$. If not there exixts $\alpha^\dagger \in [0,1]$ such that $p_{\alpha^\dagger}(z,Qz) > 0$. By condition (iii), we have $\beta(x_n,x) \geq 1$ for all $n \in \mathbb{N}$. Now we have

$$\begin{aligned}\xi(p_{\alpha^\dagger}(z,Tz)) &\leq \xi(d(z,x_{n+1}) + p_\alpha(x_{n+1},Qz))\\ &\leq \xi(d(z,x_{n+1})) + \xi(D_\alpha(Qx_{n+1},Qz))\\ &\leq \xi(d(z,x_{n+1})) + \psi\Big(\xi\big(J(z,x_n) + lK(z,x_n)\big)\Big)\end{aligned}$$

where

$$\begin{aligned}J(z,x_n) &= \max\left\{d(z,x_n), p_{\alpha^\dagger}(z,Qz), p_{\alpha^\dagger}(x_n,Qx_n), \frac{p_{\alpha^\dagger}(z,Qx_n)+p_{\alpha^\dagger}(x_n,Qz)}{2}\right\}\\ &= \max\left\{d(z,x_n), p_{\alpha^\dagger}(z,Qz), p_{\alpha^\dagger}(x_n,x_{n+1}), \frac{p_{\alpha^\dagger}(z,x_{n+1})+p_{\alpha^\dagger}(x_n,Qz)}{2}\right\}\end{aligned}$$

and

$$\begin{aligned}K(z,x_n) &= \min\left\{p_{\alpha^\dagger}(z,Qz), p_{\alpha^\dagger}(x_n,Qx_n), p_{\alpha^\dagger}(z,Qx_n), p_{\alpha^\dagger}(x_n,Qz)\right\}\\ &= \min\left\{p_{\alpha^\dagger}(z,Qz), p_{\alpha^\dagger}(x_n,x_{n+1}), p_{\alpha^\dagger}(z,x_{n+1}), p_{\alpha^\dagger}(x_n,Qz)\right\}\end{aligned}$$

Taking limit as $n \to \infty$ gives that

$$\xi_{\alpha^\dagger}(z,Qz)) \leq \psi\big(\xi(p_{\alpha^\dagger}(z,Qz))\big) < \xi_{\alpha^\dagger}(z,Qz)),$$

which is a contradiction. Therefore, we have $\xi(p_{\alpha^\dagger}(z,Qz))$ that means $p_\alpha(z,Qz) = 0$ for each $\alpha \in [0,1]$. By Lemma 2.2, we get $x_\alpha \subset Qx$. This complete the proof.

□

Next, we give some examples to support the validity of our result.

Example 3.2 *Let $X = [0,1]$ and $d : X \times X \to [0,\infty)$ as $d(x,y) = |x-y|$ for all $x, y \in X$. Define a mapping $Q : X \to I^X$ as follows:*

$$(Qx)(t) = \begin{cases} \frac{2}{5} & , 0 \le t \le \frac{x}{6}, \\ 0 & , \frac{x}{6} < t \le \frac{x+1}{6}, \\ \frac{1}{4} & , \frac{x+1}{6} < t \le 1. \end{cases}$$

Let $\alpha = \frac{2}{5}$. We observe that

$$[Qx]_\alpha = [Qx]_{\frac{2}{5}} = \left[0, \frac{x}{6}\right]$$

for all $x \in X$. Therefore, Q is fuzzy mapping from X to $\mathcal{W}_\alpha(X)$.

Define $\beta : X \times X \to [0,\infty)$ by

$$\beta(x,y) = \begin{cases} 1 & , x = y, \\ \frac{1}{|x-y|} & , x \ne y. \end{cases}$$

Then it is easy to check that Q is an β_M-admissible. For each $x, y \in X$, we get

$$\begin{aligned} \xi(D_\alpha(Qx, Qy)) &= \xi\big(H([Qx]_\alpha, [Qy]_\alpha)\big) \\ &= \xi(\frac{1}{6}|x-y|) \\ &= \xi(\frac{1}{6}d(x,y)) \\ &< \frac{1}{2}\xi(d(x,y)) \\ &\le \psi(\xi(J(x,y) + lK(x,y))), \end{aligned}$$

where $\psi(t) = \frac{t}{2}$ and $\xi(t) = \sqrt{t}$ for all $t > 0$ and $l \ge 0$. It is easy to see that conditions (ii) and (iii) in Theorem 3.1 hold. Therefore all conditions of Theorem 3.1 hold. Thus Q has an α-fuzzy fixed point $x \in X$, that is, a point $x = 0$.

□

 ISBN: 978-84-617-8694-7

By using Remark 2.5, we get the following result.

Theorem 3.3 *Let (X,d) be a complete metric space, $\alpha \in [0,1]$ and Q be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$. Suppose that there exist $\psi \in \Psi$, $\xi \in \Xi$ and $\beta : X \times X \to [0,\infty)$ such that*

$$\beta(x,y) \geq 1 \Rightarrow \xi(D_\alpha(Qx,Qy)) \leq \psi(\xi(J(x,y)+lK(x,y))), \tag{3.9}$$

for all $x,y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x,y) &= \max\Big\{d(x,y), p_\alpha(x,Qx), p_\alpha(y,Qy), \frac{p_\alpha(x,Qy)+p_\alpha(y,Qx)}{2}\Big\}, \\ K(x,y) &= \min\big\{p_\alpha(x,Qx), p_\alpha(y,Qy), p_\alpha(x,Qy), p_\alpha(y,Qx)\big\}. \end{aligned}$$

If the following condition holds :

(i) Q is β_M-admissible,

(ii) there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ such that $\beta(x_0,x_1) \geq 1$,

(iii) if $\{x_n\}$ is sequence in X such that $\beta(x_n,x_{n+1}) \geq 1$ and $x_n \to x$ as $n \to \infty$, then $\beta(x_n,x) \geq 1$,

then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

In Theorems 3.1 and 3.3, we taking $\xi(t) = t$ then we have the following corollary.

Corollary 3.4 *Let (X,d) be a complete metric space, $\alpha \in [0,1]$ and Q be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$. Suppose that there exist $\psi \in \Psi$ and $\beta : X \times X \to [0,\infty)$ such that*

$$\beta(x,y) \geq 1 \Rightarrow D_\alpha(Qx,Qy) \leq \psi(J(x,y)+lK(x,y)), \tag{3.10}$$

for all $x,y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x,y) &= \max\Big\{d(x,y), p_\alpha(x,Qx), p_\alpha(y,Qy), \frac{p_\alpha(x,Qy)+p_\alpha(y,Qx)}{2}\Big\}, \\ K(x,y) &= \min\big\{p_\alpha(x,Qx), p_\alpha(y,Qy), p_\alpha(x,Qy), p_\alpha(y,Qx)\big\}. \end{aligned}$$

If the following condition holds :

(i) Q is β_M-admissible,

(ii) there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ such that $\beta(x_0,x_1) \geq 1$,

(iii) if $\{x_n\}$ is sequence in X such that $\beta(x_n,x_{n+1}) \geq 1$ and $x_n \to x$ as $n \to \infty$, then $\beta(x_n,x) \geq 1$,

 ISBN: 978-84-617-8694-7

then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

Corollary 3.5 *([10]) Let (X, d) be a complete metric space, $\alpha \in [0, 1]$ and Q be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$. Suppose that there exist $\psi \in \Psi$ and $\beta : X \times X \to [0, \infty)$ such that*

$$\beta(x, y) D_\alpha(Qx, Qy) \leq \psi(J(x, y)) + lK(x, y), \tag{3.11}$$

for all $x, y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x, y) &= \max\Big\{d(x, y), p_\alpha(x, Qx), p_\alpha(y, Qy), \frac{p_\alpha(x, Qy) + p_\alpha(y, Qx)}{2}\Big\}, \\ K(x, y) &= \min\big\{p_\alpha(x, Qx), p_\alpha(y, Qy), p_\alpha(x, Qy), p_\alpha(y, Qx)\big\}. \end{aligned}$$

If the following condition holds :

(i) Q is β_M-admissible,

(ii) there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ such that $\beta(x_0, x_1) \geq 1$,

(iii) if $\{x_n\}$ is sequence in X such that $\beta(x_n, x_{n+1}) \geq 1$ and $x_n \to x$ as $n \to \infty$, then $\beta(x_n, x) \geq 1$,

then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

In corollary 3.4, we taking $\psi(t) = kt$ where $k \in (0, 1)$ then we have the following corollary.

Corollary 3.6 *Let (X, d) be a complete metric space, $\alpha \in [0, 1]$ and Q be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$. Suppose that there exist $k \in (0, 1)$ and $\beta : X \times X \to [0, \infty)$ such that*

$$\beta(x, y) \geq 1 \Rightarrow D_\alpha(Qx, Qy) \leq kJ(x, y) + lK(x, y)), \tag{3.12}$$

for all $x, y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x, y) &= \max\Big\{d(x, y), p_\alpha(x, Qx), p_\alpha(y, Qy), \frac{p_\alpha(x, Qy) + p_\alpha(y, Qx)}{2}\Big\}, \\ K(x, y) &= \min\big\{p_\alpha(x, Qx), p_\alpha(y, Qy), p_\alpha(x, Qy), p_\alpha(y, Qx)\big\}. \end{aligned}$$

If the following condition holds :

(i) Q is β_M-admissible,

(ii) there exist $x_0 \in X$ and $x_1 \in [Qx_0]_\alpha$ such that $\beta(x_0, x_1) \geq 1$,

 ISBN: 978-84-617-8694-7

(iii) if $\{x_n\}$ is sequence in X such that $\beta(x_n, x_{n+1}) \geq 1$ and $x_n \to x$ as $n \to \infty$, then $\beta(x_n, x) \geq 1$,

then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

If we set $\beta(x, y) = 1$ for all $x, y \in X$ in Corollary 3.4, we get the following result.

Corollary 3.7 *Let (X, d) be a complete metric space, $\alpha \in [0, 1]$ and T be fuzzy mapping from X to $W_\alpha(X)$. Suppose that there exist $\psi \in \Psi$ such that*

$$D_\alpha(Qx, Qy) \leq \psi(J(x, y) + lK(x, y)), \tag{3.13}$$

for all $x, y \in X$, where $l \geq 0$ and

$$\begin{aligned} J(x, y) &= \max\left\{d(x, y), p_\alpha(x, Qx), p_\alpha(y, Qy), \frac{p_\alpha(x, Qy) + p_\alpha(y, Qx)}{2}\right\}, \\ K(x, y) &= \min\left\{p_\alpha(x, Qx), p_\alpha(y, Qy), p_\alpha(x, Qy), p_\alpha(y, Qx)\right\}. \end{aligned}$$

Then there exists $x \in X$ such that x_α is a fuzzy fixed point of T.

If $\psi(t) = \theta t$ where $\theta \in (0, 1)$, $l = 0$ and $\beta(x, y) = 1$ for all $x, y \in X$ in Corollary 3.4, , then we have the following Corollary.

Corollary 3.8 *Let (X, d) be a complete metric linear space, $\alpha \in [0, 1]$ and T be fuzzy mapping from X to $\mathcal{W}_\alpha(X)$ such that*

$$D_\alpha(Qx, Qy) \leq k \max\left\{d(x, y), p_\alpha(x, Qx), p_\alpha(y, Qy), \frac{p_\alpha(x, Qy) + p_\alpha(y, Qx)}{2}\right\} \tag{3.14}$$

for all $x, y \in X$, where $k \in (0, 1)$. Then there exists $x \in X$ such that x_α is a fuzzy fixed point of Q.

Abstract

Based on the classical epidemiological SIR model, we propose a similar model to analyze the spreading of a false rumor in an homogeneous mixing population. The individuals of the population can be ignorants to a certain rumor, or they can either believe or unbelieve on the rumor, depending on the level of the knowledge about the rumor achieved. Hence, an individual can decide to search for real information, or not, in order to be informed and believe, or not, on the rumor. This search for information can have costs but can also be very advantageous to the individual. Hence, we introduce the expected learning payoff of an individual to find the his/her best learning strategy.

Key words: Rumor, SIR model, Nash

1 Introduction

The first mathematical model for rumor spreading was proposed by Daley and Kendall in 1964 (see [1]), and became known as the D-K model. In this model, the population is divided in three groups: ignorants - people who are ignorant to the rumor; spreaders - people who are actively spreading the rumor; stiflers - people who have heard the rumor, but are no longer interested in spreading it. Even before Daley and Kendall's work, Goffman and Newill (see [3]) published a paper generalizing the epidemics theory, with a clear analogy between the spreading of an infectious disease and the transmission of ideas. Since then, several authors developed the rumor spreading models, with new transitions capable of describing

 ISBN: 978-84-617-8694-7

different issues in the spreading process (see [2, 8, 10]). The analogy between epidemics and rumors states that: people can be *infective*, those who are host to the infectious material, as *believers and spreaders* of a certain rumor; people can be *susceptible*, those who can be infective given a contact with infectious material, as *ignorants*, those who can be believers given a contact with the rumor provided by a believer; and people can be *removals*, those who have been removed by death, immunization, hospitalization, etc., as *stiflers*, those who do not spread the rumor any more.

A rumor is defined as an information disseminated with neither a official confirmation nor an official refutation, but, typically, it has a negative impact on the society (see [10]). A rumor can appear in one of many forms: it can be a scientific result that as been published in a certain paper; it can be the idea that some food has cancer-causing compounds; it can be the idea that a bank is near the bankruptcy; etc.. Since the rumors have the power to provoke high changes in population behaviors, sometimes causing even panic for society, there are always some risks associated with them, especially when they are false. Nowadays, with the social media and all the technologies of information, a rumor can easily spread and reach larges scales of individuals. Hence, the study about how a rumor spreads, done to prevent or minimize its negative effects, is an extremely important task.

In this work, we study the spread of false rumors using a mathematical model based on the classical SIR epidemic model. Instead of being suscepitbles, infecteds or removed, in our model the individuals can be either *ignorants*, *believers* or *unbelievers* to a certain rumor. The ignorants are those who have not heard the rumor yet, while the believers are the individuals that already heard, believe and spread the rumor. The unbelievers are the individuals that do not believe on the rumor by one of the following two reasons: they believed before but no longer believe by absence of proofs; or, they are well informed and they do not believe on a false rumor because they know the reality. Obviously, the unbeliever individuals do not spread the rumor.

Depending on the belief on the rumor, people can have different attitudes. Individuals that believe on false rumors can easily take some wrong decisions, with possible negative consequences. Hence, being informed is a necessary condition to do not believe on false rumors and avoid wrong decisions. On the other hand, the access to information might have significant costs and sometimes not being informed is the best solution. Facing the benefits of being informed against the costs of accessing the information, we will make a game theoretical analysis (see [5]) about the individuals' decisions regarding the search, or not, for real information. We introduce the individual learning payoff, that can be used to compute the most profitable strategies.

 ISBN: 978-84-617-8694-7

2 The spreading model

Based on the classical SIR epidemiological model, we purpose a similar model to describe the spread of a rumor in a homogeneous population.

In the classical SIR epidemiological model, proposed originally by Kermack and McKendrik in 1927 (see [6]), the population is assumed to be divided in three distinct compartments: S - the susceptible individuals; I - the infecteds; and R - the individuals that have recovered from infection and are now immune. The reaction schemes for transitions of the SIR system are given by

$$\begin{aligned} S+I &\xrightarrow{\beta} I+I \\ I &\xrightarrow{\gamma} R \\ S,I,R &\xrightarrow{\mu} S \end{aligned}$$

where: β is the mean infection rate; γ is the mean recovery rate and so $1/\gamma$ is the mean infectious period; and μ is the mean birth and death rate, hence $1/\mu$ is the mean life expectancy at birth. The reaction schemes of the SIR model result in the following ODE system

$$\begin{aligned} \frac{dS}{dt} &= \mu - \beta SI - \mu S \\ \frac{dI}{dt} &= \beta SI - \mu I - \gamma I \\ \frac{dR}{dt} &= \gamma I - \mu R\,. \end{aligned}$$

In the following years, several authors used the SIR model to develop more complex epidemic models, in which temporary and/or partial immune protection were considered (see [4, 9]). The introduction of a vaccination transition from susceptible to recovered

$$S \xrightarrow{\nu} R$$

was also explored (see [4]). Besides the epidemiology, the SIR epidemic model has been used to describe the evolution of several phenomena in many other fields, like informatics and sociology. Based on the SIR model, we propose a rumor spreading model where individuals can be either *Ignorant*, *Believers* or *Unbelievers* on a certain rumor. This model will be designated by *IBU model*. A direct analogy between the SIR model and the IBU model can be done by taking the following identifications on the state variables:

- S - *Susceptibles* are the I - *Ignorants*;
- I - *Infecteds* are the B - *Believers* on the rumor;

 ISBN: 978-84-617-8694-7

- R - *Recovered* are the U - *Unbelievers* on the rumor.

We will make the following assumptions about the IBU rumor spreading model: (i) all individuals are distributed homogeneously in the population and have the same possibilities to access information, hence they all make decisions under the same conditions; (ii) the believer individuals are the active spreaders, i.e. they are the individuals that transmit the rumor to the ignorants; (iii) once a believer stops believing on the rumor and becomes an unbeliever, he/she will also stops transmitting the rumor. Hence, the unbelievers are not active spreaders. Similarly to the vaccination in the SIR epidemic model, the IBU model comprises a learning transition that puts the ignorants automatically unbelievers, because an individual becomes informed about the reality after learning and do not believe on false rumors.

To find the learning strategies that are more likely to be adopted by an ignorant individual we will define the Nash equilibria strategies (see [5, 7]). We start by assuming that: P is the probability that an individual will choose to be informed, i.e. it is the individual's learning strategy; and p is the proportion of individuals who will choose to learn. With this notation, P^* is a population Nash learning strategy if

$$\Delta_{P^*\to Q} = E(Q, P^*) - E(P^*, P^*) \leq 0 \ , \quad \text{for every strategy} \quad Q \in [0, 1],$$

where $E(P, p)$ denotes the learning expected payoff of an individual that learns with probability P. Hence, if P^* is a population Nash learning strategy then no single individual has the incentive to deviate his/her learning strategy from P^* to any other strategy $Q \neq P^*$.

The learning expected payoff will be studied depending on the benefits and the costs of learning but also depending on the cost of believing on a false rumor. Maximizing the learning expected payoff, we will characterize the most profitable learning strategies.

3 Conclusions and future work

Based on the SIR epidemic model, we propose a rumor spreading model to describe the spread of false rumors. In this model, individuals can be either ignorants, believers or unbelievers on the rumor. Depending on the costs of believing on false rumors, and depending on the benefits and costs of being informed, we introduce the individual learning expected payoff. This expected payoff can now be used to compute the Nash learning strategies that are more likely to be adopted. Future work can also include the characterization of the evolutionary stable learning strategies in the IBU rumor spreading model or, possibly, in models where the rumor do not need to be false.

High order in space and time discretization for the numerical solution of anisotropic wave equations

A. M. Portillo[1]

[1] *Departamento de Matemática Aplicada, Universidad de Valladolid, Spain*

emails: anapor@mat.uva.es

Abstract

Two-dimensional wave equation in anisotropic media, on a rectangular domain with initial conditions and periodic boundary conditions, is considered. The space discretization is done with second and forth order finite differences on a uniform grid, paying attention to the mixed derivative of the equation. For the time integration of the system of ordinary differential equations obtained, a fourth order exponential splitting method, which is a geometric integrator, is proposed. The stability condition for time step and space step ratio is deduced. Numerical experiments comparing the discrete energy of the semi-discrete problem with the energy of the continuous problem are showed. Experiments displaying the good behavior in the long time integration and the efficiency of the numerical solution are too provided.

Key words: Anisotropic, Mixed derivative term, Energy, Finite differences, Splitting method

1 Introduction

We study the two dimensional time-dependent anisotropic and dispersive wave equation

$$\partial_{tt}u = \alpha_{11}\partial_{xx}u + 2\alpha_{12}\partial_{xy}u + \alpha_{22}\partial_{yy}u - s^2u, \tag{1}$$

in a rectangular domain $R = [a, b] \times [c, d]$, for the unknown $u(x, y, t)$, with initial-boundary conditions. We asume that the coefficients of the anisotropic wave equation (1) α_{ij} and s^2 are constant and

$$\alpha_{11} > 0,\ \alpha_{22} > 0,\ \alpha_{11}\alpha_{22} - \alpha_{12}^2 > 0, \tag{2}$$

 ISBN: 978-84-617-8694-7

so that in the steady state the equation is elliptic.

We impose periodic boundary conditions,

$$\begin{aligned} u(a,y,t) &= u(b,y,t), \qquad y \in [c,d], && (3)\\ \partial_x u(a,y,t) &= \partial_x u(b,y,t), \quad y \in [c,d], && (4)\\ u(x,c,t) &= u(x,d,t), \qquad x \in [a,b], && (5)\\ \partial_y u(x,c,t) &= \partial_y u(x,d,t), \quad x \in [a,b]. && (6) \end{aligned}$$

In addition, we consider the initial conditions,

$$u(x,y,0) = u_0(x,y), \quad \partial_t u(x,y,0) = v_0(x,y), \tag{7}$$

which satisfy periodic boundary conditions in R.

2 Energy of the continuous problem

An energy,

$$\begin{aligned} E(t) &= \frac{1}{2}\iint_R ((\partial_t u(x,y,t))^2 + \alpha_{11}(\partial_x u(x,y,t))^2 + 2\alpha_{12}\partial_x u(x,y,t)\partial_y u(x,y,t)\\ &+ \alpha_{22}(\partial_y u(x,y,t))^2 + s^2 u(x,y,t)^2)dxdy, \end{aligned}$$

can be introduced. The energy $E(t)$ is constant with time

$$\begin{aligned} E(t) = E(0) = \frac{1}{2}\iint_R (v_0(x,y)^2 + \alpha_{11}(\partial_x u_0(x,y))^2 + 2\alpha_{12}\partial_x u_0(x,y)\partial_y u_0(x,y)\\ +\alpha_{22}(\partial_y u_0(x,y))^2 + s^2 u_0(x,y)^2)dxdy, \end{aligned} \tag{8}$$

and, in this way, we can compute the energy of the problem calculating the initial energy through the initial conditions.

3 Spatial discretization

We start approximating the spatial derivatives in (1) by using finite differences. For the sake of simplicity, we consider the same size step in both directions x and y, that is, for a value of N, $h = \dfrac{b-a}{N}$ and $M = \dfrac{d-c}{h}$. Let $x_j = a + (j-1)h$, $j = 1, \ldots, N+1$, and $y_l = c + (l-1)h$, $l = 1, \ldots, M+1$, be the nodes of the spatial discretization. This produces a uniform grid in the computational domain and a matrix of unknowns $u_{jl}(t) = u(x_j, y_l, t)$.

 ISBN: 978-84-617-8694-7

3.1 Second order spatial discretization

Second order spatial derivatives in the direction x and in the direction y are approximated by second order central finite differences

$$\begin{aligned} \partial_{xx}\, u_{jl} &\approx \frac{u_{j-1,l} - 2u_{jl} + u_{j+1,l}}{h^2}, \\ \partial_{yy}\, u_{jl} &\approx \frac{u_{j,l-1} - 2u_{jl} + u_{j,l+1}}{h^2}, \end{aligned}$$

in stencil form

$$\frac{1}{h^2}\begin{pmatrix} 0 & 0 & 0 \\ 1 & -2 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \quad \frac{1}{h^2}\begin{pmatrix} 0 & 1 & 0 \\ 0 & -2 & 0 \\ 0 & 1 & 0 \end{pmatrix},$$

respectively.

For second order mixed derivatives we consider second order approximation with stencil forms

$$\frac{1}{2h^2}\begin{pmatrix} -1 & 1 & 0 \\ 1 & -2 & 1 \\ 0 & 1 & -1 \end{pmatrix}, \quad \frac{1}{2h^2}\begin{pmatrix} 0 & -1 & 1 \\ -1 & 2 & -1 \\ 1 & -1 & 0 \end{pmatrix}. \tag{9}$$

The first stencil form should be used in the case $\alpha_{12} > 0$, whereas the second is suitable when $\alpha_{12} < 0$. Taking this into account, here mixed derivative is approximated as follows

$$\begin{aligned} &\text{if} \quad \alpha_{12} > 0, \\ &\qquad 2\partial_{xy}\, u_{jl} \approx \frac{u_{j-1,l} + u_{j+1,l} - 2u_{jl} + u_{j,l-1} + u_{j,l+1} - u_{j-1,l+1} - u_{j+1,l-1}}{h^2}, \\ &\text{if} \quad \alpha_{12} < 0, \\ &\qquad 2\partial_{xy}\, u_{jl} \approx \frac{-u_{j-1,l} - u_{j+1,l} + 2u_{jl} - u_{j,l-1} - u_{j,l+1} + u_{j-1,l-1} + u_{j+1,l+1}}{h^2}. \end{aligned}$$

Let it be $\mathbf{u}_j$ the approximations to the unknowns $(u(x_j, y_1), \ldots, u(x_j, y_{M+1}))^T$, for fixed x_j. Denoting $\mathbf{u}_h = [\mathbf{u}_1^T, \ldots, \mathbf{u}_{N+1}^T]^T$, we achieve the second order in time ODEs system

$$\frac{d^2\mathbf{u}_h}{dt^2} = A\mathbf{u}_h, \tag{10}$$

where the matrix of the problem is

$$A = \frac{1}{h^2}B - s^2 I, \tag{11}$$

I is the identity matrix of dimension $(N+1)(M+1)$ and matrix B comes from second order spatial derivatives approximation.

 ISBN: 978-84-617-8694-7

Lemma 1. *The eigenvalues of matrix B, for the coefficients α_{ij} meeting (2), satisfy*

$$\sigma(B) \subset [-4(\alpha_{11}+\alpha_{22}) - 8|\alpha_{12}|, 0].$$

Lemma 2. *The matrix*

$$A = \frac{1}{h^2}B - s^2 I$$

is symmetric negative definite.

Theorem 3. *The discrete energy*

$$E_h(t)(\mathbf{u},\mathbf{v}) \;=\; \frac{h^2}{2}(\mathbf{v}^T\mathbf{v} - \mathbf{u}^T A\mathbf{u}), \tag{12}$$

is conserved for $(\mathbf{u}_h, d\mathbf{u}_h/dt)$, being $\mathbf{u}_h$ the solution of (10).

3.2 Fourth order spatial discretization

Computational cost becomes especially important when the number of equations in the system increases. In order to approach equation (1) with periodic boundary conditions (3)-(6) and initial conditions (7), with higher accuracy, we consider fourth order approximation of the spatial derivatives.

Second order spatial derivatives in the direction x and in the direction y are approximated by fourth order central finite differences

$$\begin{aligned}
\partial_{xx}\, u_{jl} &\approx \frac{1}{h^2}(-\frac{1}{12}u_{j-2,l} + \frac{4}{3}u_{j-1,l} - \frac{5}{2}u_{jl} + \frac{4}{3}u_{j+1,l} - \frac{1}{12}u_{j+2,l}),\\
\partial_{yy}\, u_{jl} &\approx \frac{1}{h^2}(-\frac{1}{12}u_{j,l-2} + \frac{4}{3}u_{j,l-1} - \frac{5}{2}u_{jl} + \frac{4}{3}u_{j,l+1} - \frac{1}{12}u_{j,l+2}),
\end{aligned}$$

in stencil form

$$\frac{1}{12h^2}\begin{pmatrix} 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0\\ -1 & 16 & -30 & 16 & -1\\ 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad \frac{1}{12h^2}\begin{pmatrix} 0 & 0 & -1 & 0 & 0\\ 0 & 0 & 16 & 0 & 0\\ 0 & 0 & -30 & 0 & 0\\ 0 & 0 & 16 & 0 & 0\\ 0 & 0 & -1 & 0 & 0 \end{pmatrix},$$

respectively.

Mixed derivative are approximated by the following fourth order finite differences

$$\begin{aligned}
\partial_{xy}\, u_{jl} \approx \frac{1}{144h^2}\;& (u_{j-2,l-2} - 8u_{j-2,l-1} + 8u_{j-2,l+1} - u_{j-2,l+2}\\
&-8u_{j-1,l-2} + 64u_{j-1,l-1} - 64u_{j-1,l+1} + 8u_{j-1,l+2}\\
&8u_{j+1,l-2} - 64u_{j+1,l-1} + 64u_{j+1,l+1} - 8u_{j+1,l+2}\\
&-u_{j+2,l-2} + 8u_{j+2,l-1} - 8u_{j+2,l+1} + u_{j+2,l+2}),
\end{aligned}$$

 ISBN: 978-84-617-8694-7

in stencil form

$$\frac{1}{144h^2}\begin{pmatrix} -1 & 8 & 0 & -8 & 1 \\ 8 & -64 & 0 & 64 & -8 \\ 0 & 0 & 0 & 0 & 0 \\ -8 & 64 & 0 & -64 & 8 \\ 1 & -8 & 0 & 8 & -1 \end{pmatrix}.$$

4 Time discretization

We rewrite problem (10) as a first order system, naming $\mathbf{v}_h = [\frac{d}{dt}\mathbf{u}_1^T, \ldots, \frac{d}{dt}\mathbf{u}_{N+1}^T]^T$,

$$\frac{d}{dt}\begin{bmatrix} \mathbf{u}_h \\ \mathbf{v}_h \end{bmatrix} = \begin{bmatrix} 0 & I \\ A & 0 \end{bmatrix}\begin{bmatrix} \mathbf{u}_h \\ \mathbf{v}_h \end{bmatrix}, \tag{13}$$

where I is the identity matrix of dimension $(N+1)(M+1)$. We notice system (13) is a Hamiltonian problem.

4.1 Exponential splitting method

Denoting k the time step, we propose to approximate the exact solution of (13),

$$\begin{bmatrix} \mathbf{u}(t+k) \\ \mathbf{v}(t+k) \end{bmatrix} = \exp\left(k\begin{bmatrix} 0 & I \\ A & 0 \end{bmatrix}\right)\begin{bmatrix} \mathbf{u}(t) \\ \mathbf{v}(t) \end{bmatrix}, t \geq 0,$$

by using an exponential splitting method as time integrator. We split the matrix of the problem (13) in two parts

$$\begin{bmatrix} 0 & I \\ A & 0 \end{bmatrix} = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ A & 0 \end{bmatrix} = M_1 + M_2.$$

The intermediate problems

$$\frac{d}{dt}\begin{bmatrix} \mathbf{u}_h \\ \mathbf{v}_h \end{bmatrix} = M_i\begin{bmatrix} \mathbf{u}_h \\ \mathbf{v}_h \end{bmatrix}, \quad i = 1, 2,$$

can be solved exactly using that $M_i^2 = 0$ for $i = 1, 2$ and,

$$\exp(kM_1) = \begin{bmatrix} I & kI \\ 0 & I \end{bmatrix}, \quad \exp(kM_2) = \begin{bmatrix} I & 0 \\ kA & I \end{bmatrix}.$$

Then, the flows of these intermediate problems applied to $[\mathbf{u}, \mathbf{v}]^T$ are

$$\begin{aligned} \psi_k^{[1]}: \quad \exp(kM_1)\begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} &= \begin{bmatrix} \mathbf{u} + k\mathbf{v} \\ \mathbf{v} \end{bmatrix}, \\ \psi_k^{[2]}: \quad \exp(kM_2)\begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} &= \begin{bmatrix} \mathbf{u} \\ \mathbf{v} + kA\mathbf{u} \end{bmatrix}. \end{aligned}$$

 ISBN: 978-84-617-8694-7

To advance a step of size k in time, once we have solved exactly each intermediate step, it is necessary combining these solutions to obtain an approximation of the solution of (13). To do this, first we use the symmetric second order Strang splitting $\mathcal{S}^{[2]}$

$$\mathcal{S}_k^{[2]} = \psi_{k/2}^{[1]} \circ \psi_k^{[2]} \circ \psi_{k/2}^{[1]}, \tag{14}$$

and then, by composition of $\mathcal{S}^{[2]}$, we consider the fourth order integrator $\mathcal{S}^{[4]}$ [8, 9]

$$\mathcal{S}_k^{[4]} = \mathcal{S}_{\alpha k}^{[2]} \circ \mathcal{S}_{\beta k}^{[2]} \circ \mathcal{S}_{\alpha k}^{[2]}, \quad \text{with} \quad \alpha = \frac{1}{2 - 2^{1/3}}, \quad \beta = 1 - 2\alpha. \tag{15}$$

The advantage of composing exact solutions in this way is that geometric properties of the true flow are preserved. Symplectic time integrators [4, 7] not only provides better qualitative properties of the numerical solution, but also better accuracy when a long time computation is made.

It is possible to save some computational cost writing (15) as

$$\begin{aligned} \mathcal{S}_k^{[4]} &= \psi_{\alpha k/2}^{[1]} \circ \psi_{\alpha k}^{[2]} \circ \psi_{\alpha k/2}^{[1]} \circ \psi_{\beta k/2}^{[1]} \circ \psi_{\beta k}^{[2]} \circ \psi_{\beta k/2}^{[1]} \circ \psi_{\alpha k/2}^{[1]} \circ \psi_{\alpha k}^{[2]} \circ \psi_{\alpha k/2}^{[1]}, \\ &= \psi_{\alpha k/2}^{[1]} \circ \psi_{\alpha k}^{[2]} \circ \psi_{(\alpha+\beta) k/2}^{[1]} \circ \psi_{\beta k}^{[2]} \circ \psi_{(\alpha+\beta) k/2}^{[1]} \circ \psi_{\alpha k}^{[2]} \circ \psi_{\alpha k/2}^{[1]}. \end{aligned} \tag{16}$$

This splitting method is explicit and it is easy to implement. However, it is not unconditionally stable and the stability has to be studied.

Theorem 4. *The value of ω_* in the stability interval of (16) is*

$$\omega_* = \sqrt{\frac{-1 + \sqrt{1 + 1152\gamma}}{48\gamma}}, \quad \gamma = \frac{6 + 5 \cdot 2^{1/3} + 4 \cdot 2^{2/3}}{36}.$$

Since the eigenvalues of $k(-A)^{1/2} = \frac{k}{h}(-B + s^2h^2 I)^{1/2}$ must be in the *stability interval*, we obtain the stability condition

$$\frac{k}{h}\sqrt{4(\alpha_{11} + \alpha_{22}) + 8|\alpha_{12}| + s^2h^2} < \sqrt{\frac{-1 + \sqrt{1 + 1152\gamma}}{48\gamma}}.$$

This will be reached, for sh small enough, when

$$\frac{k}{h} < \frac{0.9711}{\sqrt{4(\alpha_{11} + \alpha_{22}) + 8|\alpha_{12}|}}. \tag{17}$$

 ISBN: 978-84-617-8694-7

5 Numerical experiments

In this Section we consider the problem described in Section 1 with initial conditions

$$u_0(x,y) = \begin{cases} \dfrac{(x+0.2)^3(0.2-x)^3(y+0.2)^3(0.2-y)^3}{(0.2)^{12}}, & -0.2 < x, y < 0.2, \\ 0, & \text{otherwise}, \end{cases}$$

and $v_0(x,y) = 0$, with compact support contained in the computational domain $[-1/4, 1/4] \times [-1/4, 1/4]$. The polynomial in u_0 is chosen so that $u_0 \in C^1([-1/4, 1/4] \times [-1/4, 1/4])$.

We set the dispersion coefficient $s^2 = 1$. For the numerical experiments we have selected three cases of coefficients α_{ij} from [3]. Table 1 displays these coefficients with the same notation used in [3]. We have numerically computed the eigenvalues of the corresponding

Run	α_{11}	α_{22}	α_{12}
1.2	0.875	0.625	-0.217
2.2	0.160	0.940	0.225
2.4	0.472	0.628	0.443

Table 1: The three cases of α_{ij} considered.

matrix B for Section 3.2, for the α_{ij} considered, and we can conclude that they are non positive real numbers.

Table 2 displays the ratio of stability between the time step and the space step. It can

Run	Second order FD	Fourth order FD
1.2	0.3491	0.3434
2.2	0.3900	0.4009
2.4	0.3445	0.3974

Table 2: Ratio of stability.

be seen in Table 2 that the stability condition for the splitting method is acceptable.

Now, we are going to compare the continuous energy (8) for the test problem with the discrete energy

$$E_h(t)(\mathbf{u}, \mathbf{v}) = \frac{h^2}{2}(\mathbf{v}^T\mathbf{v} - \mathbf{u}^T A\mathbf{u}),$$

of the semi-discrete problems. We denote by $E_{h,2}(t)$ the discrete energy where matrix A is the matrix obtained when second order finite differences are used, and $E_{h,4}(t)$ the

 ISBN: 978-84-617-8694-7

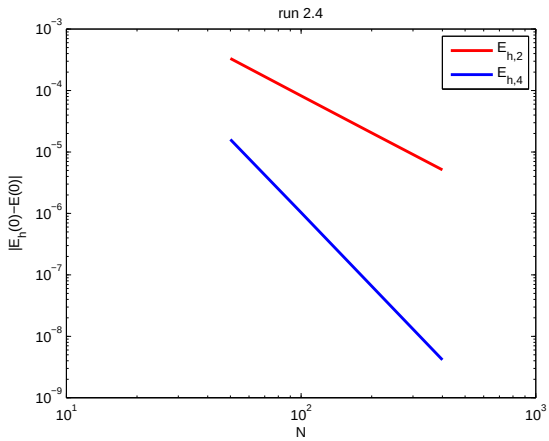

Figure 1: Energy error for the second order finite differences and the fourth-order finite differences for run 2.4.

discrete energy where matrix A is the matrix obtained when fourth order finite differences are considered. Energy error for the second order finite differences and the fourth-order finite differences for run 2.4 are shown in Figure 1. It can be appreciated the second and fourth order of the discretization of Subsections 3.1 and 3.2, respectively.

Finally, in the following experiments we compare the behavior of the splitting scheme and the fourth-order four-stage Runge-Kutta method when fourth order finite differences introduced in Section 3.2 and the energy norm $E_{h,4}(t)$ are considered. We measure the relative energy error $|E_{h,4}(t) - E_{h,4}(0)|/|E_{h,4}(0)|$. We set $N = M = 200$ and $k = 10^{-3}$. Figure 2 displays relative energy error for the exponential splitting integrator and the fourth-order four-stage Runge-Kutta method, for times from 0 to 100, for run 1.2 and run 2.2. The splitting method maintains the same size error throughout the interval of time $[0, 100]$. This agrees with the fact that scheme (16) is a geometric integrator. Whereas for the Runge-Kutta method the size of the error grows when the time increases.

Lastly, we study the efficiency of the splitting scheme by comparing with the fourth-order four-stage Runge-Kutta method measuring the computational cost in terms of CPU time. For the exponential splitting integrator, if the last step in the composition (16) of $\mathcal{S}_k^{[4]}$ for one step and the first one in $\mathcal{S}_k^{[4]}$ for the next step are joined together, that is, $\psi_{\alpha k/2}^{[1]} \circ \psi_{\alpha k/2}^{[1]} = \psi_{\alpha k}^{[1]}$, only three times of step 1 are needed for each step in time. A similar analysis of the efficiency of the algorithms to the one done in [1] can be done here. Then, regarding the products required, for the Runge-Kutta method and the splitting method, the relation is four to three. It can be seen in Figure 3 that the splitting method is better than the Runge-Kutta method. For the same error the computational cost is smaller.

 ISBN: 978-84-617-8694-7

The numerical experiments confirm the good behavior in the long time integration and the efficiency of the splitting method considered.

Abstract

The paper deals with the description of the mathematical model of photosynthesis process in two interacting (peripheral and shaded) leaves. The bioenergetic phenomena is described by six equations for surfaces, thicknesses and levels of substrates of photosynthesis contents in two types of leaves. The well-posedness of the problem and the uniqueness of its solution are proved.

Key words: photosynthesis, differential equations
MSC 2000: 34A12, 92D25, 92D40

1 Introduction

A mathematical model of photosynthesis shows the relationships between the variables which influence the dynamics of photosynthesis taking place in green leaves. A general mathematical model of photosynthetic processes is presented in the work [4]. In paper [3] dedicated to the mathematical modelling of photosynthesis another model has been presented by the authors. It takes into account the positioning of a leaf in the conditions of full light access (in the peripheral part of the tree crown) and of a leaf shaded inside the tree crown. A completely shaded leaf can function in the tree crown on condition it is self-sufficient, i.e. capable of nourishing its tissues with photosynthetic products. Such a leaf, in case of higher light intensity and increasing day length in relation to night length, may also effectively provide the produced biomass for other plant tissues which do not participate in the process of photosynthesis (e.g. tissues of the root system or stem) [1, 8, 11, 12].

 ISBN: 978-84-617-8694-7

The process of photosynthesis also depends on the accessibility of water and mineral salts dissolved in it. In some papers authors put a considerable emphasis on bioenergetic processes working out mathematical models of plant bioenergetics (see [2, 5, 6, 7, 9, 10] and the references therein).

The mathematical model of photosynthesis presented in this work takes into consideration both the water balance differential model of a plant and the dissolved mineral salts which get to the tissues assimilating carbon dioxide together with water, being used in the course and for regulation of metabolic processes as well as for building the anatomical structures of the plant, i.e. its biomass.

Conduction of water and mineral salts to particular leaves in the tree crown is dependent on the local light conditions and on the positioning of a leaf in the topography of the tree crown, as well as on the distance between the leaf and the root system, which is connected with the water and energy balance of plant. The empiric data used in this paper come from the doctors dissertation [11] (in Polish language).

2 Variables of model

There are six basic variables in our model:

- $x_1(t)$ the surface of a peripheral leaf;
- $x_2(t)$ the surface of a shaded leaf;
- $y_1(t)$ the thickness of a peripheral leaf;
- $y_2(t)$ the thickness of a shaded leaf;
- $z_1(t)$ the mineral salt (substrates of photosynthesis) content in a peripheral leaf;
- $z_2(t)$ the mineral salt (substrates of photosynthesis) content in a shaded leaf.

Let φ be the degree of leaf insolation. It is clear that φ is a time function and is positive only at day time. Let $A(\tau)$ denotes any increasing function for small arguments and which equals zero for $\tau > \tau_0$ where τ_0 is the leaf insolation sufficient for photosynthesis process. The function A describes the influence of the leaf growth on the photosynthesis process.

3 Model assumptions

First of all, surface growth is assumed to be caused by photosynthesis which depends on the insolated leaf surface, volume of photosynthetic substrates and degree of insolation. It is believed here that in case of poor insolation the leaf builds up its surface and thickness, whilst in case of high insolation it only builds up its thickness (palisade and spongy

 ISBN: 978-84-617-8694-7

mesophylls). The decrease in surface caused by respiration is directly proportional to the biomass. Hence, the equation for x_1 will be the following

$$x_1'(t) = A(\varphi(t))x_1(t)z_1(t) - ax_1(t)y_1(t) \tag{1}$$

where coefficient a is a certain constant characterized by growth due to respiration. For the leaf shaded by the peripheral one the equation will look similar apart from the degree of insolation which will be lower due to the fact that part of the light will be shaded by the peripheral leaf. Therefore, the equation will be the following

$$x_2'(t) = A(\varphi(t) - \lambda x_1(t))x_2(t)z_2(t) - ax_2(t)y_2(t) \tag{2}$$

where λ is the coefficient of solar exposure reduction. It is obvious that the biomass will be directly proportional to the product of surface and thickness. Its growth will be directly proportional to insolation, surface and mineral salt content. Similarly, as in the case of surface, this growth is caused by respiration. Therefore, it can be put down as follows

$$(x_1y_1)'(t) = \varphi(t)x_1(t)z_1(t) - bx_1(t)y_1(t)$$

where the coefficient b describes the slowdown of the biomass caused by the respiration process. It should be noted, however, that leaf biomass cannot increase unlimitedly, which could be observed in equation (3). Therefore, its right part should be multiplied by the expression $J(y(t))$ where $J(\tau)$ equals 1 for arguments $\tau < C$ and 0 for $\tau > C + \eta$. Here η is sufficient small and C is the highest possible leaf thickness. We assume that J is differentiable on its domain. The equation in this case is the following

$$(x_1y_1)'(t) = (\varphi(t)x_1(t)z_1(t) - bx_1(t)y_1(t))J(y_1(t))$$

After applying Leibniz rule and making some transformations, and after inserting equation (1), the following equation can be obtained

$$y_1'(t) = (\varphi(t)z_1(t) - by_1(t))\, J(y_1(t)) - A(\varphi(t))y_1(t)z_1(t) + ay_1^2(t). \tag{3}$$

The equation for y_2 is analogical to the above, but we replace $\varphi(t)$ with $\varphi(t) - \lambda x_1(t)$

$$y_2'(t) = \big((\varphi(t) - \lambda x_1(t))^+ z_2(t) - by_2(t)\big)\, J(y_2(t)) - A(\varphi(t) - \lambda x_1(t))y_2(t)z_2(t) + ay_2^2(t). \tag{4}$$

What is left to be done is to put down equations for variables z_1 and z_2. For this purpose it should be noted that due to the fact that mineral salts are drawn by the same capillary, their total intake per time unit is a constant value. Let v_1 and v_2 denote, respectively, the intensity of mineral salt inflow to the peripheral and shaded leaves. It follows that the total consumption of mineral salt per unit time is constant value Q. Thus, the following assumption can be made

$$v_1 + v_2 = Q.$$

 ISBN: 978-84-617-8694-7

Moreover, the rate of v_1 and v_2 is directly proportional to particular biomasses and distances between the leaf and the root. In addition, the shaded leaf, being closer to the root, has a better access to the source of mineral salts. The following relationship can be observed:

$$v_1 = k\frac{x_1(t)y_1(t)}{x_2(t)y_2(t)}v_2. \tag{5}$$

The constant $k > 1$ denotes the coefficient characterizing access to mineral salts. Denoting

$$\frac{x_1(t)y_1(t)}{x_2(t)y_2(t)} = w(t)$$

we obtain

$$v_1(t) = \frac{Qkw(t)}{1+kw(t)}, \tag{6}$$

$$v_2(t) = \frac{Q}{1+kw(t)}. \tag{7}$$

To define the derivative of z_1 and z_2, the intensity of photosynthesis should be subtracted from v_1 and v_2. Thus, the following set of equations can be obtained:

$$\begin{aligned} z_1'(t) &= \frac{Qkw(t)}{1+kw(t)} - \gamma A(\varphi(t))x_1(t)z_1(t), \\ z_2'(t) &= \frac{Q}{1+kw(t)} - \gamma A(\varphi(t)-\lambda x_1(t))x_2(t)z_2(t) \end{aligned} \tag{8}$$

where γ is transformation coefficient expressing the consumption of mineral salt. Finally, we get the following system of the equations

$$\left\{\begin{array}{rcl} x_1'(t) &=& A(\varphi(t))x_1(t)z_1(t) - ax_1(t)y_1(t) \\ y_1'(t) &=& (\varphi(t)z_1(t) - by_1(t))\,J(x_1(t)y_1(t)) - A(\varphi(t))y_1(t)z_1(t) + ay_1^2(t) \\ z_1'(t) &=& \frac{Qkw(t)}{1+kw(t)} - \gamma A(\varphi(t))x_1(t)z_1(t) \\ x_2'(t) &=& A(\varphi(t)-\lambda x_1(t))x_1(t)z_2(t) - ax_2(t)y_2(t) \\ y_2'(t) &=& ((\varphi(t)-\lambda x_1(t))^+ z_2(t) - by_2(t))\,J(x_2(t)y_2(t)) \\ &-& A(\varphi(t)-\lambda x_1(t))y_2(t)z_2(t) + ay_2^2(t) \\ z_2'(t) &=& \frac{Q}{1+kw(t)} - \gamma A(\varphi(t)-\lambda x_1(t))x_2(t)z_2(t). \end{array}\right. \tag{9}$$

4 Existence and uniqueness of the solutions

Let us consider system (9) with the initial conditions

$$x_1(0) = x_1^0,\ y_1(0) = y_1^0,\ z_1(0) = z_1^0,\ x_2(0) = x_2^0,\ y_2(0) = y_2^0,\ z_2(0) = z_2^0. \tag{10}$$

 ISBN: 978-84-617-8694-7

Theorem 1. *Let* $x_i^0, y_i^0, z_i^0 > 0$ *for* $i = 1, 2$ *and* $y_1^0, y_2^0 \leqslant M$ *for some positive* M*. Assume that*

i) $A(\tau)$ *is an increasing function for small arguments and which equals zero for* $\tau > \tau_0$ *where* $\tau_0 > 0$ *is fixed;*

ii) φ *is positive bounded and Lipschitz function;*

iii) $J : [0, T] \to [0, 1]$ *is a differentiable function such that* $J(\tau)$ *equals* 1 *for arguments* $\tau < C$ *and* 0 *for* $\tau > C + \eta$*, where* $\eta, C > 0$ *are fixed.*

Then system of differential equations (9) *with initial conditions* (10) *has exactly one non-negative solution on the interval* $[0, T]$*.*

The assumptions of the theorem have justifiable biological interpretation. The proof of the theorem is based on the a priori estimations and the Banach fixed point theorem. But to avoid the necessity of the extension of the solution we use Bielecki's idea. In this section we will also attempt the discussion about the stability of the solution.

5 Computer simulation and comparison with empirical results

The authors have used the MAPLE 15 program to solve the system (9)–(10). The choice of coefficients is quite general because even within the same plant there are cells with very different functions among which there are cells whose mass is sometimes 50 000 times high-end than that of other cells. The graphs presented below (Figs. (1) and (2)) illustrate the solution and the most interesting result, that the peripheral leaf builds first of all its thickness and the shaded one its area. Obtained theoretical results confirm empirical results of measurement of a tree *Fagus silvatica L.* (Figs. (3) and (4)) growing in the south of Poland [11].

Abstract

Active Flow Control is implemented over NACA 2412 airfoil using Steady Suction and Steady Blowing techniques. The pre-stall angle of attack (AOA) 12^0 is studied at a high Reynolds number (Re_{chord}) of $3.1*10^6$ for two-dimensional, incompressible and steady flow conditions. A wide range of parametric value set is considered for Slot location (l_s), Velocity magnitude ratio (U_j/U_0), slot width (w) and angle of perturbation (β) using both steady suction and steady blowing independently. The numerical modeling is done using the corresponding solver in OpenFOAM, an open source CFD framework. The turbulence modeling is done using Reynolds Averaged Navier Stokes (RANS) equations, specifically k-k_l-ω model implementation in OpenFOAM. The impact of the parametric set on aerodynamic coefficients, lift (C_l) and drag(C_d), and flow separation is illustrated. Along with, the relevant boundary layer physics are explained.

Key words: Steady Suction, Steady Blowing, Aerodynamic Performance, Boundary layer analysis, High Reynolds number

1 Introduction

Flow Control provides a means for drag reduction, lift enhancement and/or noise reduction of aircraft operating at off-design flight conditions. Control Techniques may be classified as passive, active and reactive[5]. Passive control has been implemented successfully in transportation vehicles, however its counterproductive effects in its non-essential flight conditions has become a topic of interest for research community. To this objective, Active Flow Control (AFC) is a conceptually proven technology for enhancing aerodynamic performance of

both bluff and streamlined (at high AoA) bodies. It has become a rapidly evolving field in fluid dynamics for the past few decades[1, 4, 15] .

A common implementation of AFC consists in injecting/subtracting fluid in/from the nearwall region through small holes. The jets can be steady or time dependent classifying the type of actuation accordingly. Steady suction and steady blowing have been shown to provide lift augmentation (and drag reduction) in the presence of adverse pressure gradients by supressing or at least retarding flow separation([3, 2]). The effect of increasing Reynolds number is studied experimentally with steady suction being observed slightly more effective with increasing Reynolds number[6]. A 2D finite volume code is utilized to study the slat noise reduction using steady suction at high Reynolds number and is proven to be effective in this objective[8].

The impact of steady blowing in effective prevention of stall is studied at low Reynolds number with varying blowing ratios and free stream turbulence[10, 11]. Also, the dynamic stall control using strong steady blowing has resulted in increased lift coefficient, reduced hysteresis and aversion of stall[14]. Steady blowing is also implemented at the rear end of generic car models to observe an overall drag reduction but with larger massflow rates [9, 13]. It is already proven that oscillatory blowing and periodic blowing & suction provide in controlling flow separation or aerodynamic performance enhancement[7, 12]. However, due to its experimentation for different physical fluid flow conditions, there is a necessity for intensive parametric analysis of both steady suction and blowing and their boundary layer manipulation dynamics to better understand the possibility of their future consideration for engineering applications. To achieve this objective, high Reynolds number flow is chosen and analysed computationally using RANS turbulence model with assumed 2D fluid flow in order to lower the computational time requirement for the wider parametric set considered.

The section 2 is used to describe the numerical model. This is followed by the results obtained from the parametric analysis of slot location, width, perturbation angle and actuation velocity ratio for steady suction, and similarly for steady blowing without varying slot width. The final section is used to present the conclusions obtained.

2 Numerical Model

The two dimensional Navier Stokes (NS) Equations for incompressible, viscous, turbulent and steady flow is resolved using RANS Turbulence Modeling. Specifically, k-kl-Ω turubulence model is used. A finite volume method (FVM) based open-source solver, simpleFoam, within the OpenFOAM solvers framework is used. The gradient, divergence and laplacian terms in the NS equations are spatially discretized using standard finite volume discretisation of Gaussian integration with hybrid first/second order limiting scheme, limitedLinear, from cell centres to face centres.

The Semi-Implicit Method for Pressure-Linked Equations (SIMPLE) algorithm is used

 ISBN: 978-84-617-8694-7

for resolving pressure-velocity coupled equations. Hence, the post processed aerodynamic coefficients and analyzed flow physics is an average state of the fully transient flow at the very high Reynolds number considered. Pressure (p) equation is solved by Geometric Algebraic Multi Grid (GAMG) solver with 2 pressure corrections while Smooth Solver is used for Velocity field (U), Turbulent kinetic energy (k_t), Laminar kinetic energy (k_l) and Specific disspation rate (Ω) with Gauss Seidel smoother for both solvers. Final residuals of order 10^{-6} for pressure and 10^{-8} for U, k_t, k_t and Ω were consistently obtained throughout the simulations.

A parabolic computational domain is considered with the outlet placed at 24 C from trailing edge and inlet at 13 C upstream of airfoil leading edge with periodic boundary conditions in spanwise direction. The Reynolds number chosen is 3.1 $*10^6$ for NACA 2412 airfoil at an angle of attack 120. The inlet boundary velocity condition is fixed (46 m/s) with a Neumann boundary condition at outlet. For pressure, Neumann boundary conditions are defined at both inlet and outlet . The airfoil pressure and suction surface is defined as no slip walls. The initial values of k_t and Ω are computed at Inlet by considering a turbulent intensity of 0.06% and viscosity ratio of (μ_t/μ) 0.01. And k_l is defined zero at all boundaries with Neumann condition at outlet. The mesh independence is primarily checked by using $y^+ < 1$, with three different values 0.33, 0.24 and 0.16, and concluding that y+ = 0.24 with respect to computational time, as the lift and drag coefficients are close to experimental data for all three values. Active Flow Control, both steady suction and steady blowing, is implemented with a numerical boundary condition with an uniform flat profile constant in time.

3 Results

3.1 SteadySuction

3.1.1 Variation of Velocity ratio and Slot location

The skin friction coefficient for the baseline flow is plotted in Figure 3(b). It can be observed that the turbulent separation is occurring at around 0.815C. The slot location is varied only in the upstream by using this position as reference. The velocity magnitude of suction expressed in terms of ratio with free stream velocity (U_j/U_0) is varied for five values i.e., 0.2, 0.3, 0.5, 0.7 and 0.9 at four different slot locations 0.4C, 0.5C, 0.6C and 0.7C. The slot width and perturbation angle are maintained constant with values of 0.15%C and 90^0 respectively. The lift coefficient (C_l) and drag coefficient (C_d) location are plotted in Figure 2(a) and 2(b) respectively.

From Figure 2(a), there is a clear increase in lift coefficient with suction velocity and interestingly even with very low value of U_j/U_0 of 0.2, the lift obtained is higher than baseline case. For an overview, with the ratios of 0.2, 0.5 and 0.9 at the slot location of

0.6 C, the lift is enhanced by 5%, 7.2% and 8.9% respectively. The Pressure Coefficient (C_p) is plotted in Figure 3(a) which illustrates this trend in lift coefficient. With increasing velocity ratio, the pressure at suction side is decreased both upstream and downstream of the slot location followed by an increase near trailing edge even compared with baseline case. Similarly, an increase in pressure at the pressure side of airfoil can be observed with an increasing suction velocity. The interesting trend in C_p is seen just before the slot where the pressure distribution has a high impact with the flow suction. But immediately after the slot there is a slight increase in pressure with increasing velocity ratio of suction, which could be due to the presence of the reverse flow or vortex. However, the impact of suction is regained farther downstream of slot with higher suction rate reducing the pressure over airfoil's upper side.

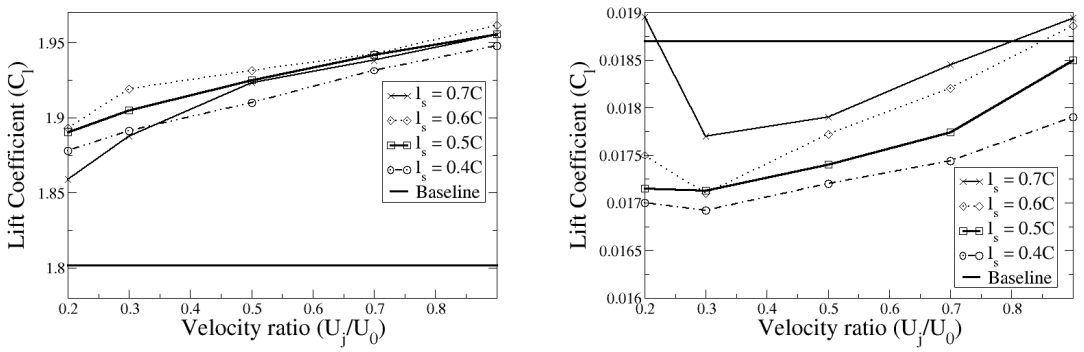

Figure 1: (a) Lift Coefficient (b) Drag Coefficient for varying velocity ratios and slot locations

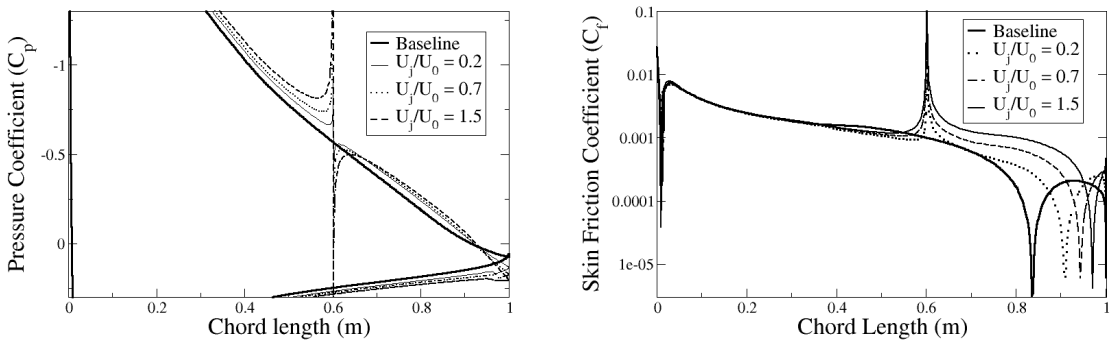
The drag coefficient(C_d) has increased with increasing velocity ratio except from 0.2 to 0.3 as illustrated in Figure 2(b) although most of the ratios and slot locations contributed for a decrease when compared to the baseline case. Numerically, a drag decrease of 8.1%, 8% and 4.3% is obtained for the ratios of 0.2, 0.5 and 0.9 respectively at slot location of 0.4C. The skin friction coefficient plotted in Figure 3(b) shows higher value of C_f with increasing suction velocity after the actuated position specifically. Also the increasing separation delay with suction velocity ratio can be seen from C_f plot where the C_f value tends to zero closer to the trailing edge locations with increasing velocity ratio. In terms of slot location, suction placed farther away to the natural separation point, significantly reduced drag as compared to a closer location, whereas a critical location at 0.6C is observed for Cl which increased the lift to maximum followed by a decrease nearer and farther to the natural separation. This trend is also seen in Figure 2(a).

 ISBN: 978-84-617-8694-7



(a) (b)

Figure 2: (a) C_p and (b) C_f for varying velocity ratios

3.1.2 Variation of Slot width

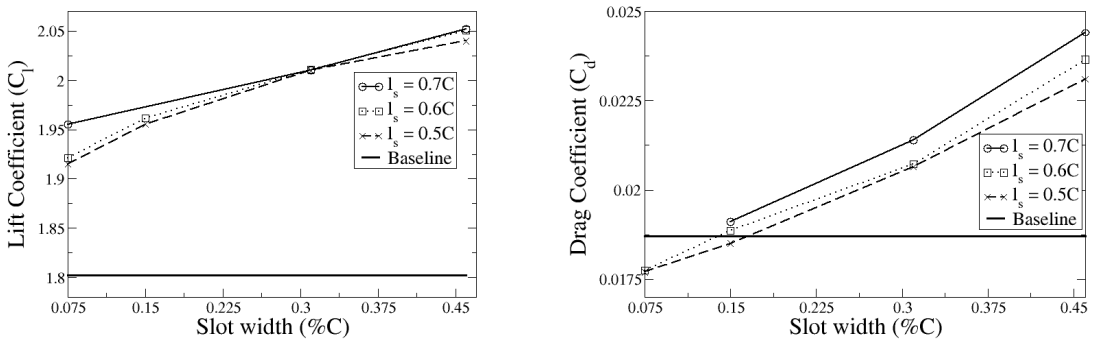
The width of the slot is varied for four parameters i.e., 0.075%C, 0.15%C, 0.31%C and 0.46%C at a constant U_j/U_0 and perturbation angle of 0.9 and 90^0 respectively. There is a clear increase in the Cl with increasing slot width as shown in Figure 4(a). The impact of slot location is low as compared to the slot width here. A drastic decrease in suction side pressure with higher slot widths was observed in the C_p. Also the C_f did show an increase in separation delay position with higher slot widths, and in the case of the slot located at 0.46%C, it is observed that there is an almost complete attachment of the boundary layer. Hence the very low flow separation is also a reason for higher lift increments.

However, the drag coefficient (C_d) in Figure 4(b) has also increased significantly by increasing the slot width. This is due to the increasing skin friction after the flow suction. The larger delayed separation is contributing to the higher C_f which probably is due the increase in the viscous component of the drag. The adverse effect here is the drag being even higher than the baseline case in most of the parametric set. The higher slot widths mean higher flow suction rates which applies to large suction velocity ratios (U_j/U_0) too. Hence, from both the velocity and slot width variation, it is observed that optimal flow suction rate is necessary in order to obtain higher lift to drag ratios.

3.1.3 Variation of Angle of Suction

The variation of angle of suction (β) has shown the trends in lift and drag coefficients as shown in the Figure 5 (a) and (b). The tangent to the location of variation on the suction side of airfoil is considered as a reference for zero degrees. The increasing values are in the clockwise rotation for this reference. The values of β are varied in the range of 30^0 to

 ISBN: 978-84-617-8694-7



(a) (b)

Figure 3: (a) C_l and (b) C_d with varying slot width and slot locations

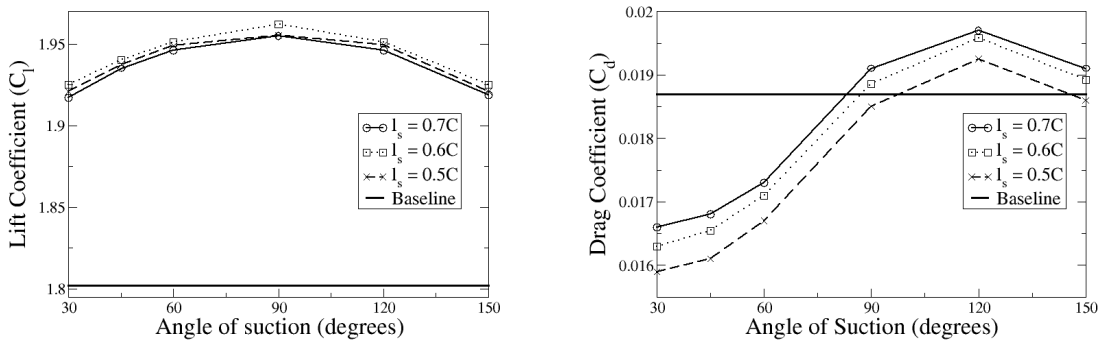
150^0. It is observed that 90^0 provided higher lift with a decreasing trend from it by either increasing or decreasing the angle of suction. Interestingly, there is a symmetry in the lift coefficient values at angles higher or lower magnitude by an equal magnitude, for example the pairs of 60^0 & 120^0 and 30^0 & 150^0. The parameter that is similar in these pairs is the vertical component of velocity that signifies the flow suction rate. As observed in the varation of velocity ratio and slot width, the impact of flow suction rate is very clear in the Figure 5 (a). The pressure coefficients also have shown similar trends supporting these conclusions with reduced pressure over the suction side. The drag is increased by increasing the angle of suction from 30^0 to 120^0 followed by a decrease from 120^0 to 150^0 which is likely to be associated with the varying horizontal component of the suction velocity combined with the viscous drag associated with flow attachment.

3.2 Steady Blowing

3.2.1 Variation of Slot location

With the same baseline case as reference, steady blowing is implemented by varying the slot location (l_s), velocity ratio (U_j/U_0) and blowing angle (β) and the trends in lift and drag are observed. The reliability on the values of the drag is low due to the highly transient nature of the flow after blowing location which resulted in a difference of 30% between the mean and the extremes values of C_d. However the C_l is not so significantly varying due to its higher magnitude and is considerably reliable. It has to be noted that the angle considered is in the counter clockwise direction with reference to the tangent to the airfoil at considered specific location.

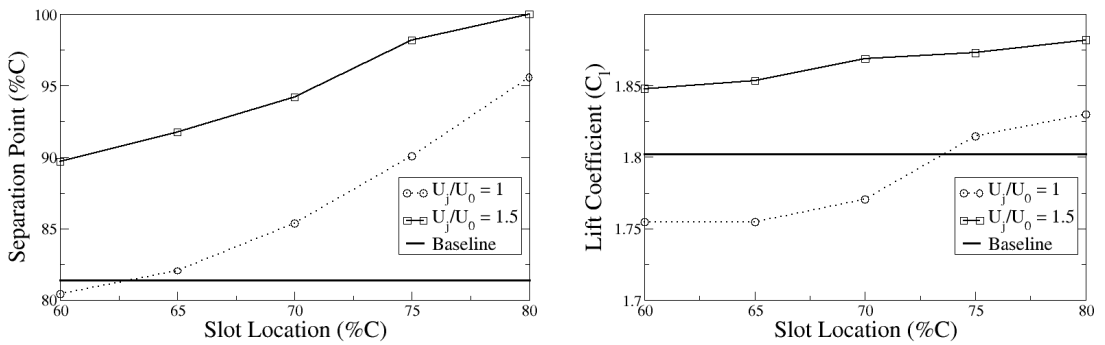
By varying the slot location(l_s) from 60%C, 65%C, 70%C, 75%C and 80%C, the lift is



(a) (b)

Figure 4: (a) C_l (b) C_d for varying Angles of suction and slot locations

increased when the slot location is closer to the natural point of separation (81%C) with reference to upstream position and it decreases as the slot is moved towards the leading edge(Figure 6(a)and 6(b)). It can also be observed that the increase in C_l is 1.55% as compared to the steady suction (8.9%) with similar magnitudes of velocity ratios (0.9 for suction and 1 for blowing). The slot width considered is 0.15%C and the angle is 30^0



(a) (b)

Figure 5: (a) Separation position (b) C_l for varying slot locations

 ISBN: 978-84-617-8694-7

3.2.2 Variation of Velocity ratio

Similary, by increasing the velocity ratio from 0.5 to 2, it can be observed from Figure 7 that the C_l is increased with U_j/U_0. To achieve performances in lift similar to suction, approximately twice the magnitudes of U_j/U_0 are necessary. It should also be noted that for lower blowing ratios, there is decrease in lift as compared to baseline case which suggests the dependency on the higher velocity magnitudes. The trend in slot location dependency can be observed here.

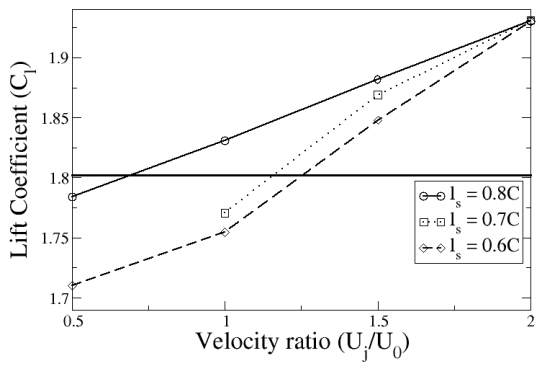


Figure 6: C_l for varying velocity ratios at different slot locations

3.2.3 Variation of Blowing Angle

The steady blowing is observed to be very sensitive to the blowing angle and any increase to the angle higher than 45^0 resulted in the divergence of numerical simulations. Hence the trends are presented from 0^0 (tangential) to 45^0. From Figure 8, it can be observed that 30^0 is the best value for blowing within the limited parametric set considered and an increase or decrease to this angle resulted in the reduction of C_l. For locations farther than 60%C from the leading edge, there is a continuous decrease with increasing angle. However, from the magnitudes of the C_l observed, these locations are of little interest.

4 Conclusions

The baseline flow is computed using RANS turbulence modeling,k-k_l-ω model, for Re_C = 3.1 *10^6 at pre-stall angle of attack 12^0. The flow is assumed to be 2D, steady and incompressible due to the sheer interest in the wide range of parametric set. A detailed parametric analysis is performed for Slot location (l_s), Velocity magnitude ratio (U_j/U_0),

 ISBN: 978-84-617-8694-7

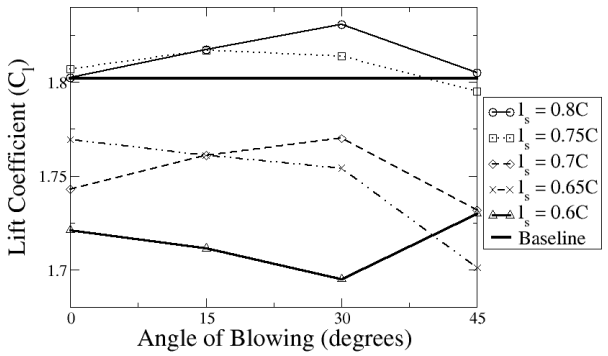

Figure 7: C_l for varying steady blowing angles at different slot locations

slot width (w) and angle of perturbation (β) using both steady suction and steady blowing independently. For steady suction, a critical slot location (60%C) is observed with natural separation of baseline flow occuring at 81%C with a decrease in aerodynamic performance with slots closer to leading and trailing edges, upstream to natural separation. An increasing velocity ratio U_j/U_0 resulted in increasing C_l and C_d. Similar trend is observed by varying slot width. However, suction angle of 90^0 is the best for suction. The dependency on net flow suction rate is explained using the observed trends, a higher rate implies better aerodynamic performance.

The similar parametric analysis is performed for steady blowing. The slot location closer to the natural separation point provided higher lift with a decreasing trend when the slot is moved towards the leading edge. Also, C_l increased with increasing velocity ratios. For a similar increase in C_l as compared to steady suction, the magnitudes of velocity ratio have to approximately twice for blowing as compared to suction. Also, the lower velocity ratios are detrimental to aerodynamic performance with respect to baseline case. With the limited parametric set considered for blowing angle, 30^0 is optimal with higher C_l and a decreasing trend is observed by either increasing or decreasing the angle.

Abstract

Virtual screening techniques provide predictions about drug bioactivity and toxicity and their activity in novel diseases. To achieve this aim, it is needed to incorporate descriptors to obtain specific information about the compounds according to the source database. In particular, we focus on the shape similarity descriptor. Recently, a new strategy for molecular shape comparison was proposed. It is an evolutionary optimization algorithm based on subpopulations which needs big population sizes to explore the search space deeply and then obtain good solutions. This translates directly into larger computational times and larger resource requirements. In view of this situation, in this work, the optimization algorithm has been parallelized. A computational study to analyze the new parallel method in terms of efficiency and effectiveness has been carried out. The use of several processors, and hence more computational resources, allows us to accelerate the molecular shape comparison procedure.

Key words: ligand based virtual screening, parallel computing, evolutionary algorithm

1 Introduction

Virtual Screening (VS) techniques allow us providing predictions about which chemical compounds might interact with a given protein target in some specified way and thus

achieving the desired biological function. VS techniques are mainly divided into Ligand Based Virtual Screening (LBVS) and Structure Based Virtual Screening (SBVS).

SBVS methods require detailed structural information about the target protein and cannot be applied in situations where this data is not available. Unfortunately, this issue is very common, for instance, in the case of membrane proteins such as GPCRs (G protein-coupled receptor), which are of the highest pharmacological relevance. In such cases, one can recur to LBVS methods, where only information about known ligands (actives and inactives, agonists and antagonists, etc) is exploited in order to predict new bioactive compounds against selected protein targets. LBVS methods will, therefore, consider all existing available information (structural, physico-chemical parameters, binding affinities, etc) about known active and inactive compounds, and this information will be referred to as molecular descriptors. There exist a large number of molecular descriptors or potentials used to compare molecules, as for example Electrostatic similarity, Atomic property fields, Aromatic potential, Desolvation potential, etc. In this work, we will focus on Shape similarity.

Molecular shape is a very important issue in computer-aided drug design. Several methods for comparing molecular shapes have been designed and numerous applications for virtual screening, scaffold hopping, and shape-feature based molecular alignment have been presented. However, due to new drug discovery paradigms, such as network pharmacology or system pharmacology, faster and more effective techniques for lead identification and optimization are required. Recently, an evolutionary algorithm, called Optipharm, has been proposed to this aim. It is a population-based algorithm which applies randomized operators over a population of candidate solutions to generate new points in the search domain. To be able to explore the search space deeply and then obtain good solutions, such an algorithm requires big population sizes. This translates into larger computational times. However, the sequential optimization method has been implemented with parallelism in mind, and hence, high performance computing can be easily incorporated to accelerate it. In this work, a master-slave strategy has been considered. The parallel version of Optipharm will be named Paral-Optipharm throughout this paper.

The rest of the paper is organized as follows. Section 2 shows how to measure the shape similarity between two molecules, which in turn is the objective function of both the sequential and parallel algorithms, Section 3 briefly describes the fundamentals of the parallel version. Finally, Section 4 shows some preliminary results and future works.

2 The problem: Shape Similarity

The shape of a molecule is an important concept in computer-aided drug design. That is supported by the importance of bindings have between ligands and receptor: if a set of different ligands bind to the same site receptor, it is possible that all of them possess a similar shape similarity [3]. Different models and applications have been developed in that

 ISBN: 978-84-617-8694-7

regard with the aim to get more accurate and efficient solutions.

Among the existing models, two of them have had more acceptance: Hard-Sphere method and Gaussian method. The first one is based on considering each atom as an sphere. The main problem with this method is its implementation, since although the analytical expression for the volume and its derivatives are known [1, 7], the formulas for the intersection of multiple spheres are not trivial. For this reason, the Gaussian method proposed by Good and Richards has been used more widely. Now each atom is represented by a gaussian function [2, 3]. In the original expression is recommended the inclusion of six terms, although in the practice, the first term is enough to get a good precision [6].

However, the Gaussian model does not consider the properties of the molecules to be evaluated. To include this information, Yan et al. add a weight factor to each atom in the evaluated molecules [8]. This consideration was based on the fact that not all the substances have the same density, and this point affects the overlap values and hence, the shape similarity scope.

In [8], the shape density of a molecule is expressed as a linear combination of weighted atomic Gaussian functions as:

$$G(r) = \sum_i w_i g_i(r) = \sum_i w_i p e^{-(\frac{3p\pi^{1/2}}{4\phi_i^3})(r-r_i)^2} \tag{1}$$

Therefore, the overlap volume of two molecules is given by:

$$V_{AB}^g = \sum_{i \in A, j \in B} w_i w_j v_{ij}^g \tag{2}$$

Because of the different size of the molecules, the value obtained in the previous expression is not comparable with a different couple of molecules. To solve that and get a normalized value, Tanimoto metric has been used:

$$S_{AB} = \frac{V_{AB}}{V_{AA} + V_{BB} - V_{AB}} \tag{3}$$

3 Paral-Optipharm: a parallel algorithm for molecular shape comparison

An evolutionary algorithm called Optipharm has been recently proposed to predict the shape similarity between two molecules. Such an algorithm inherits some ideas and fundamentals from UEGO [5]. In Algorithm 1, its main structure is depicted. Optipharm, as UEGO, works with a population of independent candidate solutions (species). This means that a single species can create a new offspring and evolve to the local or global optima without

 ISBN: 978-84-617-8694-7

Algorithm 1 Algorithm Optipharm

```
1 Init_species_list
2 Optimize_species(n_1)
3 FOR i = 2 to L
4     Determine R_i, new_i, n_i
5     Create_species(new_i)  # budget_per_species = new_i/length(species_list_i)
6     Select_species(R_i)
7     Optimize_species(n_i)  # budget_per_species = n_i/max_spec_num
```

participation of the remaining ones. Therefore, there exists an intrinsic parallelism that can be exploited by dividing the species among the available processing elements.

This work explores and evaluates a master-slave strategy applied to Optipharm, which leads to a parallel version named Paral-Optipharm. A master-slave technique is a "global parallel model", i.e. the management of the population is global and all the individuals in the population are considered when selection or creation procedures are carried out. Two kinds of processing elements can be distinguished, the *master* and the *slaves*. The master processor sees into making global decisions and delivering information among the slaves, which execute different tasks in a concurrent way.

In our particular master-slave (MS) model, the master processor executes Optipharm sequentially. The parallelism comes from the simultaneous evaluation of the candidate solutions in the Create_species function, and from the concurrent execution of the Optimize_species procedure. Therefore, new creation and optimization procedures have been designed to cope with the parallel model. These new procedures, called Create_species_paral and Optimize_species_paral, are described now:

- *Create_species_paral*: At each level i, the master obtains a new offspring of candidate solutions. The evaluation of the objective function is carried out in a parallel way. To this aim, the master processor divides the list of candidate solutions by the number of processors P and delivers the resulting sublists among all the processing elements (including itself). Each processing element receives a species sublist from the master processor and evaluate it.

  The master processor does not receive information from the slaves until it has finished its work (first synchronization point). When it does, it passes to a reception state, where it picks up the evaluated sublists sent by the slaves. Once the master has received all the information from the slaves, it updates the candidate solutions list.

  Following with the general structure of Optipharm, a selection procedure is carried out. This procedure is accomplished by the master, while the slaves stay idle (second synchronization point). If the list length is larger than the maximum allowed, then

 ISBN: 978-84-617-8694-7

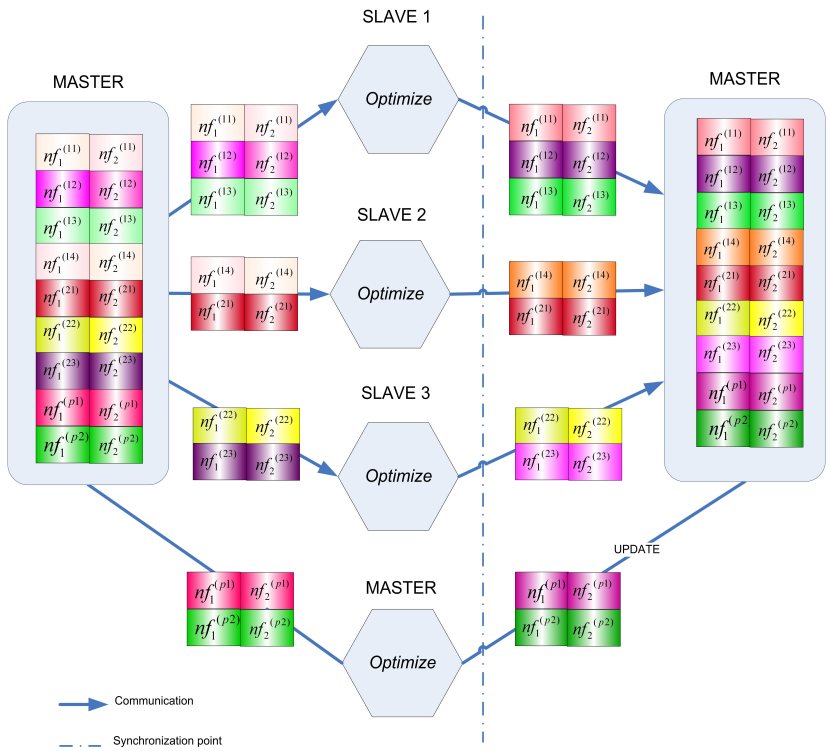

Figure 1: Master-slave strategy: delivering species for optimization.

the best candidate solutions in terms of the objective function, are selected.

- *Optimize_species_paral*: To perform the optimization process, the master divides the species list among all the processors (again including itself). In this case, each slave executes the Optimize_species procedure to every species in its sublist, i.e. a local optimization process is applied (see Figure 1). When the master finishes its work, it begins to receive the new species sublists from the slaves (third synchronization point).

Note that the synchronization points are imposed because the master is managing the whole species list.

4 Preliminary results and conclusions

In this work, a parallel global evolutionary algorithm for shape comparison between molecules has been presented. In particular, a master-slave method has been proposed. The perfor-

mance of the parallel method has been tested by using the well-known Directory of Useful Decoys (DUD) database [4]. It contains 40 different targets. Each target has associated a number of ligands and decoys. Decoys are molecules physically similar to the ligands but topologically distinct. In total, DUD is made up by 3961 ligands and 124413 decoys.

Results have shown that the efficiency of the parallel method highly depends on the two input molecules to be compared, i.e. the particular properties of the molecules may affect the speedup of the parallel strategy. Even so, the results are promising, and in some cases, efficiencies close or equal to the ideal one have been obtained.

As a future work, we will test the parallel method with different databases and develop other parallel versions based on different paradigms.

Abstract

The study of MIMO systems with large number of antennas and high-order constellations is currently generating considerable interest since provides significantly higher espectral efficiency. Unfortunately, increased complexity of the signal detection stage is the price to pay for large MIMO systems. The *Subspace Marginalization with Interference Suppression* (SUMIS) detector exhibits good performance with reduced complexity and its design allows massively parallel algorithmic implementations. This paper presents practical parallel approaches of the SUMIS detector for large MIMO systems: using multicore processors. Parallel approaches have been evaluated and compared in terms of performance and complexity with other detectors for different system parameters. Results show how these parallel versions allow to accelerate dramatically the detection, especially if very large systems and high order modulations are considered.

1 Introduction

Multiple-Input Multiple-Output (MIMO) systems provide significant capacity improvement using multiple antennas at both sides of digital communication systems. This capacity

 ISBN: 978-84-617-8694-7

increases with the minimum number of transmit and receive antennas [1]. This technology has become essential for wireless communications and has been incorporated into many communication wireless standards like IEEE 802.11n/ac (Wi-Fi)[2], wiMAX (4G)[3] and Long Term Evolution (4G)[4].

An emerging research area are so-called Large MIMO systems, often referred to as massive MIMO systems. It can be defined as those systems that use very large number of antennas, e.g., one hundred ore more [5], in contrast to conventional MIMO systems, which employ up to ten antennas. The price to pay is increased complexity and energy consumption at both ends. Particularly the MIMO detection problem is generally computationally very expensive to deal with. Thus, an adequate balance between efficiency and complexity is critical, especially in large MIMO systems [6] and large sizes constellation.

The optimal detector, which solves the MIMO detection problem optimally, computes the log-likelihood ratios (LLRs) values exactly and holds prohibitively high computational complexity, which grows with the size of the signal constellation and the number of antennas. In the above context, several detectors and exhibit different trade-offs between complexity and performance have been recently proposed. "*Single Tree Search*" (STS) [7] and "*Repeated Tree Search*" (RTS) [8] algorithms are the most common detectors which achieve the max-log approximation exactly. Both algorithms are based on the "*Sphere Decoder*" (SD) method and their computational complexity varies depending on the channel and noise realization. Sub-optimal max-log algorithms reduce the complexity at the expense of a certain performance loss. Examples of such detectors are: "*Soft Fixed Sphere Decoder*" (SFSD) [9], "*List Sphere Decoder*" (LSD) [10] or "*Soft Output k-Best*" [11], among others. On the other hand, "*Partial Marginalization*" (PM) [12] and SUMIS [13] algorithms represent an intermediate approach between the optimal detector and its max-log approximation. The SUMIS algorithm offers a good trade-off between exact and approximate computation of the LLR values and a given complexity. Even so, SUMIS detector can be the bottleneck for the overall system performance if large number of antennas or high order constellations are used. A reduction of the SUMIS detector complexity based on Box Optimization was presented in [14] but at the expense of a slight performance degradation.

This paper aims to reduce the computational cost of the SUMIS method, not only from a theoretical point of view, but through its scalable and versatile implementation for efficient processing thereof e.g. multicore processors. This allows to guarantee the SUMIS detection performance in large MIMO systems with higher throughput.

2 Background

2.1 System Model

Let us consider a complex-valued MIMO system model, using n_T transmit and n_R receive antennas with $n_T \leq n_R$. At the transmitter, the information bits are encoded, interleaved

 ISBN: 978-84-617-8694-7

and then mapped to symbols. Each symbol s_j is taken independently from the M-ary constellation Ω. The symbol contains $k = \log_2(M)$ encoded and interleaved bits. The corresponding bits are denoted by $s_{j,b}$, where the indices refer to the bth bit associated with the jth symbol. At each signaling period, the relation between the transmitted symbol vector, $\mathbf{s}_c \in \mathbb{C}^{n_T}$, and the associated received vector, $\mathbf{y}_c \in \mathbb{C}^{n_R}$, can be expressed as

$$\mathbf{y}_c = \mathbf{H}_c\mathbf{s}_c + \mathbf{v}_c, \tag{1}$$

where $\mathbf{H}_c \in \mathbb{C}^{n_R \times n_T}$denotes a fading channel matrix with independent elements $h_{j,i} \sim \mathcal{N}(0,1)$ and it is assumed to be perfectly known by the receiver. Vector $\mathbf{v}_c \sim \mathcal{N}(\mathbf{0}, \frac{N_o}{2}\mathbf{I})$ denotes an additive Gaussian noise (AWGN). Since separable complex-value constellation can be considered (quadrature amplitude modulation (M-QAM)), we can easily transform the $(n_R \times n_T)$-dimensional complex equation (1) into an equivalent $(2n_R \times 2n_T)$-dimensional real-valued representation as described in [15]:

$$\begin{bmatrix}\Re(\mathbf{y}_c)\\ \Im(\mathbf{y}_c)\end{bmatrix} = \begin{bmatrix}\Re(\mathbf{H}_c) & -\Im(\mathbf{H}_c)\\ \Im(\mathbf{H}_c) & \Re(\mathbf{H}_c)\end{bmatrix}\begin{bmatrix}\Re(\mathbf{s}_c)\\ \Im(\mathbf{s}_c)\end{bmatrix} + \begin{bmatrix}\Re(\mathbf{v}_c)\\ \Im(\mathbf{v}_c)\end{bmatrix} \tag{2}$$

where $\Re(\cdot)$ and $\Im(\cdot)$ denote the real and imaginary part of $(\cdot)$, respectively. Thereby, the real model can be described as $\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{v}$.

Let $\sqrt{M}$-PAM with $P_M = \{-\sqrt{M}+1, \cdots, -1, 1, \cdots, \sqrt{M}-1\}$ be the real-valued representation of a M-QAM constellation where $\Omega = \{a+bj : a, b \in P_M\}$. As is explained in [13], this model offers some advantages for the SUMIS algorithm. For this reason, throughout the rest of this paper we assume the real-valued model represented in (2).

At the receiver, the demodulator computes soft information in form of LLR values for each of the encoded and interleaved bit $s_{j,b}$. This soft information expresses how likely is the hypothesis that the $s_{j,b}$ bit was equal to 1 or 0. Assuming equal a priori probabilities and using Bayes' theorem, it can be expressed as

$$L_{j,b} = \log \frac{\sum_{\mathbf{s}\epsilon\chi^1_{j,b}} \exp(-\frac{1}{N_0}\|\mathbf{y} - \mathbf{H}\mathbf{s}\|^2)}{\sum_{\mathbf{s}\epsilon\chi^0_{j,b}} \exp(-\frac{1}{N_0}\|\mathbf{y} - \mathbf{H}\mathbf{s}\|^2)}, \tag{3}$$

where $\chi^u_{j,b}$ denotes the set of possible transmitted vectors for which $s_{j,b}$ bit is equal to u. The computational complexity of (3) grows exponentially with n_T and polynomially with M. Thus, the exact MIMO detection scheme becomes prohibitive. The most common approach to cope with this limitation is the max-log approximation [10] where

$$L_{j,b} \approx \min_{\mathbf{s}\epsilon\chi^0_{j,b}} \frac{1}{N_o}\|\mathbf{y} - \mathbf{H}\mathbf{s}\|^2 - \min_{\mathbf{s}\epsilon\chi^1_{j,b}} \frac{1}{N_o}\|\mathbf{y} - \mathbf{H}\mathbf{s}\|^2. \tag{4}$$

However, the max-log approximation does not lead to a complexity reduction by itself. Eq (4) requires the computation of the same metrics than (3). Nonetheless, it can be

 ISBN: 978-84-617-8694-7

exploited to design low-complexity algorithms [7]–[11]. In other works, some authors propose an alternative to max-log approximation [16]–[13] and consider a new approach to the problem of computing (3). The basic idea is to define the following partitioning model, which is based in (1),

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n} = [\overline{\mathbf{H}} \quad \widetilde{\mathbf{H}}] \quad [\overline{\mathbf{s}}^T \quad \widetilde{\mathbf{s}}^T]^T + \mathbf{v} = \overline{\mathbf{H}}\overline{\mathbf{s}} + \widetilde{\mathbf{H}}\widetilde{\mathbf{s}} + \mathbf{v} \tag{5}$$

where $\overline{\mathbf{H}} \in \mathbb{C}^{n_R \times n_s}$, $\widetilde{\mathbf{H}} \in \mathbb{C}^{n_R \times (n_T - n_s)}$, $\overline{\mathbf{s}} \in \Omega^{n_s}$ and $\widetilde{\mathbf{s}} \in \Omega^{n_T - n_s}$ for fixed $n_s \in 1, \cdots, n_T$.

The partitioned model carries intrinsically an optimal permutation of the columns of $\mathbf{H}$ that determines $\overline{\mathbf{H}}$ and $\widetilde{\mathbf{H}}$. It is important to note that this optimal permutation is difficult to find out and depends on the selected detection method.

2.2 SUMIS algorithm review

SUMIS [13] algorithm is composed by two main stages and employs the partitioning model (5). This partition uses a permutation based on $\mathbf{H}^T\mathbf{H}$ as it is explained in [13]. In Stage I, a first approximation to the LLRs values are computed and then, in Stage II, new refined LLRs values are calculated using these approximate values.

Here we give a brief revision of SUMIS algorithm [13]. It is important to note that in [13] referring to a symbol is equivalent to a bit, which is not the case here.

Stage I: The algorithm begins with the partitioned model (5) denoting the new model as

$$\overline{\mathbf{y}} = \overline{\mathbf{H}}\overline{\mathbf{s}} + \mathbf{e} \tag{6}$$

where $\mathbf{e} = \widetilde{\mathbf{H}}\widetilde{\mathbf{s}} + \mathbf{v}$ is a Gaussian stochastic vector $\mathbf{e} \sim \mathcal{N}(\mathbf{0}, \mathbf{Q})$ with $\mathbf{Q} = \widetilde{\mathbf{H}}\widetilde{\mathbf{H}}^T + \frac{N_o}{2}\mathbf{I}$. We compute the approximate $\lambda_{j,b}$ LLR using the next operator $\|\mathbf{x}\|^2_{\mathbf{Q}} \triangleq \mathbf{x}^T\mathbf{Q}^{-1}\mathbf{x}$, as

$$\lambda_{j,b} = \log \frac{\sum_{\overline{\mathbf{s}} \epsilon \chi^0_{j,b}} \exp(-\frac{1}{2}\|\mathbf{y} - \overline{\mathbf{H}}\overline{\mathbf{s}}\|^2_Q)}{\sum_{\overline{\mathbf{s}} \epsilon \chi^1_{j,b}} \exp(-\frac{1}{2}\|\mathbf{y} - \overline{\mathbf{H}}\overline{\mathbf{s}}\|^2_Q)}. \tag{7}$$

Stage I is performed for all bits $b = 1, \cdots, k$ in all symbols $j = 1, \cdots, n_T$.

Stage II: In the second stage, the LLR values are computed again over a new model. In this context, the interfering vector $\widetilde{\mathbf{s}}$ is suppressed in (6) and the purified model is given by

$$\mathbf{y}' \triangleq \mathbf{y} - \widetilde{\mathbf{H}}\mathbb{E}\{\widetilde{\mathbf{s}}|\mathbf{y}\} \approx \overline{\mathbf{H}}\overline{\mathbf{s}} + \mathbf{n}', \tag{8}$$

where $\mathbb{E}\{\widetilde{\mathbf{s}}|\mathbf{y}\}$ is the conditional expected value of vector $\widetilde{\mathbf{s}}$, and $n' \backsim \mathcal{N}(\mathbf{0}, \mathbf{Q}')$ with $\mathbf{Q}' \triangleq \widetilde{\mathbf{H}}\widetilde{\mathbf{\Upsilon}}\widetilde{\mathbf{H}}^T + \frac{N_o}{2}\mathbf{I}$. $\widetilde{\mathbf{\Upsilon}}$ is the conditional covariance matrix of $\widetilde{\mathbf{s}}$ and can be computed by

$$\widetilde{\mathbf{\Upsilon}} = \mathbb{E}\{\mathrm{diag}(\widetilde{\mathbf{s}})^2|\mathbf{y}\} - \mathbb{E}\{\mathrm{diag}(\widetilde{\mathbf{s}})|\mathbf{y}\}^2 \tag{9}$$

 ISBN: 978-84-617-8694-7

where diag(∇) gives a diagonal matrix with the elements of ∇ vector on its diagonal. Hence, the refined LLR values can be computed as

$$L_{j,b} \approx \log \frac{\sum_{\bar{\mathbf{s}} \epsilon \chi^0_{j,b}} \exp(-\frac{1}{2}\|\mathbf{y}' - \overline{\overline{\mathbf{H}}}\bar{\mathbf{s}}\|^2_{Q'})}{\sum_{\bar{\mathbf{s}} \epsilon \chi^1_{j,b}} \exp(-\frac{1}{2}\|\mathbf{y}' - \overline{\overline{\mathbf{H}}}\bar{\mathbf{s}}\|^2_{Q'})}. \quad (10)$$

Note that the processing per bit can be performed in parallel. This allows for massively parallel algorithmic implementations such as those presented in this paper.

3 Proposed Parallelization

The use of the last generation of High Performance Computing (HPC) systems such as multi-core CPUs has become attractive for the efficient implementation of parallel signal processing algorithms with high computational requirements, such as high throughput MIMO detectors [17] or fast LDPC. The implementation of advanced algorithms able to use both architectures is crucial in MIMO research, since it allows to fully exploit the capabilities of the modern machine architectures and to reduce the response time of computationally expensive problems. The programming challenge involves the developers to know in depth different programming languages and the features of the architecture. In this sense, high performance libraries become valuable tools for specialists of a particular field, since they ease the development of scientific codes. The SUMIS algorithm computes the $\lambda_{j,b}$ and $L_{j,b}$ values using (7) and (10) respectively, where the number of terms in the two summations over $\bar{\mathbf{s}}$ is M^{n_s}. This implies that SUMIS algorithm has to compute the terms $\exp(-\frac{1}{2}\|\mathbf{y} - \overline{\overline{\mathbf{H}}}\bar{\mathbf{s}}\|^2_Q)$, a number of times M^{n_s} to get the total $\lambda_{j,b}$ or $L_{j,b}$ values in each stage. That is why almost the 98% of the total time of the detector is consumed in these two steps. Therefore, the parallelization is focused in reduce the computational cost of (7) and (10).

For the multicore implementation we are using the Intel Math Kernel Library (MKL) [18], which is composed of several optimized math routines including BLAS, LAPACK, ScaLAPACK, sparse solvers, fast Fourier transforms, etc, and is optimized specifically for Intel processors.

4 Results

Using Monte Carlo simulations we evaluate the performance of SUMIS and the algorithms chosen for comparison in terms of Bit Error Rate and Mutual Information. The transmitted symbols are assumed to be independent and uniformly distributed. The transmitted bits are encoded using a 1/2 LDPC code of codeword size 648 bits, which is available from http://www.csl.cornell.edu/vstuder/software ldpc.html and implements a LDCPC code from the IEEE 802.11n wireless LAN standard. There is no iteration between

 ISBN: 978-84-617-8694-7

the detector and the decoder and the sum-product algorithm option has been chosen as the decoding option. A machine with two multicore Intel processors has been employed. Each multicore is an Intel Xeon CPU E5-2697 at 2.70 GHz with 12 cores per CPU. We measure the execution time of the detection, with different number of antennas and constellation sizes to evaluate the SUMIS efficiency of the proposed parallel prototypes.

It is interesting to note how parallel versions allow to boost the performance of the system with a speed comparable to a low-complexity linear detector such as MMSE.

Thus, we can detect signals with a similar and even higher throughput than the MMSE detector with much better BER.

5 Conclusion

In this paper, we have proposed and analyzed parallel SUMIS Soft Detector implementations. We have also studied its performance in terms of BER performance, mutual information, complexity and speedup. These measures have been compared with those of the state-of-art soft-output detectors such as FPFSD and MMSE detectors. Furthermore, the experiments have been realized considering very large MIMO systems reaching up to 200 transmitter/receiver antennas and up to 1024-QAM constellations. This comparison shows the robust behavior of the SUMIS algorithm. This detector behaves much more efficiently than the other detectors in terms of BER, achieving up to 5 dB improvement in SNR compared to FPFSD.

Résumé

In this work, an Alternating Direction Implicit method (ADI) for solving monodomain model that describes the propagation of the electrical potential in cardiac tissue is presented. The proposed numerical algorithm is of second order in space and time and allows the use of large grids for accurate simulation of the cardiac electrical wave fronts. Two-dimensional numerical results are presented illustrating the advantages of the proposed method in terms of computational time and memory consumption.

Key words: Alternating Direction Implicit Method, Monodomain Model, Aliev-Panfilov Model.

1 Introduction

The bidomain model and its simplified version, the monodomain model, are considered the most used mathematical equations for simulating the cardiac electrical activity. The numerical solution of these models is a computationally challenging problem and is known that they require high space and time resolutions (see Clayton et al. [5]).

Many methods have been developed in the literature to decrease the computational cost of the simulations. Different approaches were implemented for time discretization, including semi-implicit methods (see Keener and Bogar [8], Franzone and Pavarino [10], and Bourgault and Ethier [9]), fully implicit methods (see Ying et al. [19], Dal et al. [7], and Belhamadia [2]), and operator splitting methods (see Schroll et al. [16], Spiteri and Ziaratgahi [17], and Sundnes et al. [18]). A variety of numerical methods were also used for space discretization using both uniform meshes (see Franzone et al. [11] and Scacchi [15]) and adapted meshes (see Whiteley [20], Cherry et al. [6], Belhamadia et al. [3, 4] and the references therein).

 ISBN: 978-84-608-6082-2

In this work, we suggest implementing the Alternating Direction Implicit Method (ADI) for solving the Aliev-Panfilov monodomain model. The proposed method is based on the original work of Peaceman and Rachford where the ADI method was proposed for the first time as a type of finite difference method for solving two dimensional parabolic and elliptic Partial differential equation. The ADI algorithm presented in this work is of se-cond order in space and time and has the advantage to use large grids for accurate and efficient simulation while reducing the computational time and the memory consumption. A comparison between the suggested scheme and the second order Crank-Nicolson-Adams-Bashforth semi-implicit scheme (CNAB) proposed in [9] is performed showing the accuracy of the suggested method.

This paper is organized as follows. Next section is devoted to the monodomain model, section 2 describes the ADI method and CNAB method, and section 3 presents two-dimensional numerical quantitative results.

2 Aliev-Panfilov Monodomain Model

A simplification of the so-called bidomain model, by assuming equal anisotropy, is the monodomain model. This model describes the cardiac electrical activity and has the form :

$$\begin{cases} \dfrac{\partial V}{\partial t} - \nabla \cdot (D \nabla V) = I_{ion}(V, W_n) \\ \dfrac{\partial W_n}{\partial t} = g(V, W_n) \end{cases} \tag{1}$$

Where V is the transmembrane potential and W_n is a set of cell-level variables such as ion concentrations and gating variables. In this work, we will use the Aliev-Panfilov ionic model [1] that contains only one gating variable but it still reproduces realistic shape of the cardiac action potential. This ionic model consists of the following nonlinear equations :

$$I_{ion}(V, W) = kV(V - \alpha)(1 - V) - VW, \tag{2}$$

$$g(V, W) = \left(\epsilon + \frac{\mu_1}{\mu_2 + V}\right)(-W - kV\,(V - \alpha - 1))\,. \tag{3}$$

All the parameters including the time t are dimensionless and will be determined in the numerical simulation section. The boundary conditions considered are homogeneous Neumann boundary conditions.

3 Numerical Method

In this work, we will consider an alternating direction implicit method (ADI) to solve the Aliev-Panfilov monodomain model. We limit our work to the two dimensional case. The

 ISBN: 978-84-608-6082-2

ADI method is a type of finite difference method and thus the continuous space domain should be discretized into a mesh with a finite number of grid points. To ensure the second order in space, we use the second-order central difference operators δ_x^2 and δ_y^2 for the second derivatives with respect to x and y respectively :

$$(\delta_x^2 V^n)_{i,j} = \frac{V_{i+1,j}^n - 2V_{i,j}^n + V_{i-1,j}^n}{(\Delta x)^2}, \qquad (\delta_y^2 V^n)_{i,j} = \frac{V_{i,j+1}^n - 2V_{i,j}^n + V_{i,j-1}^n}{(\Delta y)^2}. \tag{4}$$

To ensure the second order in time the following time-dependent algorithm will be used :

Step 1 : on the interval $[t_n, t_{n+\frac{1}{2}}]$

We first get the solutions $(V^{n+\frac{1}{2}}, W^{n+\frac{1}{2}})$ at the mid time $t_{n+\frac{1}{2}}$, based on the following equations :

$$\begin{cases} \dfrac{V^{n+\frac{1}{2}} - V^n}{\frac{\Delta t}{2}} &= D\delta_x^2 V^{n+\frac{1}{2}} + D\delta_y^2 V^n + \dfrac{3}{2} I_{ion}(V^n, W^n) - \dfrac{1}{2} I_{ion}(V^{n-1}, W^{n-1}) \\ \dfrac{W^{n+\frac{1}{2}} - W^n}{\frac{\Delta t}{2}} &= \dfrac{3}{2} g(V^n, W^n) - \dfrac{1}{2} g(V^{n-1}, W^{n-1}) \end{cases} \tag{5}$$

This steps applies an implicit update in the x-direction and explicit update in the y-direction on the time interval $[t_n, t_{n+\frac{1}{2}}]$.

Step 2 : on the interval $[t_{n+\frac{1}{2}}, t_{n+1}]$

The final solutions (V^{n+1}, W^{n+1}) at the time step t_{n+1} is then calculated using the following equations :

$$\begin{cases} \dfrac{V^{n+1} - V^{n+\frac{1}{2}}}{\frac{\Delta t}{2}} &= D\delta_x^2 V^{n+\frac{1}{2}} + D\delta_y^2 V^{n+1} + \dfrac{3}{2} I_{ion}(V^n, W^n) - \dfrac{1}{2} I_{ion}(V^{n-1}, W^{n-1}) \\ \dfrac{W^{n+1} - W^{n+\frac{1}{2}}}{\frac{\Delta t}{2}} &= \dfrac{3}{2} g(V^n, W^n) - \dfrac{1}{2} g(V^{n-1}, W^{n-1}) \end{cases} \tag{6}$$

In this step, the method applies an implicit update in the y-direction and explicit update in the x-direction on the time interval $[t_{n+\frac{1}{2}}, t_{n+1}]$.

The above algorithm is of second order is space and time (see Rammal [14]) and is based on the work of Peaceman and Rachford [13]. Since the monodomain model is combined with homegenous homogenous boundary conditions, and in order to keep the second-order accuracy, the central-difference approximation will be used to discretize these boundary

conditions. This implies the introduction of the virtual points by expanding the region with Δx to the left and right and with Δy to the bottom and top, and for more details the reader is referred to [14].

To verify the efficiency of the above-mentioned ADI method, a comparison with the second order Crank-Nicolson-Adams-Bashforth semi-implicit scheme (CNAB) will be presented. The CNAB method was proposed in [9] as an impressive scheme compared to different type of first, second, and third other schemes and this is why it was chosen for this study. The algorithm for CNAB method for solving the Aliev-Panfilov monodomain model takes the form :

$$\begin{cases} \dfrac{V^{n+1}-V^n}{\Delta t} &= \dfrac{1}{2}(D\delta_x^2 V^{n+1} + D\delta_y^2 V^{n+1}) + \dfrac{1}{2}(D\delta_x^2 V^n + D\delta_y^2 V^n) \\ & \quad + \dfrac{3}{2} I_{ion}(V^n, W^n) - \dfrac{1}{2} I_{ion}(V^{n-1}, W^{n-1}) \\ \dfrac{W^{n+1}-W^n}{\Delta t} &= \dfrac{3}{2} g(V^n, W^n) - \dfrac{1}{2} g(V^{n-1}, W^{n-1}) \end{cases} \tag{7}$$

This method is of second order in space and time and for more details the reader is refereed to [9].

4 Numerical Results

This section is devoted to a quantitative comparison of the solutions obtained with ADI and CNAB methods. The computational domain is $[0,\ 100] \times [0,\ 100]$. The initial transmembrane potential V and the recovery variable W are given by :

$$V(x,t) = \begin{cases} 1 & \text{if } \sqrt{(x-50)^2 + (y-50)^2} < 10 \\ 0 & \text{if } \sqrt{(x-50)^2 + (y-50)^2} \geq 10, \end{cases} \quad \text{and } W(x,t) = 0.$$

In the numerical simulations, the following physical parameters are used :

parameter	k	α	ϵ	μ_1	μ_2	D
value	8	0.15	0.002	0.2	0.3	1

The time evolution of the transmembrane potential is presented in Figure 1. As can be seen, the wave is initiated as a circular wave in the center of the computational domain and

 ISBN: 978-84-608-6082-2

it propagates in a similar manner till it reaches the boundaries, an expected behaviour of this model.

Now, to illustrate the efficiency of the ADI scheme applied to the Aliev-Panfilov monodomain model, a comparison with CNAB scheme is presented in terms of memory and run time. Both methods are tested using the same number of time iterations to obtain the same numerical solution, are executed using MATLAB, and are run using the same computer with Intel(R) Core(TM) i7 − 4790 CPU processor, and 8.00 GB installed memory functioning with a 64-bit operating system.

First, figure 2 shows a memory consumption required for both the CNAB and ADI methods. As can be seen in this figure, the memory consumption of the CNAB increases dramatically. However, the ADI keeps running even with large grids, and while doing so, the memory consumption remains considerably low compared to what is consumed by CNAB method.

Second, figure 3 shows the computational time required for both the CNAB and ADI methods. As can be seen, the time required to run CNAB with 400 space steps is close to that needed by the ADI to run with 1200 space steps. The rapid results provided by the ADI is a powerful advantage for simulating a model that aims to capture the behaviour of a sharp cardiac electrical wave.

5 Conclusion

A numerical algorithm based on the alternation direction implicit method for solving the Aliev-Panfilov monodomain model was presented. The efficiency of the this algorithm was provided though demonstrating the difference in the run-time and memory requirements between this method and Crank-Nicolson-Adams-Bashforth method. The numerical simulations has shown that the ADI algorithm not only speeds up the run-time but also reduces memory usage over the standard numerical methods used for solving the electrocardiology models.

Abstract

In this work we study the zero forcing problem and some variants of it attending to the connectivity of the subgraph generated by the zero forcing set. A set Z of vertices of a graph G is a zero forcing set of G if iteratively adding to Z vertices from $V(G)\backslash Z$ that are the unique neighbor in $V(G)\backslash Z$ of some vertex in Z, results in the entire vertex set $V(G)$ of G. The zero forcing number $Z(G)$ of G is the minimum cardinality of a zero forcing set of G.
This study is restricted to maximal outerplanar graphs. We establish tight combinatorial bounds for zero forcing, total zero forcing and connected zero forcing for any n-vertex maximal outerplanar graph.

Key words: zero forcing, maximal outerplanar graphs
MSC 2000: AMS codes 05C69, 05C85

1 Introduction

Given a graph $G = (V, E)$ a zero forcing set is a set $Z \subseteq V$ such that every proper subset $\bar{Z} \subseteq V$ with $\bar{Z} \subseteq Z$ contains a vertex that has exactly one neighbour in $V\backslash\bar{Z}$. Equivalently, the Zero Forcing process is a discrete-time process in which we have a set of vertices of a graph G that is initially colored black, while the remaining vertices are colored white. At each time step, the color change rule is applied. Once a vertex has been changed to black, it remains black forever. The process terminates if all of the vertices are colored black in finite time. Otherwise, if there are some white vertices that are unable to be colored in finite time, then we may artificially halt the process. The zero forcing number $Z(G)$ of G is the minimum cardinality of a zero forcing set of G.

 ISBN: 978-84-617-8694-7

The zero forcing problem was introduced in [2] as an upper bound for the maximum nullity of real symmetric matrices whose nonzero pattern of off-diagonal entries is described by a given graph, and independently by mathematical physicists studying control of quantum systems. Furthermore, it is related with the power domination concept, which was first studied by Haynes et al. [3] for monitoring electric power systems. The relationship between both was stablished in [4].

Results on the zero forcing number for trees and unicyclic graphs were stablished in [5]. Also, Davila et al. studied this problem for graphs with a given girth in [6]. They proved that $Z(G) \geq \delta + (\delta - 2)(\delta - 3)$ where G is a graph with a given girth $g \geq 3$ and minimum degree $\delta \geq 2$. Moreover, results on the connected and total zero forcing were shown in [7] and [8] respectively.

The domination problem in outerplanar graphs has received special attention in recent years [1]. A graph is outerplanar if it has a crossing-free embedding in the plane such that all vertices are on the boundary of its outer face (the unbounded face). An outerplanar graph is maximal if it is not possible to add an edge such that the resulting graph is still outerplanar. A maximal outerplanar graph embedded in the plane corresponds to a triangulation of a polygon.

In this study we establish tight combinatorial bounds for the zero forcing number and the following zero forcing variants: connected and total. Our results are restricted to maximal outerplanar graphs.

2 Connected and Total Zero Forcing in MOPs

Let G be a graph of order n and Z a zero forcing set of G. By imposing different connectivity conditions to the subgraph generated by Z, $G[Z]$, we have some variants on zero forcing. In this work we will study the following ones: connected zero forcing, if $G[Z]$ is connected; total zero forcing, if $G[Z]$ does not contain isolated vertices. We denote the connected and total forcing number by $Z_C(G)$ and $Z_T(G)$ respectively.

A triangle face T is a separator triangle of G, maximal outerplanar graph, if it has no edges in the outer face. The number of separator triangles of G is denoted by t. A MOP is serpentine if $t = 0$. We denote with G_Δ to the subgraph formed by the separator triangles of G.

The dual tree of G (weak dual) is denoted by H. We describe as serpentine leaf to the

 ISBN: 978-84-617-8694-7

set of triangles corresponding to the only path in H that connects a leaf of H with a vertex u with $degree(u) > 2$. We denote the number of serpentine leafs by h, and the number of serpentine leafs with fan structure, called fan leafs, by h_F such as $h_F \leq h$. In addition, we denoted by c to the number of minimum paths in H between vertices with degree 3.

3 Results

According to the previous definitions we establish the following theorems.

Theorem 1. *If G is a serpentine graph, then*

$$Z(G) = Z_T(G) = Z_C(G) = 2$$

Theorem 2. *If G is a maximal outerplanar graph with $t = 1$ and $h_F \geq 0$, then*

1. *If $h_F \geq 2$, $Z(G) = Z_T(G) = 3$*
2. *If $h_F = 1$, $Z(G) = 3$ and $Z_T(G) = 4$*
3. *If $h_F = 0$, $Z(G) = Z_T(G) = 4$*

In addition, the zero forcing set of minimum cardinality is explicitly obtained for each maximal outerplanar graph.

Theorem 3. *If G is a maximal outerplanar graph with h serpentine leafs and h_F fan leafs, whose G_Δ is connected, then*

$$Z(G) \leq Z_T(G) \leq 2\lceil \tfrac{h}{2} \rceil$$

with equality if and only if $h_F = 0$.

In the extended version of this work, we explain how the zero forcing set of minimum cardinality is obtained when $h_F = 0$.

Now, take into account the above theorems, we may establish an upper bound on the zero forcing number and the total zero forcing number for any maximal outerplanar graph.

Theorem 4. *If G is a maximal outerplanar graph with h serpentine leafs and c serpentine paths, then*

$$Z(G) \leq Z_T(G) \leq 2\lceil \tfrac{h+c}{2} \rceil$$

and these bounds are tight when G_Δ is connected.

As future work we are working on an algorithm to find the minimum zero forcing set for any maximal outerplanar graph. New theorems and results will be presented in an extended version of this work.

Abstract

This work considers a generalized family of Rosenau-RLW equations depending on an arbitrary function $f(u)$. This family of equations is interesting from the point of view of shallow water waves theory, because particular equations in the family have been shown to model wave interactions that are not possible to be described with the Korteweg-de Vries equation. We will present a complete classification of conservation laws for this dispersive wave equation and we will apply Lie symmetry analysis to the equation in order to find exact solutions.

Key words: Nonlinear partial differential equation, Lie symmetries, Conservation laws

1 Introduction

The Rosenau equation [8, 9], given by

$$u_t \pm (u + u^2)_x + u_{xxxxt} = 0, \tag{1}$$

is a fifth-order dispersive wave equation that provides a good model for a two-sided wave propagation, nonlinear wave-wave and wave-wall interactions. Some of these interactions cannot be described by the Korteweg-de Vries (KdV) equation $u_t - \alpha u u_x + u_{xxx} = 0$.

Another well-known third-order dispersive wave equation that improves the KdV equation for long waves is the Benjamin-Bona-Mahony or regularized long-wave (RLW) equation, given by

$$u_t + (u + u^2)_x - u_{xxt} = 0. \tag{2}$$

 ISBN: 978-84-617-8694-7

Recently, a viscous Rosenau equation, given by

$$u_t + au_x + \epsilon(u^4)_x - bu_{xx} - cu_{xxt} - du_{xxxxt} = 0, \tag{3}$$

with a, ϵ, b, c and d arbitrary constants, has been considered and its solitary wave solution has been studied numerically [7].

In this paper, we consider a more general family of Rosenau-RLW equations, that includes equations (1), (2) and (3), given by

$$\Delta \equiv u_t + au_x + (f(u))_x - bu_{xx} - cu_{xxt} - du_{xxxxt} = 0, \tag{4}$$

for $u(t, x)$ where the nonlinear advective term depends on an arbitrary function $f(u)$ and a, b, c and d are arbitrary constants. Since particular equations in the family (4) have been shown to describe some interactions that cannot be explained with the KdV equation, we are interested in finding exact solutions that model this kind of behaviour.

Local conservation laws are continuity equations that provide physical conserved quantities for all solutions. In addition, they can be used to check the accuracy of numerical methods. We will carry out a complete classification of local conservation laws for the Rosenau-RLW equation (4) by using a general method based on multipliers [1, 2, 3, 4, 5].

Symmetry methods applied to partial differential equations lead to reductions and exact invariant solutions. In particular, invariant solutions can be used to study analytical properties such as asymptotic behaviour and blow-up behavior and to check the accuracy of numerical integrators. A point symmetry classification of equation (4) is presented in terms of the function $f(u)$. The required theory can be found in [5, 6].

2 Conservation Laws

A local conservation law for the generalized Rosenau-RLW equation (4) is a space-time divergence expression

$$D_t T + D_x X = 0 \tag{5}$$

holding for all solutions $u(t, x)$ of equation (4), where the conserved density T and the flux X are functions of t, x, u and its derivatives. If a conserved density is a total x-derivative, $T = D_x\Psi$, when it is restricted to the solution space, then the conservation law (5) holds trivially, with the flux being a total t-derivative, $X = -D_t\Psi$, when it is restricted to the solution space. Such conservation laws are called locally trivial, and any conservation laws that differ by a locally trivial conservation law are called locally equivalent. The set of all admitted conservation laws forms a vector space, in which the set of locally trivial conservation laws is a subspace.

All nontrivial local conservation laws can be obtained by the multiplier method [6, 3, 4, 1]. A function Q of t, x u, and derivatives of u is a multiplier for a local conservation law iff

 ISBN: 978-84-617-8694-7

the product of Q and the equation (4) is a total divergence with respect to t and x. All multipliers can be determined by the condition that a function $h(t, x, u, u_x, u_t, u_{xx}, u_{tx}, u_{tt}, \ldots)$ is such a divergence iff $E_u(h) = 0$ holds identically, where E_u denotes the Euler operator. It is straightforward to show that multipliers are related to conserved densities by $Q = E_u(T)$. As a consequence, all locally equivalent conservation laws have the same multiplier, and hence there is a one-to-one correspondence between multipliers and conserved densities (up to local equivalence). This result holds more generally for any evolution equation [6, 3, 4, 1].

For dispersive nonlinear evolution equations, conservation laws of physical importance come from low-order multipliers [1]. For the Rosenau-RLW equation (4), the dependence of low-order multipliers Q in terms of u and derivatives of u is given by those variables that can be differentiated to obtain a leading derivative of equation (4). This yields

$$Q(t, x, u, u_t, u_x, u_{xt}, u_{xx}, u_{xxt}, u_{xxx}, u_{xxxt}, u_{xxxx}) \tag{6}$$

as the general form for a low-order multiplier. All low-order multipliers (6) can be found by solving the determining equation $E_u((u_t + au_x + (f(u))_x - bu_{xx} - cu_{xxt} - du_{xxxxt})Q) = 0$, yielding an overdetermined system in Q, f and the parameters a, b, c, d.

The complete classification of low-order multiplier and corresponding densities and fluxes will be presented in the talk.

3 Lie symmetries

A point symmetry of the generalized Rosenau-RLW equation (4) is a one-parameter Lie group of transformations on (t, x, u) generated by a vector field of the form

$$\mathbf{X} = \tau(t, x, u)\partial_t + \xi(t, x, u)\partial_x + \eta(t, x, u)\partial_u, \tag{7}$$

whose prolongation leaves invariant equation (4).

The condition for a vector field (7) to generate a point symmetry of equation (4) is given by

$$\mathrm{pr}^{(5)}\mathbf{X}(\Delta) = 0 \quad \text{when} \quad \Delta = 0, \tag{8}$$

where $\mathrm{pr}^{(5)}\mathbf{X}$ is the fifth prolongation of the vector field (7). The equation (8) splits with respect to the x and t derivatives of u giving an overdetermined linear system of equations for the infinitesimals $\xi(t, x, u)$, $\tau(t, x, u)$, $\eta(t, x, u)$, f and the parameters a, b, c, d. Solving this system we obtain:

Theorem 1 *Group Classification Theorem:*
The Lie point symmetry group of the generalized Rosenau-RLW equation (4) with $f(u)$ an arbitrary function, is determined by the generators

$$\mathbf{X}_1 = \partial_t, \quad \mathbf{X}_2 = \partial_x. \tag{9}$$

 ISBN: 978-84-617-8694-7

If $f(u) = \alpha(\beta - u)^n - a$, *the symmetry group is determined by generators* $\mathbf{X}_1$ *and* $\mathbf{X}_2$ *and*

$$\mathbf{X}_3 = t\partial_t + \frac{1}{n}(\beta - u)\partial_u. \tag{10}$$

Abstract

The aim of this paper is to obtain new inequalities involving the first general Zagreb index, and characterize graphs which are extremal with respect to them. We also obtain inequalities involving the forgotten and second general Zagreb indices.

Key words: Graph invariant, Topological index, forgotten index, variable Zagreb index, general Zagreb index
MSC 2000: 05C07, 92E10

1 Introduction

A topological index is defined as a single number that represents a chemical structure in graph-theoretical terms, and that correlates with a molecular property; it is used to understand physicochemical properties of chemical compounds. Topological indices are interesting since they capture some of the properties of a molecule in a single number.

Although only about 1000 benzenoid hydrocarbons are known, the number of possible benzenoid hydrocarbons is huge. For instance, the number of possible benzenoid hydrocarbons with 35 benzene rings is 5851000265625801806530 [32]. Therefore, the modeling of their physico-chemical properties is very important in order to predict properties of currently unknown species.

 ISBN: 978-84-617-8694-7

Hundreds of topological indices have been introduced and studied, starting with the seminal work by Wiener [33] in which he used the sum of all shortest-path distances of a (molecular) graph for modeling physical properties of alkanes.

Topological indices based on end-vertex degrees of edges have been used over 40 years. Among them, several indices are recognized to be useful tools in chemical researches. Probably, the best known of such descriptors is the Randić connectivity index (R) [22]. There are more than thousand papers and a couple of books dealing with this index (see, e.g., [11], [14], [27], [28] and the references therein). During many years, scientists were trying to improve the predictive power of the Randić index. This led to the introduction of a large number of new topological descriptors resembling the original Randić index.

The reason for introducing a new index is to gain prediction of some property of molecules somewhat better than obtained by already presented indices. Therefore, a test study of predictive power of a new index must be done.

Two of the main successors of the Randić index are the first and second Zagreb indices, denoted by M_1 and M_2, respectively, and introduced by Gutman et al. in 1972 (see [12]). They are defined as

$$M_1(G) = \sum_{u \in V(G)} d_u^2, \qquad M_2(G) = \sum_{uv \in E(G)} d_u d_v,$$

where uv denotes the edge of the graph G connecting the vertices u and v, and d_u is the degree of the vertex u.

In the same paper, where Zagreb indices were introduced, the *forgotten topological index* (or *F-index*) is defined as

$$F(G) = \sum_{u \in V(G)} d_u^3.$$

Both the forgotten topological index and the first Zagreb index were employed in the formulas for total π-electron energy in [12], as a measure of branching extent of the carbon-atom skeleton of the underlying molecule. However, this index never got attention except recently, when Furtula et al. in [9] established some basic properties of the F-index and showed that its predictive ability is almost similar to that of first Zagreb index and for the entropy and acetic factor, both of them yield correlation coefficients greater than 0.95. Besides, [9] pointed out the importance of the F-index: it can be used to obtain a high accuracy of the prediction of logarithm of the octanol-water partition coefficient (see also [1]). Recently, this index has been studied for different graph operations [6]. The coindex version of the forgotten index is also introduced in [7]. The extremal trees with respect to the F-index have been investigated in [1]. Furthermore, [5] and [26] contain more lower and upper bounds for the forgotten index.

Miličević and Nikolić defined in [18] the *first and second variable Zagreb indices* as

$$^{\alpha}M_1(G) = \sum_{u \in V(G)} d_u^{2\alpha}, \qquad ^{\alpha}M_2(G) = \sum_{uv \in E(G)} (d_u d_v)^{\alpha},$$

 ISBN: 978-84-617-8694-7

with $\alpha \in \mathbb{R}$. In [16] and [4] the *first and second general Zagreb indices* are introduced as

$$M_1^\alpha(G) = \sum_{u \in V(G)} d_u^\alpha, \qquad M_2^\alpha(G) = \sum_{uv \in E(G)} (d_u d_v)^\alpha,$$

respectively. It is clear that these indices are equivalent to the previous ones, since ${}^\alpha M_1(G) = M_1^{2\alpha}(G)$ and ${}^\alpha M_2(G) = M_2^\alpha(G)$. We prefer to use $M_1^\alpha(G)$ instead of ${}^\alpha M_1(G)$ since the inequalities obtained in this paper become simpler with it.

Note that M_1^1 is $2m$, M_1^2 is the first Zagreb index M_1, M_1^{-1} is the inverse index $ID(G)$ [8], M_1^3 is the forgotten index $F(G)$, etc.; also, $M_2^{-1/2}$ is the usual Randić index, M_2^1 is the second Zagreb index M_2, M_2^{-1} is the modified Zagreb index [20], etc. Note that it is interesting to study M_1^α for $\alpha \neq 0, 1$, and M_2^α for $\alpha \neq 0$, since if G has n vertices and m vertices, then $M_1^0(G) = n$, $M_1^1(G) = 2m$ and $M_2^0(G) = m$.

The concept of the variable molecular descriptors was proposed as a new way of characterizing heteroatoms in molecules (see [23], [24]), but also to assess the structural differences (e.g., the relative role of carbon atoms of acyclic and cyclic parts in alkylcycloalkanes [25]). The idea behind the variable molecular descriptors is that the variables are determined during the regression so that the standard error of estimate for a studied property is as small as possible. The second variable Zagreb index is used in the structure-boiling point modeling of benzenoid hydrocarbons [21]. Various properties and relations of these indices are discussed in several papers (see, e.g., [3], [15], [17], [30], [34], [35]).

The aim of this paper is to obtain new inequalities involving the first general Zagreb index, and characterize graphs which are extremal with respect to them. We also obtain inequalities involving the forgotten and second general Zagreb indices.

Throughout this paper, $G = (V(G), E(G))$ denotes a (non-oriented) finite simple (without multiple edges and loops) nontrivial ($E(G) \neq \emptyset$) graph.

2 Some bounds for M_1^α

We start with some bounds for M_1^α involving different parameters.

Theorem 2.1. *Let G be a nontrivial graph with m edges, maximum degree Δ and minimum degree δ, and $\alpha \in \mathbb{R}$. Then*

$$2\Delta^{\alpha-1}m \leq M_1^\alpha(G) \leq 2\delta^{\alpha-1}m, \qquad \text{if } \alpha < 1,$$
$$2\delta^{\alpha-1}m \leq M_1^\alpha(G) \leq 2\Delta^{\alpha-1}m, \qquad \text{if } \alpha \geq 1,$$

and the equality holds in each inequality for some $\alpha \neq 1$ if and only if G is regular.

Theorem 2.2. *Let G be a nontrivial graph with n vertices and m edges, and $\alpha \in \mathbb{R}$. Then*

$$M_1^\alpha(G) \geq 2m\alpha + n(1-\alpha), \qquad \text{if } \alpha \leq 0 \text{ or } \alpha \geq 1,$$
$$M_1^\alpha(G) \leq 2m\alpha + n(1-\alpha), \qquad \text{if } 0 < \alpha < 1.$$

 ISBN: 978-84-617-8694-7

The equality holds in the inequality for some $\alpha \neq 0, 1$ if and only if G is a union of pairwise disjoint edges.

Next, we have inequalities relating two indices M_1^α and M_1^β.

Theorem 2.3. *Let G be a nontrivial graph with n vertices, maximum degree Δ and minimum degree δ, and $\alpha, \beta \in \mathbb{R}$. Then*

$$\begin{aligned} M_1^\alpha(G) &\leq \delta^{\alpha-\beta} M_1^\beta(G), && \text{if } \alpha \leq \beta, \\ M_1^\alpha(G) &\leq \Delta^{\alpha-\beta} M_1^\beta(G), && \text{if } \alpha \geq \beta, \\ M_1^\alpha(G) &\geq \frac{\Delta^{\alpha+\beta} n^2}{M_1^\beta(G)}, && \text{if } \alpha \leq -\beta, \\ M_1^\alpha(G) &\geq \frac{\delta^{\alpha+\beta} n^2}{M_1^\beta(G)}, && \text{if } \alpha \geq -\beta. \end{aligned}$$

The equality is attained in the lower bound with $(\alpha, \beta) \neq (0, 0)$ if and only if G is regular; if $\alpha = \beta = 0$, then the lower bound is attained for every graph. The equality holds in the upper bound for some $\alpha \neq \beta$ if and only if G is regular; if $\alpha = \beta$, then the upper bound is attained for every graph.

Proposition 2.4. *Let G be a nontrivial graph with n vertices, $s > 0$ and $\alpha \in \mathbb{R}$. Then*

$$2sn \leq s^2 M_1^\alpha(G) + M_1^{-\alpha}(G),$$

Theorem 2.5. *Let G be a nontrivial graph with n vertices, $\alpha \in \mathbb{R}$ and $\beta > 0$. Then*

$$n^{\beta+1} \leq M_1^{-\alpha\beta}(G) M_1^\alpha(G)^\beta,$$

and the equality is attained for some values $\alpha \neq 0$ and β if and only if G is regular.

The following result appears in [31].

Lemma 2.6. *If $\alpha \geq 1$ is an integer and $0 \leq x_1, \ldots, x_n \leq n-1$, then*

$$\Big(\sum_{j=1}^n x_j^\alpha \Big)^{1/\alpha} \leq (n-1)^{1-1/\alpha} \sum_{j=1}^n x_j^{1/\alpha}.$$

We have a generalization of this lemma which is interesting by itself.

Lemma 2.7. *Consider real numbers $0 < \beta \leq 1 \leq \alpha$, $\Delta > 0$ and $0 \leq x_1, \ldots, x_n \leq \Delta$. Then*

$$\Big(\sum_{j=1}^n x_j^\alpha \Big)^{1/\alpha} \leq \Delta^{1-\beta} \sum_{j=1}^n x_j^\beta.$$

 ISBN: 978-84-617-8694-7

This lemma allows to prove the following result.

Proposition 2.8. *Let G be a nontrivial graph with maximum degree Δ, and consider real numbers $0 < \beta \leq 1 \leq \alpha$. Then*

$$M_1^{\alpha}(G)^{1/\alpha} \leq \Delta^{1-\beta} M_1^{\beta}(G).$$

Theorem 2.9. *Let G be a nontrivial graph with n vertices, maximum degree Δ and minimum degree δ, and $\alpha \in \mathbb{R}$. Then*

$$\frac{2(\Delta\delta)^{\alpha/2}}{\Delta^{\alpha}+\delta^{\alpha}} \sqrt{nM_1^{2\alpha}(G)} \leq M_1^{\alpha}(G) \leq \sqrt{nM_1^{2\alpha}(G)}\,.$$

The lower bound is attained for every value of α if G is regular. The upper bound is attained for some $\alpha \neq 0$ if and only if G is regular.

Proposition 2.10. *Let G be a nontrivial graph with n edges, maximum degree Δ and minimum degree δ, and $\alpha \in \mathbb{R}$. Then*

$$M_1^{\alpha}(G) + (\Delta\delta)^{\alpha} M_1^{-\alpha}(G) \leq n(\Delta^{\alpha}+\delta^{\alpha}),$$

and the equality holds for some $\alpha \neq 0$ if and only if $d_u \in \{\Delta, \delta\}$ for every $u \in V(G)$.

Theorem 2.11. *Let G be a nontrivial graph with n vertices, and $\alpha, \beta \in \mathbb{R}$ with $\alpha > 0$. Then*

$$\begin{aligned} n + \alpha M_1^{\beta}(G) &\leq \left(M_1^{\alpha\beta}(G)^{1/\alpha} + n^{1/\alpha}\right)^{\alpha}, && \text{if } \alpha \geq 1, \\ n + \alpha M_1^{\beta}(G) &\geq \left(M_1^{\alpha\beta}(G)^{1/\alpha} + n^{1/\alpha}\right)^{\alpha}, && \text{if } 0 < \alpha < 1. \end{aligned}$$

Theorem 2.12. *Let G be a nontrivial graph with n vertices, and $\alpha, \beta \in \mathbb{R}$ with $\beta > 0$. Then*

$$\begin{aligned} M_1^{\alpha+\beta}(G) &\geq \frac{1}{n} M_1^{\alpha}(G) M_1^{\beta}(G), && \text{if } \alpha \geq 0, \\ M_1^{\alpha+\beta}(G) &\leq \frac{1}{n} M_1^{\alpha}(G) M_1^{\beta}(G), && \text{if } \alpha \leq 0, \end{aligned}$$

and the equality holds in the inequality for some $\alpha \neq 0$ if and only if G is regular.

Since $M_1^1(G) = 2m$, Theorem 2.12 has the following consequence.

Corollary 2.13. *Let G be a nontrivial graph with n vertices and m edges, and $\alpha \in \mathbb{R}$. Then*

$$\begin{aligned} M_1^{\alpha+1}(G) &\geq \frac{2m}{n} M_1^{\alpha}(G), && \text{if } \alpha \geq 0, \\ M_1^{\alpha+1}(G) &\leq \frac{2m}{n} M_1^{\alpha}(G), && \text{if } \alpha \leq 0, \end{aligned}$$

and the equality holds in the inequality for some $\alpha \neq 0$ if and only if G is regular.

 ISBN: 978-84-617-8694-7

3 Inequalities for M_1^α involving other topological indices

The previous results for the first general Zagreb index hold, in particular, for the forgotten index. Next, we obtain particular bounds for the forgotten index.

Theorem 3.1. *Let G be a nontrivial graph with maximum degree Δ and minimum degree δ. Then*

$$\frac{4M_2^2(G)}{\Delta^2} - 2M_2(G) \leq F(G) \leq \frac{4M_2^2(G)}{\delta^2} - 2M_2(G),$$

and each inequality is attained if and only if G is regular.

We also have some inequalities relating the first and second general Zagreb indices.

Theorem 3.2. *Let G be a nontrivial graph with maximum degree Δ and minimum degree δ, and $\alpha \in \mathbb{R}$. Then*

$$\begin{aligned} 2\Delta^{1-\alpha}M_2^{\alpha-1}(G) \leq M_1^\alpha(G) \leq 2\delta^{1-\alpha}M_2^{\alpha-1}(G), \qquad & \text{if } \alpha \geq 1, \\ 2\delta^{1-\alpha}M_2^{\alpha-1}(G) \leq M_1^\alpha(G) \leq 2\Delta^{1-\alpha}M_2^{\alpha-1}(G), \qquad & \text{if } \alpha \leq 1, \end{aligned}$$

and the equality holds in each inequality for some $\alpha \neq 1$ if and only if G is regular.

The *modified Narumi-Katayama index*

$$NK^*(G) = \prod_{u \in V(G)} d_u^{d_u} = \prod_{uv \in E(G)} d_u d_v$$

is introduced in [10], inspired in the Narumi-Katayama index defined in [19]. Finally, we present an inequality relating the modified Narumi-Katayama and the first general Zagreb indices.

Theorem 3.3. *Let G be a nontrivial graph with m edges, and $\alpha \in \mathbb{R}$. Then*

$$M_1^\alpha(G) \geq 2m\, NK^*(G)^{(\alpha-1)/(2m)},$$

and the equality holds for some $\alpha \neq 1$ if and only if G is regular.

A new LES model using non linear viscosity

José M. Rodríguez[1] and Raquel Taboada-Vázquez[1]

emails: jose.rodriguez.seijo@udc.es, raquel.taboada@udc.es

Abstract

We present in this paper a new Large Eddy Simulation (LES) model obtained filtering the Navier-Stokes equations, where the viscosity has been substituted by a non linear function of the strain rate tensor. This model is a generalization of the model introduced in [8]. Here we show some numerical results, comparing them with those of [2] and [4].

Key words: Large Eddy Simulation, nonlinear viscosity
MSC 2000: 35Q35, 35Q30, 76F65, 76D05

1 Introduction

Large Eddy Simulation (LES) models are widely used to simulate turbulent flows (see [1] for example). Usually, these models are presented as "averaged" or "filtered" versions of Navier–Stokes equations because one of the possible ways to derive them is to apply a filter operator to the Navier-Stokes equations, obtaining a new equation governing the behavior of the filtered velocity.

In [8] a new LES model was deduced by applying a filter, not to the Navier-Stokes equations, but to these generalized Navier–Stokes equations with a nonlinear effective viscosity

$$\rho_0 \left(\frac{\partial \mathbf{u}}{\partial t} + (\nabla \mathbf{u})\, \mathbf{u} \right) = \rho_0 \mathbf{f} + \nabla \cdot \mathbf{T}, \tag{1}$$

$$\nabla \cdot \mathbf{u} = 0, \tag{2}$$

where $\mathbf{u}$ is the velocity field, $\mathbf{f}$ is the acceleration due to external forces and the stress tensor $\mathbf{T}$ is given by

$$\mathbf{T} = -p\mathbf{I} + 2\mu_e(|\mathbf{D}|)\mathbf{D}, \qquad \mathbf{D} = \frac{1}{2}\left(\nabla \mathbf{u} + \nabla \mathbf{u}^T\right), \tag{3}$$

 ISBN: 978-84-617-8694-7

where p is the pressure and the *effective viscosity* μ_e, depending on the norm of the strain rate tensor $\mathbf{D}$, was chosen as

$$\mu_e(|\mathbf{D}|) = \mu_0 \left(1 + \lambda^2 |\mathbf{D}|^2\right)^{1/2}, \quad \lambda > 0 \tag{4}$$

The parameter λ was considered constant in [8].

In this previous work, we applied to the following Gaussian filter equations (1)-(2):

$$\bar{f}(t, \mathbf{x}) = \int_{-\infty}^{\infty} \int_{\mathbb{R}^3} G(s - t, \mathbf{y} - \mathbf{x}) f(s, \mathbf{y}) \, \mathrm{d}\mathbf{y} \, \mathrm{d}s \tag{5}$$

with

$$G(s, \mathbf{y}) = \frac{\gamma_T^{1/2} \gamma_L^{3/2}}{16\pi^2 \eta^4} \exp\left(-\frac{\gamma_T s^2 + \gamma_L |\mathbf{y}|^2}{4\eta^2}\right) \tag{6}$$

where $\eta > 0$ is a small parameter related to the size of the filter, and $\gamma_T > 0$, $\gamma_L > 0$ are parameters related to the shape of the filter.

The model thus obtained is as follows:

$$\begin{aligned} &\frac{\partial \bar{\mathbf{u}}}{\partial t} + (\nabla \bar{\mathbf{u}}) \, \bar{\mathbf{u}} + \frac{1}{\rho_0} \nabla \bar{p} = \bar{\mathbf{f}} + \nabla \cdot (\mathbf{S} - \tau), \\ &\nabla \cdot \bar{\mathbf{u}} = 0, \end{aligned} \tag{7}$$

where τ (the so called *subgrid-scale stress tensor*) is given by

$$\tau_{ij} = \overline{u_i u_j} - \bar{u}_i \bar{u}_j \tag{8}$$

$$= 2 \left[\frac{1}{\gamma_T} \frac{\partial \bar{u}_i}{\partial t} \frac{\partial \bar{u}_j}{\partial t} + \frac{1}{\gamma_L} \nabla \bar{u}_i \cdot \nabla \bar{u}_j\right] \eta^2 + O(\eta^4), \tag{9}$$

and $\mathbf{S}$ is given by

$$\begin{aligned} S_{ij} &= \frac{2}{\rho_0} \left(\overline{\mu_e(|\mathbf{D}|)\mathbf{D}}\right)_{ij} \\ &= 2\nu \Big[\left(1 + \lambda^2 K_1\right)^{1/2} + \lambda^2 \left(1 + \lambda^2 K_1\right)^{-1/2} K_2 \eta^2 \\ &\quad - \frac{\lambda^4}{4} \left(1 + \lambda^2 K_1\right)^{-3/2} K_3 \eta^2 \Big] \bar{D}_{ij} \\ &\quad + 2\nu\lambda^2 \left(1 + \lambda^2 K_1\right)^{-1/2} \hat{K}_{ij} \eta^2 + O(\eta^4) \end{aligned} \tag{10}$$

 ISBN: 978-84-617-8694-7

The notation introduced is:

$$\nu = \mu_0/\rho_0, \quad K_1 = |\bar{\mathbf{D}}|^2, \tag{11}$$

$$K_2 = \sum_{m,n=1}^{3} \left[\frac{1}{\gamma_T} \left(\frac{\partial \bar{D}_{mn}}{\partial t} \right) \left(\frac{\partial \bar{D}_{mn}}{\partial t} \right) + \frac{1}{\gamma_L} \nabla \bar{D}_{mn} \cdot \nabla \bar{D}_{mn} \right], \tag{12}$$

$$K_3 = \frac{1}{\gamma_T} \left(\frac{\partial K_1}{\partial t} \right)^2 + \frac{1}{\gamma_L} \nabla K_1 \cdot \nabla K_1, \tag{13}$$

$$\hat{K}_{ij} = \frac{1}{\gamma_T} \frac{\partial K_1}{\partial t} \frac{\partial \bar{D}_{ij}}{\partial t} + \frac{1}{\gamma_L} \nabla K_1 \cdot \nabla \bar{D}_{ij}. \tag{14}$$

So, a nonlinear viscosity was introduced in (4) as part of the model itself rather than using it as a procedure to close the subgrid-scale stress tensor in (8), where we have used the Clark approximation instead (see [3] and [9]).

This new model thus obtained reminds us of the dynamic procedure of Germano (see [6]).

2 New model when lambda is not constant

We are interested in investigating what happens when λ in (4) is allowed to depend on the time and spatial variables ($\lambda = \lambda(t, \mathbf{x})$). If we now apply the filter (5)-(6) to equations (1)-(2), but with non-constant λ, we obtain again (7)-(9) but now $\mathbf{S}$ is given by

$$\begin{aligned} S_{ij} = 2\nu \Big[& (1+K_1)^{1/2} + (1+K_1)^{-1/2} K_2 \eta^2 - \frac{1}{4} (1+K_1)^{-3/2} K_3 \eta^2 \\ & + 2\bar{\lambda} (1+K_1)^{-1/2} K_4 \eta^2 \Big] \bar{D}_{ij} \\ & + 2\nu (1+K_1)^{-1/2} \hat{K}_{ij} \eta^2 + O(\eta^4) \end{aligned} \tag{15}$$

where the notation used is:

$$\nu = \mu_0/\rho_0, \quad K_1 = \bar{\lambda}^2 |\bar{\mathbf{D}}|^2, \tag{16}$$

$$K_2 = \sum_{m,n=1}^{3} \left[\frac{1}{\gamma_T} \left(\frac{\partial (\bar{\lambda} \bar{D}_{mn})}{\partial t} \right) \left(\frac{\partial (\bar{\lambda} \bar{D}_{mn})}{\partial t} \right) + \frac{1}{\gamma_L} \nabla (\bar{\lambda} \bar{D}_{mn}) \cdot \nabla (\bar{\lambda} \bar{D}_{mn}) \right], \tag{17}$$

$$K_3 = \frac{1}{\gamma_T} \left(\frac{\partial K_1}{\partial t} \right)^2 + \frac{1}{\gamma_L} \nabla K_1 \cdot \nabla K_1, \tag{18}$$

$$K_4 = \sum_{m,n=1}^{3} \left[\frac{1}{\gamma_T} \frac{\partial \bar{\lambda}}{\partial t} \frac{\partial \bar{D}_{mn}}{\partial t} + \frac{1}{\gamma_L} \nabla \bar{\lambda} \cdot \nabla \bar{D}_{mn} \right] \bar{D}_{mn}, \tag{19}$$

$$\hat{K}_{ij} = \frac{1}{\gamma_T} \frac{\partial K_1}{\partial t} \frac{\partial \bar{D}_{ij}}{\partial t} + \frac{1}{\gamma_L} \nabla K_1 \cdot \nabla \bar{D}_{ij}. \tag{20}$$

 ISBN: 978-84-617-8694-7

3 Numerical results

With the aim of comparing the model proposed in [8] with the model we have just proposed, we have solved first equations (1)-(4) with constant and variable λ, and then we have compared the results obtained with Armaly et al. experimental measures (see [2]) and the numerical results presented by Chacón and Lewandowski with different turbulence models (see [4]) for the backward facing step test case. This test is widely used for turbulence validation, we want to examine the ability of our models to accurately compute the steady turbulent 2D backward step flow. The test consists in prescribing an inflow at a certain distance from the step, then the flow suddenly encounters the expansion of a wall, causing a flow separation, a large vortex is formed behind the step front. Armaly et. al. used to conduct their study a channel that had a height of 1.01 cm downstream the step and whose inlet was 0.52 cm (h) in height. The definition of the Reynolds number which they used is given by

$$Re = \frac{4hV_{max}}{3\nu} \tag{21}$$

where V_{max} is the maximum inlet velocity (the incoming flow is parabolic) and ν is the kinematic viscosity. Predictions of this flow, in a geometry equivalent to the case used for the experiments, were obtained by numerically solving the models proposed employing FreeFem++ (see [5]). The step length considered has been $l = 4h$ and the length of the computational domain 20 times the step height, in the same way as in [4].

When a variable λ is chosen, it is constant (λ_c) in the inner part of the domain and it goes linearly to zero at the boundaries (with limit layer thickness 10^{-3}).

Several numerical simulations have been performed for different values of λ (considered both constant and a function of $\mathbf{x}$) and different values of the Reynolds number. All the results have been obtained with a mesh width $h/20$ and a time step 0.01. The test stop for the time-stepping procedure has been set to

$$\frac{\|u_1^{n+1} - u_1^n\|_\infty}{\|u_1^{n+1}\|_\infty} < 10^{-5} \tag{22}$$

Re	X_r/h measured [2]	X_r/h computed [4]	X_r/h constant λ	X_r/h $\lambda = 0$
100	3	$2.76 - 2.86$	3.02	2.83
500	10	$9.18 - 10.61$	10.09	9.23
5000	6.7	$7.29 - 7.9$	6.51	14.85
6000	7	$7.58 - 8.29$	7.02	14.89
10000	8	$8.02 - 8.85$	7.96	–

Table 1: Reattachment points (X_r/h) for different Reynolds numbers

 ISBN: 978-84-617-8694-7

In table 1 we present the computed (or measured) length of the main vortex formed. This length has been calculated by X_r/h where X_r is the reattachment length.

We can conclude that our models are able to compute the 2D backward step flow, reobtaining the reattachment lengths measured by Armaly et al. as accurately as Chacón and Lewandowski's models do for different Reynolds numbers (corresponding to laminar and turbulent regimes). When we consider non-constant λ we achieve similar results for the main vortex and the predictions of the secondary vortex are generally improved.

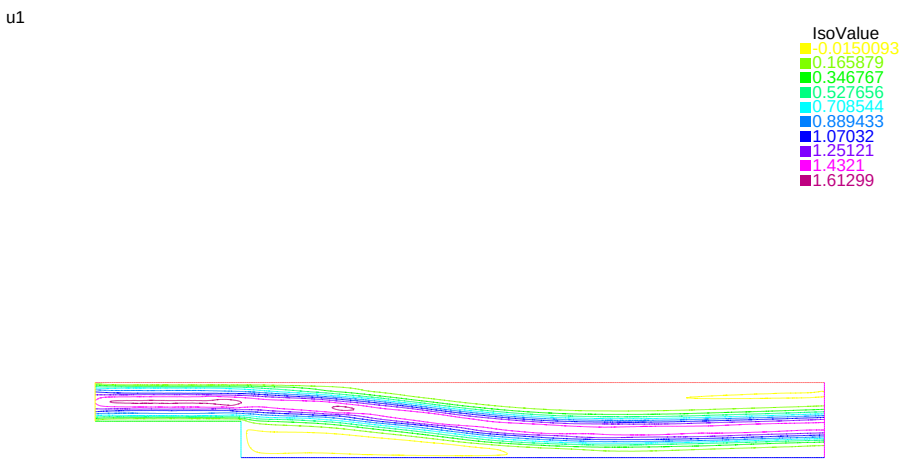

Figure 1: u_1 component of the velocity for $Re = 10000$, $\lambda = 0.1$

Figures 1 and 2 show the first component of the velocity map provided by the model considering in the first place constant and then non-constant λ, with $Re = 10000$. For this Reynolds number, with $\lambda = 0$ the scheme does not converge for the mesh width chosen.

The numerical simulations of the 'filtered' models are still ongoing, but we expect very similar results to the ones presented in [7] and [8].

 ISBN: 978-84-617-8694-7

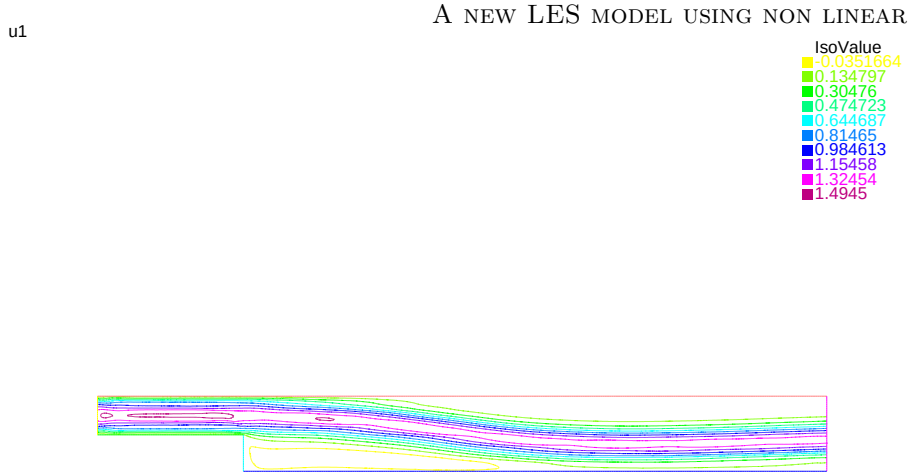

Figure 2: u_1 component of the velocity for $Re = 10000$, non-constant λ, $\lambda_c = 0.2$

Abstract

In this paper a video summarization technique based on the analysis of a video time series is presented. Time series is a relevant research field with a great number of different applications. Furthermore, the representation of such series and the extraction of information from them can be made using different techniques like for example fuzzy logic [1]. In this proposal, the information composing such time series is obtained from the H264/AVC [2] compressed domain. H264/AVC is a video coding standard to compress and decompress a video stream that balances a high visual quality with an efficient file size. It combines a transformation of pixel values into a frequency-domain representation [3], typically used to encode still images, with motion compensation techniques specific of video compression techniques. This motion compensation information is stored in the motion vectors. More concretely, the field of motion vectors in a frame can be considered as the sparse and imprecise approximation of the optical flow field. So, we consider the encoding process using motion compensation and estimation a motion segmentation process allowing to obtain information about the motion patterns of the different elements or objects in the scene [4].

In order to generate summaries identifying global patterns of motion in video we propose the use of statistical measures obtained directly from the values of the motion vectors in every frame of the video. So, we establish a correspondence between every frame in the video and a class where such class is characterized by the statistical correlation between several motion vectors organized by groups, where the organization of groups is derived from the spatial position in the picture or frame of the motion vectors. Then, as the frame is divided into several areas or groups of motion vectors more

ISBN: 978-84-617-8694-7

than one correlation measure is needed and a combination of such measures allows the definitions of some frames as the class representative models. Working in compressed domain and using basic statistical measures drives to the generation of video summaries in an efficient way [5, 6, 7].

In our proposal, the first step is to obtain from an unique video a set of class representative models

$$Classes = \{(f, C_i),\ f \in CRM\} \tag{1}$$

where CRM is the set of frames considered as class representative models in the video and C_i represents the class identified in the frame f.

After that another video is taken as input and a summary is generated and it is a represented as a set of frames associated with a class previously identified and represented in *Classes*. A frame is associated with a class if the correlation with such class is greater than or equal to 0.9.

$$Summary = \{(f, C_i),\ f \in F\} \tag{2}$$

where C_i represents the class associated to the frame f and F is the total set of frames of the video. An example is shown in Table 1.

Table 1: Summary obtained from a video.

$Initial frame$	$Final frame$	C_i
1	37	1
38	38	2
39	103	1
104	105	2
106	107	3

Finally, the experimentation of this paper is driven to the comparison of the motion patterns of several videos captured from different vehicles driving the same distance in the same road. Summaries can be compared in order to identify different ranges of velocities or trajectories for each one of the vehicles with respect to the original video. From the experimentation results it can be concluded that classes are mainly associated to traffic events, like the presence of another cars in the scene, and to concrete variations in the road geometry where the different classes are associated to bends, left or right,

 ISBN: 978-84-617-8694-7

or to situations where the vehicle is moving in a straight line. For instance, Figure 1 shows different classes corresponding to these situations described above.

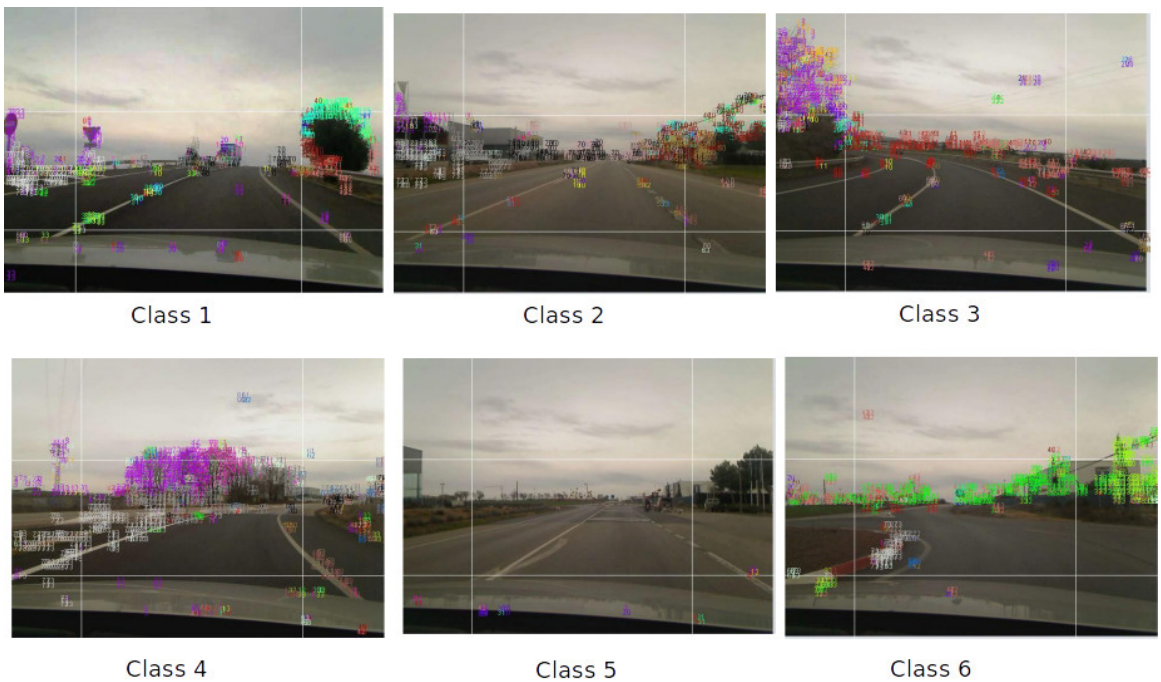

Figure 1: Frames corresponding with class representative models

Abstract

The realm of HPC systems lies in sharing computational resources efficiently. Their challenge is to turn massively large data into valuable information and meaningful knowledge. To accomplish this, I/O subsystems have to provide scalable bandwidth and capacity in order to deliver on the increasing demand for their requests. Emerging technologies, new programming paradigms and virtualized environments need novel ways to offer optimised solutions to support heavy data flows in storage services.

In this paper, we propose a distributed storage layer on computer nodes that can be used as a robust data storage service to handle intensive I/O operations. Preliminary experiments show that our platform outperforms other distributed data storage solutions.

Key words: Data storage, high performance computing, supercomputers, communication networks, file systems

1 Introduction

HPC centres are service providers, where multiple specialized computational resources provide different services. Some of these resources are designed to run simulations and generate data. Others provide post-processing or analysis of the generated data, while some are responsible for visualization of the raw or reduced data. The common denominator in

 ISBN: 978-84-617-8694-7

all of these scenarios is data. Data must be shared among these systems in an efficient manner.

I/O is mainly used in scientific applications to store output from simulations for later analysis, for implementing algorithms that process more data that can fit in system memory and must page data to and from disk and for checkpointing to save the state of application in case of system failure.

Modern distributed storage systems employ techniques that can help improve application performance, alleviate I/O bandwidth bottleneck, mask failures, and ensure data availability.

It is needed to develop both the theoretical and practical aspects of building efficient and scalable distributed storage that will scale and be tolerant of the inevitable node failures and service partitioning that come with multiple nodes. Raicu et al. [10] proposes a distributed storage architecture that will make exascale computing more tractable, touching virtually all disciplines in high-end computing and fueling scientific discovery. Chen et al.[1] proposes a Parallel, Reliable and Scalable Storage Software Infrastructure (PASSI) to support the design and prototyping of next-generation active storage environment.

Some tools have been created to modeling large-scale HPC I/O workload. Snyder et al.[12] have defined a novel workload abstraction layer that may be used by diverse tools to regenerate and analyze I/O workloads. They implemented three workload generators based on distinct representations of I/O workloads: I/O traces, synthetic I/O kernels, and I/O characterizations. They used a simulation model of an HPC storage system to analyse and compare each IOWA workload generation technique in detail, and they used an I/O replay engine to evaluate large-scale workloads on a production HPC storage system.

Ghoshal et al.[7] present their results in benchmarking the I/O performance over different cloud and HPC platforms to identify the major bottlenecks in existing infrastructure.

Multiple failure are inevitable in large storage systems, and designers must consider to avoid lost of data. The core technology for protecting data from failures is erasure coding, which has a rich 50+ year history stemming communication systems, and as such, can be confusing to the storage systems community. Plank [9] presents a primer on erasure coding as it applies to storage systems, and summarizes some interesting research on erasure coding.

In our paper, we provide a short background of a high performance data storage system in Section 2. We show a design overview in Section 3. We present some preliminary results in Section 4 and we conclude the paper in Section 5.

2 Background

A high performance data storage system is composed of several basic elements: different communication layers, storage units, data manipulation algorithms and control software.

 ISBN: 978-84-617-8694-7

All these elements are continually evolving to push the limits of existing technology. There are several aspects to managing a distributed high-performance storage system:

- Try to take full advantage of all resources: CPUs, storage and networks with a fast asynchronous client/server communication layer.
- Define a reliable system to manage resources: There are several software solutions: etcd[5], Consul[8], Zookeeper.
- Support different topologies: create storage volumes composed of several units and group them according to their performance: i.e: SSD for fast storage and HDD for slow operations.
- Redundancy management: To define how many units are needed to use for storage.
- Dynamic storage management: The less used files go to slow units.
- Use erasure codes to optimise integrity.

3 Design Overview

A distributed high-performance storage system requires to control resources in a efficient way and demands low latencies and high data bandwidth. Thus this complex system have to be decomposed into small services that solve different requirements. On a previous publication, we have shown a metadata system applied to HPC [11] and how to improve data sharing on Infiniband Networks [4].

The proposed model, AbFS3_L3 (AbFS3 Low Level Layer), is not a generic filesystem but rather a flexible platform to store any kind of data, defining a low level layer for a unified data storage (ie. object storage, files or blocks).

The main subsystem are:

- Resource management and service discovery system: It detects all available resources and changes in configuration. It supervises that all components are properly working. It is based on etcd [5].
- Fast data transfer system: It is a fluent data transport which adapts to different conditions (real and virtualized networks).
- Data balancing and redistribution: It is responsible for deciding how to distribute data among servers, replace data into new locations and recover accidental.
- Data storage API: It is the service that clients can access and provides cache and block control to accelerate interoperability.

 ISBN: 978-84-617-8694-7

Clients has a reduced configuration in order to achieve a coherent image and they "learn" new configuration profiles as they demand resources and, therefore, they need not be notified of general changes.

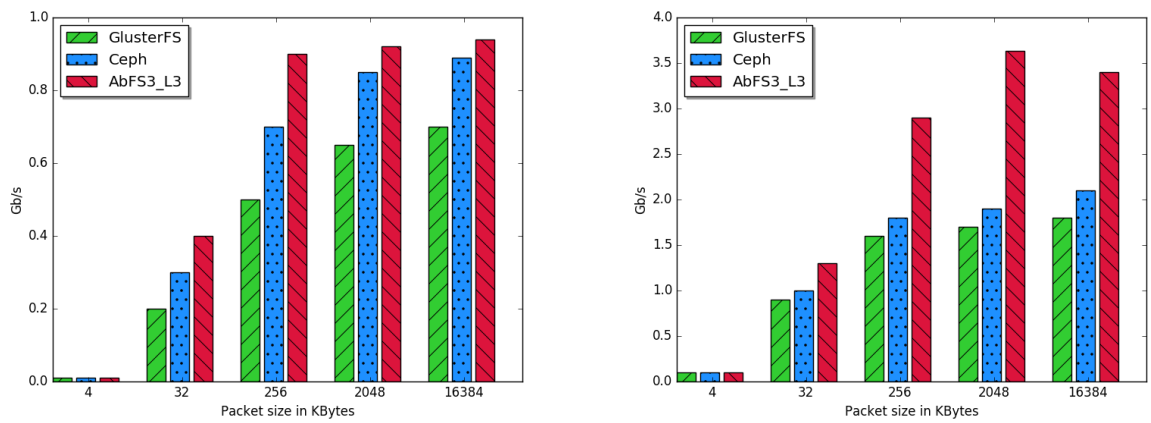
Clients can request operations to any server who will resolve the queries, and the server can "suggest" any other server to improve response times.

Administrator can select multiple configuration options to define redundancy, restrictions, migration policies or strict working conditions to support no single point of failure (NSPOF).

4 Results

The system has been tested in a cluster with 16 server nodes equipped with: Dual 2.27GHz Intel(R) Xeon(R) E5520 CPUs, 16GB RAM memory, 1TB Local Disk and OS CentOS 6.6. Our scenario has 4 servers and 10 clients. These nodes have two Broadcom Corporation NetXtreme II BCM5716 Gigabit Ethernet interfaces and a IBA7220 InfiniBand HCA.

We have compare our system with other implementations based on distributed filesytems, such as GlusterFS[3] and Ceph[2] with two different networks: Infiniband and Gigabit Ethernet.



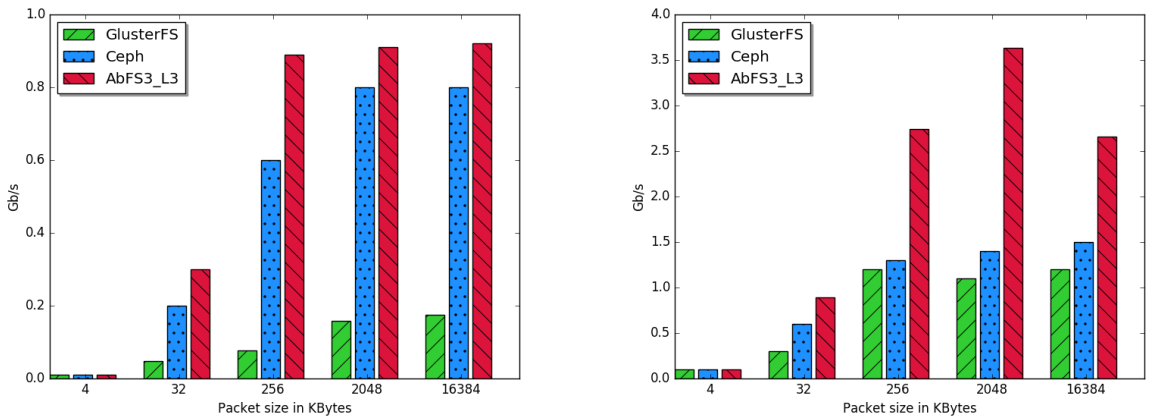
(a) with Gigabit Network

(b) with Infiniband Network

Figure 1: Read bandwidth obtained

We show the throughput with a variety of block sizes ranging from 4 KB to 16 MB. Figure 1(a) shows read bandwidth obtained from a Gigagit Network and Figure 1(b) from a Infiniband and, Figure 2(a) shows write bandwidth using Gigabit Network and Figure 2(b) using Infiniband.

 ISBN: 978-84-617-8694-7



(a) with Gigabit Network

(b) with Infiniband Network

Figure 2: Write bandwidth obtained

Both figures show that our proposed system outperform Ceph and GlusterFS in all conditions: reads, writes, with diverse block sizes and different networks.

5 Conclusions and future work

In this paper we have presented a flexible platform for data storage in HPC systems. This system can be used as a robust low level interface to store and retrieve data efficiently. Preliminary experiments show that our platform outperforms other distributed data storage solutions. As future work, we want to combine this platform with an optimised metadata support and a virtual filesytem layer to perform fast I/O based on file operations.

Improving Energy Efficiency in Virtual Data Centers: A real-world case study

Julio Rodríguez-Soares[1], Alberto Cocaña-Fernández[1], Raquel Cortina[1], Luciano Sánchez[1] and José Ranilla[1]

Abstract

Cloud computing era has posed important challenges in the energy and operational costs of data centers and, therefore, efforts to efficiently manage these computing infrastructures are essential. In this work, the power consumption of medium-scale Virtualized Data Centers operated by a multi-service IT provider is analysed. After modelling and profiling the workload, some experimental studies have been conducted to improve power savings through Virtual Machines allocation and migration. Our preliminary results are competitive compared to those obtained using commercial systems.

Key words: Data Center, Resource Management, Virtual Machine Migration, Energy efficiency

1 Introduction

Information and Communications Technology (ICT) has played a key role in the transformation of modern society by consistently delivering innovative products and services, increasing productivity and supporting economic growth. Nevertheless, ICT environmental impact is far from negligible as data centers alone are responsible for over 1% of the world's electricity consumption, and 14% of its carbon footprint [1]. Moreover, data center-related power consumptions continue to grow, and are estimated to increase by 53% between 2013 and 2020 according to [2]. Given so, substantial efforts have been done by the leading ICT service providers to maximise the energy efficiency of large-scale data centers in the pursuit of reducing power consumptions and operating costs. However, large-scale infrastructures

 ISBN: 978-84-617-8694-7

only represent 5% of the data centers' energy use, with the remaining 95% used by the far less efficient small and medium-scale ones [2]. As a result of this, efforts focused in improving the efficiency of multi-purpose small and medium-scale infrastructures with common workload patterns may yield greater overall power savings.

Virtualized Data Centers (VDC) are the cornerstone of most Infrastructure as a Service (IaaS) providers. In a VDC, applications are wrapped within Virtual Machines (VMs) representing their execution environment. VMs are then mapped to Physical Machines (PMs) by optimising a set of predefined objectives such as service quality, operating costs, reliability, network load, etc. Hence, energy optimisation techniques in these environments must tackle one or more layers of the VDC stack: Application, Virtual Machine and Physical Machine [3, 4, 5].

With regard to VMs, the problem of finding the best mapping of VMs onto the PMs is well-known and already has been extensively studied in the literature. Essentially, schedulers implementing the mapping algorithms are composed of two modules: allocation and migration. The allocation module performs the initial VM placement, while the migration module consolidates the VM load onto the minimum possible number of PMs. Recently, some authors stated that whenever the cluster workload is well-defined and exhibits a relatively low variability, migration can be also be addressed as a VM reallocation within decision intervals of several minutes.

In this work, the power consumption of medium-scale Virtualized Data Centers operated by a multi-service IT provider is analysed in order to build a representative environment to assess the results attained with a set of VM migration algorithms. In a full paper a Genetic Fuzzy Rule-Based System implementing the migration mechanism will be presented to improve the energy savings achieved with state-of-the-art commercial virtualization software.

2 Reference Data Center setup

ASAC Comunicaciones[1], an IT company established in 1996 offering a portfolio private-cloud services, was chosen as real-world case study to assess the performance of the proposed algorithms. Such provider was selected given that its mid-size TIER III-certified[2] data centers make an excellent representation of the vast amount of medium-scale service providers operating under reasonable quality standards, but with great room to improve power savings.

Figure 1 depicts briefly ASAC data centers architecture. Basically, computing resources are grouped in VDCs, which are then organised in clusters, each one comprised of multiple PMs hosting the VMs. The number of VDCs, clusters and PMs/VMs per cluster depends

[1] http://www.asac.as

[2] These certifications are granted by the Uptime institute according to the availability and redundancy of its physical infrastructure. Further information can be found on its website https://uptimeinstitute.com

 ISBN: 978-84-617-8694-7

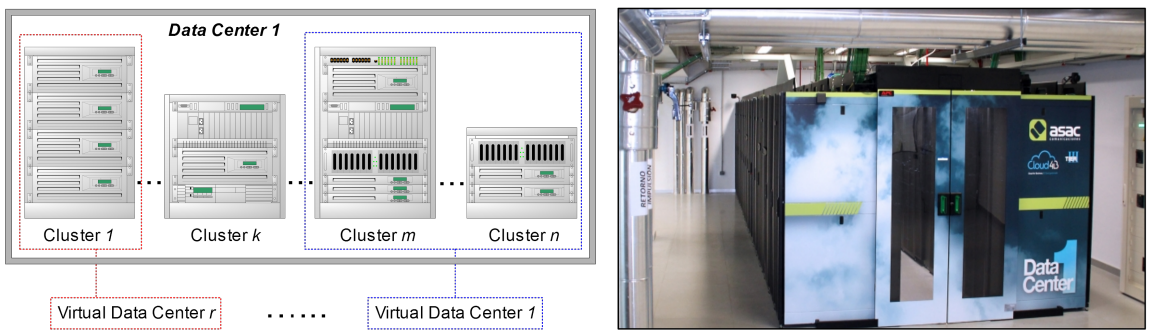

Figure 1: ASAC Data Center 1 architecture.

heavily on the applications deployed and their resource requirements (CPU, memory, network throughput, etc.), with an overall VMs/cluster ratio ranging from 9 to 1500 deployed over between 2 and 12 PMs. ASAC VDCs are built using VMware vSphere as the virtualization platform[3]. In particular, the experimental testbed consists of a single cluster with 12 PMs, each one with 32 physical cores, hosting a total of 200 VMs with 2-4 vCPUs. As for the workload, it was determined according to the trace logs of the last six months, providing quantitative and accurate data on resource consumptions regarding CPU and memory usage, network traffic, Input/Output Operations Per Second (IOPS), etc. After careful analysis of the recorded workload, two patterns were found:

1. **Stationary Workload**, featuring slight fluctuations in resource consumption but which does not change substantially over time. In our study three levels were defined: 1) *LowCharge* load following a uniform distribution with VMs using less than 40% of resources requested at startup, 2) *MedCharge* load, same as the former though rising VMs' occupancy threshold from 40% to 65%, and 3) *HighCharge* load with the occupancy threshold between VMs 65% and 100%.

2. **Dynamic Workload**, where VMs' occupancy evolves overtime with a certain daily seasonality.

3 Experimental results

Given the productive nature of ASAC data centers, experimentations were done using the well-known CloudSim framework [6, 7]. This framework was customized in order to suit the evolving nature of the workload described in the preceding section by implementing temporal series of *cloudlets* (the minimum unit of VM load), as well as including two additional VM

[3]https://www.vmware.com//products/vsphere.html

 ISBN: 978-84-617-8694-7

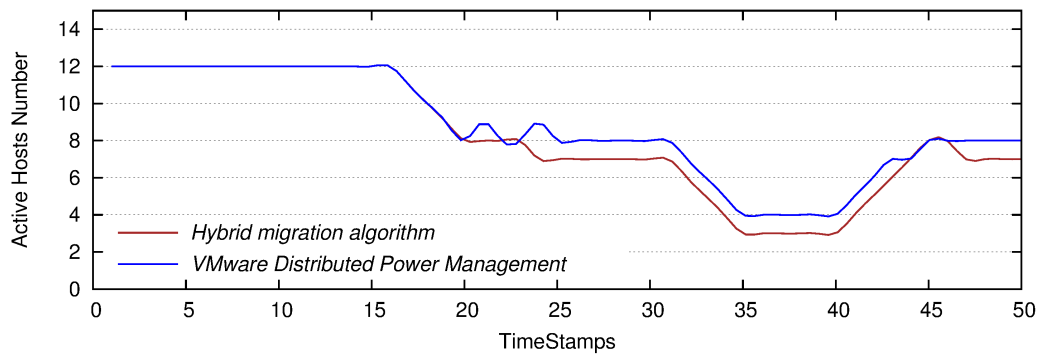

Figure 2: Results obtained with Dynamic Workload and both algorithms.

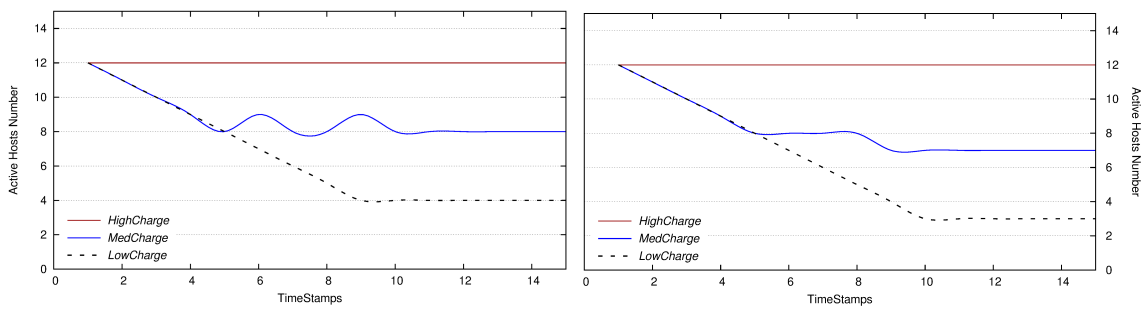

(a) (b)

Figure 3: Results obtained with (a) VMware Distributed Power Management and (b) Hybrid migration algorithm under three different scenarios of Stationary Workload.

allocation algorithms used as benchmark. The first one, called *VMware Distributed Power Management* within the figures, is a modified version of the median absolute deviation-based migration algorithm used by VMware's Distributed Power Management module, extending it to comply with predetermined occupancy intervals. In particular, the minimum and maximum occupancy thresholds used in the experiment were set at 40% and 80%, respectively. Migration rules were based on the CPU's utilization rate.

The second algorithm uses a weighted function with multiple criteria to adjust the migrations. This algorithm, called *Hybrid Migration Algorithm* (HMA), uses the same set of predefined thresholds as those used in the previous one. Preliminary results are depicted in Figures 2 and 3, and show that VM migrations with the proposed HMA attain greater energy savings by achieving a higher degree of consolidation without impact on service quality.

 ISBN: 978-84-617-8694-7

4 Future Work

Given that initial results show substantial room for improvements over commercial virtualization solutions in mid-size data centers, in the full paper a set of state-of-the-art solutions will be compared against our reactive decision-making mechanism presented in [8, 9]. This mechanism consists of a utility function implemented by means of a Genetic Fuzzy Ruled-Based System (GFRBS), elicited from workload records to optimise a weighed fitness involving multiple criteria such as service quality, energy savings, hardware reliability, etc. This utility function will be used to assess the value (utility) of every possible VM migration to a different PM, and also including the possibility of rejecting any migration.

In the same way, a proactive migration and allocation mechanism based on the one described in [10] for High Performance Computing clusters will be adapted, since actual workloads suggest that load in these infrastructures are rather predictable.

Finally, given the amount of service-related concerns regarding data centers operation, learning algorithms based on many-objective optimization techniques will be leveraged to cope with the growing dimensionality of Pareto fronts.

Abstract

The aim of this work is to introduce a new class of generalized metric spaces (called *RS-spaces*) that unify and extend, at the same time, Branciari's generalized metric spaces and Jleli and Samet's generalized metric spaces. In order to show its great applicability, we present some fixed point theorems in the setting of RS-spaces that extend well-known results in this line of research.

Key words: Generalized metric space, Branciari metric space, Fixed point, Contractive mapping
MSC 2000: 46T99, 47H10, 47H09, 54H25.

1 Introduction

Fixed point theory is currently one of the most active branches of nonlinear analysis. In the last years, there have been introduced many fixed point results in the setting of natural extensions of metric spaces: quasimetric-spaces [1], Mustafa and Sims' generalized metric spaces [2], Czerwik's b-metric spaces [3], Hitzler and Seda's dislocated metric spaces [4], Nakano's modular spaces [5], Musielak and Orlicz's spaces [6], Bakhtin b-metric spaces [1], etc.

Very recently, two very general families of generalized metric spaces have attracted the attention of researchers. On the one hand, Branciari's generalized metric spaces were introduced in [7] in order to show some fixed point theorems. Although these spaces have metrically non-intuitive properties, these drawbacks have not been a limitation for developing fixed point theory in this environment (see [9, 10, 11, 12, 13]). On the other hand, Jleli and Samet [14] introduced a kind of generalized metric spaces which are not endowed with a proper triangle inequality: it was replaced by a weaker condition involving convergent sequences.

At a first sight, Branciari's spaces and Jleli and Samet's spaces seem to be incompatible: for instance, in the second kind of spaces, the limit of a convergent sequence is unique, and two points can be placed having infinite distance between them.

In this work, we introduce a new class of spaces, that we call *RS-spaces*, that are natural extensions of both Branciari's spaces and Jleli and Samet's spaces. We also show some fixed point results.

2 Preliminaries

Henceforth, $\mathbb{N} = \{0, 1, 2, \ldots\}$ stands for the set of all non-negative integer numbers, and let $\mathbb{N}^* = \mathbb{N} \setminus \{0\}$. From now on, X will denote a nonempty set and $T : X \to X$ will be a self-mapping.

Given a point $x_0 \in X$, the *Picard sequence of T based on x_0* is the sequence $\{x_n\}_{n\geq 0}$ given by $x_{n+1} = Tx_n$ for all $n \in \mathbb{N}$. In particular, $x_n = T^n x_0$ for all $n \in \mathbb{N}$, where T^n denotes the n^{th}-iterates of T (we assume that T^0 denotes the identity mapping on X). A Picard sequence satisfies $x_{n+m} = T^m x_n = T^n x_m$ for all $n, m \in \mathbb{N}$. The *orbit of x_0 by T* is the set $\mathcal{O}_T(x_0) = \{\, T^n x_0 : n \in \mathbb{N} \,\}$.

A *binary relation on X* is a nonempty subset $\mathcal{S}$ of the Cartesian product $X \times X$. For simplicity, we denote $x\mathcal{S}y$ if $(x, y) \in \mathcal{S}$. We say that x and y are *$\mathcal{S}$-comparable* if $x\mathcal{S}y$ or $y\mathcal{S}x$. A binary relation $\mathcal{S}$ on X is *reflexive* if $x\mathcal{S}x$ for all $x \in X$; it is *transitive* if $x\mathcal{S}z$ for all $x, y, z \in X$ such that $x\mathcal{S}y$ and $y\mathcal{S}z$; and it is *antisymmetric* if $x\mathcal{S}y$ and $y\mathcal{S}x$ imply $x = y$. Given a non-empty subset A of X, we will say that $\mathcal{S}$ is *transitive on A* if

$$x, y, z \in A, \quad x\mathcal{S}y, \quad y\mathcal{S}z \quad \Rightarrow \quad x\mathcal{S}z.$$

A sequence $\{x_n\} \subseteq X$ is *$\mathcal{S}$-nondecreasing* if $x_n\mathcal{S}x_{n+1}$ for all $n \in \mathbb{N}$.

A *preorder* (or a *quasiorder*) is a reflexive, transitive binary relation and a *partial order* is an antisymmetric preorder.

An *extended comparison function* (or, simply, a *comparison function*) is a function $\phi : [0, \infty] \to [0, \infty]$ such that

($\mathcal{P}_1$) ϕ is nondecreasing;

 ISBN: 978-84-617-8694-7

$(\mathcal{P}_2)$ for all $t \in (0,\infty)$, $\lim_{n\to\infty} \phi^n(t) = 0$.

Let $\mathcal{F}_{\text{com}}$ be the family of all (extended) comparison functions.

2.1 Branciari N-generalized metric spaces

The following notion was introduced by Branciari in [7].

Definition 1 *(Branciari [7]) Given $N \in \mathbb{N}^*$, a* Branciari N-generalized metric space *(for short, a* B_N-space*) is a pair (X,d), where X is a non-empty set and $d : X \times X \to [0,\infty)$ is a function such that the following properties hold:*

(B_1) $d(x,y) = 0$ *if, and only if,* $x = y$.

(B_2) $d(y,x) = d(x,y)$.

(B_3) $d(x,y) \leq d(x,u_1) + d(u_1,u_2) + d(u_2,u_3) + \ldots + d(u_{N-1},u_N) + d(u_N,y)$ *for any $x, u_1, u_2, \ldots, u_N, y \in X$ such that $x, u_1, u_2, \ldots, u_N, y$ are all different.*

If $N = 2$, then (X,d) is a Branciari generalized metric space *(for short, a* B-space*).*

A B_1-space is a metric space. However, if $N \geq 2$, it was proved that B_N-spaces can satisfy some properties that are not metrically desirable (see [8, 9]). For instance, in a B_N-space,

- there may exist convergent sequences that are not Cauchy sequences;
- there may exist convergent sequences with two different limits;
- the metric $d : X \times X \to [0,\infty)$ may not be a continuous function;
- there may exist open balls centered in different points that are never disjoint although their radius are arbitrarily small.

Surprisingly, in [11], Suzuki *et al.* proved that, for $N \geq 2$, only B_3-spaces have a compatible symmetric topology.

2.2 Jleli and Samet's generalized metric spaces

Henceforth, let $\mathcal{D} : X \times X \to [0,\infty]$ be a given mapping. For every $x \in X$, define the set

$$C(\mathcal{D}, X, x) = \left\{ \{x_n\} \subseteq X : \lim_{n\to\infty} \mathcal{D}(x_n, x) = 0 \right\}. \tag{1}$$

Generalized metric and generalized metric space are defined as follows.

 ISBN: 978-84-617-8694-7

Definition 2 *(Jleli and Samet [14], Definition 2.1) Let X be a nonempty set and let $\mathcal{D} : X \times X \to [0, \infty]$ be a function which satisfies:*

$(\mathcal{D}_1)$ $\mathcal{D}(x, y) = 0$ *implies* $x = y$;

$(\mathcal{D}_2)$ $\mathcal{D}(x, y) = \mathcal{D}(y, x)$ *for all* $x, y \in X$;

$(\mathcal{D}_3)$ *there exists* $C > 0$ *such that*

$$\text{if } x, y \in X \text{ and } \{x_n\} \in C(\mathcal{D}, X, x), \quad \text{then} \quad \mathcal{D}(x, y) \leq C \limsup_{n\to\infty} \mathcal{D}(x_n, y). \tag{2}$$

Then $\mathcal{D}$ is called a generalized metric *and the pair $(X, \mathcal{D})$ is called a* generalized metric space *(in the sense of Jleli and Samet; for short, a* JS-space*).*

Jleli and Samet presented in [14] a large list of abstract metric spaces that can be seen as particular cases of JS-spaces: metric spaces, b-metric spaces, Hitzler-Seda metric spaces and modular spaces with the Fatou property. Given a JS-space $(X, \mathcal{D})$ and a point $x \in X$, a sequence $\{x_n\} \subseteq X$ is said to be:

- $\mathcal{D}$*-convergent to* x if $\{x_n\} \in C(\mathcal{D}, X, x)$ (in such a case, we will write $\{x_n\} \overset{\mathcal{D}}{\to} x$);
- $\mathcal{D}$*-Cauchy* if $\lim_{n,m\to\infty} \mathcal{D}(x_n, x_m) = 0$.

A JS-space $(X, \mathcal{D})$ is *complete* if every $\mathcal{D}$-Cauchy sequence in X is $\mathcal{D}$-convergent.

Definition 3 *(Branciari [7]) A* rectangular metric on X *is a mapping $d : X \times X \to [0, \infty)$ satisfying the following properties:*

(RM_1) $d(x, y) = 0$ *if, and only if,* $x = y$;

(RM_2) $d(x, y) = d(y, x)$ *for all* $x, y \in X$;

(RM_3) $d(x, y) \leq d(x, u) + d(u, v) + d(v, y)$ *for all* $x, y \in X$ *and all distinct points* $u, v \in X \setminus \{x, y\}$.

In such a case, (X, d) is called a rectangular metric space *(in short* RM-space*).*

 ISBN: 978-84-617-8694-7

3 RS-generalized metric spaces

In this section we present the class of generalized metric spaces in which we are interested and we show that well-known abstract metric spaces belong to this new class.

Definition 4 (Roldán López de Hierro and Shahzad [16]) *An* RS-generalized metric space *(for short, an* RS-space*) is a pair $(X, \mathcal{D})$ where X is a non-empty set and $\mathcal{D} : X \times X \to [0, \infty]$ is a function such that the following properties are fulfilled:*

$(\mathcal{D}_1)$ *If $\mathcal{D}(x, y) = 0$ then $x = y$;*

$(\mathcal{D}_2)$ *$\mathcal{D}(x, y) = \mathcal{D}(y, x)$ for all $x, y \in X$;*

$(\mathcal{D}'_3)$ *there exists $C > 0$ such that if $x, y \in X$ are two points and $\{x_n\}$ is a $\mathcal{D}$-Cauchy infinite sequence in X such that $\{x_n\} \overset{\mathcal{D}}{\to} x$ then*

$$\mathcal{D}(x, y) \leq C \limsup_{n\to\infty} \mathcal{D}(x_n, y). \tag{3}$$

If X is endowed with a binary relation $\mathcal{S}$, then an RS-space *is a triple $(X, \mathcal{D}, \mathcal{S})$ satisfying $(\mathcal{D}_1)$, $(\mathcal{D}_2)$ and $(\mathcal{D}'_3)$ assuming that the sequence $\{x_n\}$ in $(\mathcal{D}'_3)$ is $\mathcal{S}$-nondecreasing.*

Let us show that the class of RS-spaces contains some important subclasses.

Lemma 5 *Every JS-space is an RS-space.*

Corollary 6 *Every b-dislocated metric is a JS-space and so it is an RS-space.*

Lemma 7 *Every B_N-space is an RS-space (where $\mathcal{D} = d$ and $C = 1$).*

4 Ćirić type fixed point theorems in the context of RS-generalized metric spaces

This section is dedicated to introduce, in the setting of RS-spaces, the main results of this manuscript inspired by the Ćirić type contractivity condition presented in [15].

Theorem 8 (Roldán López de Hierro and Shahzad [16]) *Let $(X, \mathcal{D}, \mathcal{S})$ be an $\mathcal{S}$-nondecreasing-complete RS-space with respect to a preorder $\mathcal{S}$ and let $T : X \to X$ be an $\mathcal{S}$-nondecreasing self-mapping. Let $x_0 \in X$ be a point such that $x_0 \mathcal{S} T x_0$ and $\delta_{n_0}(\mathcal{D}, T, x_0) < \infty$ for some $n_0 \in \mathbb{N}$. Suppose that there exists $\phi \in \mathcal{F}_{\text{com}}$ such that*

$$\mathcal{D}(Tx, Ty) \leq \phi(\max\{\mathcal{D}(x, y), \mathcal{D}(x, Tx), \mathcal{D}(y, Ty), \mathcal{D}(x, Ty), \mathcal{D}(y, Tx)\}) \tag{4}$$
$$\text{for all } x, y \in \mathcal{O}_T(x_0).$$

Additionally, assume that

 ISBN: 978-84-617-8694-7

(a) T is $\mathcal{S}$-nondecreasing-continuous.

Then the Picard sequence $\{x_n\}_{n\in\mathbb{N}}$ of T based on x_0 $\mathcal{D}$-converges to a fixed point ω of T. Furthermore, $\mathcal{D}(\omega,\omega)=0$ and

$$\mathcal{D}(x_n,\omega)\leq C\,\phi^{n-n_0}\left(\delta_{n_0}(\mathcal{D},T,x_0)\right)\quad \text{for all } n\in\mathbb{N} \text{ such that } n\geq n_0,$$

where $C=C_{X,\mathcal{D}}$ is the (lowest) constant for which $(X,\mathcal{D})$ satisfies property $(\mathcal{D}_3')$.

In addition to this, if condition (4) holds for all $x,y\in X$ such that $x\mathcal{S}y$, and ω' is another fixed point of T such that $\omega\mathcal{S}\omega'$, $\mathcal{D}(\omega,\omega')<\infty$ and $\mathcal{D}(\omega',\omega')<\infty$, then $\omega=\omega'$.

Abstract

Ordering fuzzy subsets is important in decision-making, data analysis and socioeconomic systems. Since fuzzy numbers do not always yield a totally ordered set as real numbers do, an importan issue in operational fuzzy set theory is how to compare fuzzy numbers. In this paper we describe an approach to ranking fuzzy numbers with compact support using a finite image of them. The method is compared with other techniques by numerical examples. Finally we consider a real application to ranking consumer products.

Key words: Fuzzy number, Finite fuzzy number, Ranking

1 Introduction

In many applications, ranking of fuzzy numbers is an important tool in decision processes. It is well-known that fuzzy numbers do not form a natural linear order, like real numbers. Many approaches have been developed different methods for ranking fuzzy numbers [1, 4, 6, 13, 18, 21]. A commonly used technique is to construct maps to transform fuzzy numbers into real number so called defuzzification, for example considering the central gravity, the median or area measurements. Each defuzzification method provides a correspondence from

 ISBN: 978-84-617-8694-7

the set of all fuzzy numbers into the set of the real number. These real numbers are then compared to obtain a ranking. Some approaches produce different rankings for the same data. Then the results of the methods proposed in the literature are often conflict and there is yet no method that can always give a satisfactory solution to every situation.

In this paper we describe an approach to ranking fuzzy numbers with compact support using a finite image of them. In [16], Roldán *et al.* did a complete study of the image of a FN. In their manuscript, they considered FNs $\mathcal{A}$ whose image (or range) $\mathcal{A}(\mathbb{R})$ is a countable (or finite) subset of $\mathbb{I}$, and they called them *finite or discrete* FNs. This kind of FNs is interesting since, in many cases, the usual computation of FNs is only referred to certain data (a finite approximation of a FN) and, in practice, most of examples of fuzzy structures (probabilistic metric spaces, fuzzy metric spaces in several senses and intuitionistic fuzzy metric spaces) are constructed using these classes of FNs. Among other properties, they succeeded in proving that such family of FNs is closed under the usual operations between FNs, that is, if $\mathcal{A}$ and $\mathcal{B}$ are discrete FNs, them $\mathcal{A}+\mathcal{B}$, $\mathcal{A}-\mathcal{B}$, $\mathcal{A}\cdot\mathcal{B}$ and $\mathcal{A}/\mathcal{B}$ (if this last FN is well defined) also are discrete FNs.

2 Preliminaries

Let $\mathbb{R}$ denote the set of all real numbers and $\overline{\mathbb{R}} = [-\infty, \infty]$ the extended real line (for simplicity, $+\infty$ will be denoted as ∞). Henceforth, $x_0 \in \mathbb{R}$ will be a real number.

Let $f : X \to Y$ be a mapping. We say that f is a *finite* (respectively, *countable*) *mapping* if its image $\operatorname{Im} f$ is a finite (respectively, countable) subset of Y. We point out that we will use the term *countable* admitting the possibility that $\operatorname{Im} f$ is *finite*.

A *fuzzy set on* $\mathbb{R}$ is a map $\mathcal{A} : \mathbb{R} \to [0,1]$. A *fuzzy number on* $\mathbb{R}$ (hereinafter, *FN*) is a fuzzy set $\mathcal{A}$ on $\mathbb{R}$ that verifies the following properties:

(1) Normality: there exists a real number $x_0 \in \mathbb{R}$ such that $\mathcal{A}(x_0) = 1$.

(2) For all $\alpha \in]0,1]$, the set $\mathcal{A}_{[\alpha]} = \{x \in \mathbb{R} : \mathcal{A}(x) \geq \alpha\}$ is a closed subinterval of $\mathbb{R}$.

The set $\mathcal{A}_{[\alpha]}$ is known as the *α-level set* (or *α-cut*) of $\mathcal{A}$. The *kernel* of a FN $\mathcal{A}$ is $\ker \mathcal{A} = \mathcal{A}_{[1]}$ and its *support* is the closure $\operatorname{supp}(\mathcal{A}) = \overline{\{x \in \mathbb{R} : \mathcal{A}(x) > 0\}}$. Let $\mathcal{F}$ be the family of all FNs.

From now on, we will denote by FFN (respectively, by CFN) the family of all FNs whose image is finite (respectively, countable).

Regarding FNs, we refer the reader to Klir and Yuan [11], Dubois and Prade [7], Mizumoto and Tanaka [12], Wu and Ma [17], and Buckley and Jowers [2]. Clearly, $\mathbb{R}$ can be embedded in $\mathcal{F}$: if $r \in \mathbb{R}$ then $\hat{r} \in \mathcal{F}$ satisfies $\hat{r}(x) = 1$ if $x = r$ and $\hat{r}(x) = 0$ if $x \neq r$. A *triangular FN* $\mathcal{A} = (a/b/c)$ is defined by three real numbers $a < b < c$ where the graph of $\mathcal{A}$ is a triangle with base on the interval $[a, c]$ and vertex at $x = b$. *Trapezoidal FNs*

 ISBN: 978-84-617-8694-7

$\mathcal{A} = (a/b/c/d)$, where $a < b < c < d$, are similarly defined (see [2, 10, 11]). Any FN $\mathcal{A}$ can be extended to $\overline{\mathbb{R}}$ defining $\mathcal{A}(\pm\infty) = 0$. Hence we only consider FNs on $\overline{\mathbb{R}}$.

Let $\mathcal{A} \in \mathcal{F}$ be a FN. Notice that $\mathcal{A}$ is completely determined by its level sets (see [7]). For every $\alpha \in]0,1]$ let $\mathcal{A}_{[\alpha]} = [\underline{a}(\alpha), \overline{a}(\alpha)]$ (this interval is open on one side if $\underline{a}(\alpha) = -\infty$ or $\overline{a}(\alpha) = \infty$), so we may consider mappings $\underline{a}, \overline{a} :]0,1] \to \overline{\mathbb{R}}$ which determine the extremes of each level set (for simplicity, we will write $\overline{a}_\alpha = \overline{a}(\alpha)$ and $\underline{a}_\alpha = \underline{a}(\alpha)$ for all $\alpha \in]0,1]$). If $0 < \alpha \leq \beta \leq 1$ and $x_0 \in \ker \mathcal{A}$, then $\mathcal{A}_{[\beta]} \subseteq \mathcal{A}_{[\alpha]}$, so $\underline{a}_\alpha \leq \underline{a}_\beta \leq x_0 \leq \overline{a}_\beta \leq \overline{a}_\alpha$. In particular, $\underline{a}_\alpha \leq \underline{a}_1 \leq x_0 \leq \overline{a}_1 \leq \overline{a}_\alpha$, $\underline{a}(]0,1]) \subseteq [-\infty, \underline{a}_1] \subseteq [-\infty, x_0]$ and $\overline{a}(]0,1]) \subseteq [\overline{a}_1, \infty] \subseteq [x_0, \infty]$.

3 Finite fuzzy numbers

In this section we define FNs whose image is finite. In general, given two nonempty sets X and Y, we will say that a function $f : X \to Y$ is *finite* if the image of f is a finite subset of Y. The following notion is a key piece of the current study.

A FN $\mathcal{A}$ is *finite* if its image, $\mathcal{A}(\mathbb{R})$, is a finite subset of $\mathbb{I}$. If Λ is a finite subset of $\mathbb{I}$, we will denote by $\mathcal{F}_\Lambda$ the family of all finite FNs $\mathcal{A} \in \mathcal{F}$ such that $\mathcal{A}(\mathbb{R}) \subseteq \Lambda$.

An equivalent way to represent finite FNs by using a real number (that can be interpreted as its *center*) and a finite set of nonnegative real numbers (that we will call its *spreads*) is as follows.

Given $n \in \mathbb{N}$, $\{\alpha_i\}_{i=0}^n \subset \mathbb{I}$ verifying $0 = \alpha_0 < \alpha_1 < \alpha_2 < \ldots < \alpha_{n-1} < \alpha_n = 1$, $A^c \in \mathbb{R}$ and $A^m, A^{\ell,1}, A^{\ell,2}, \ldots, A^{\ell,n-1}, A^{r,1}, A^{r,2}, \ldots, A^{r,n-1} \in [0, \infty)$, there exists a unique finite FN $\mathcal{A}$ such that

$$\underline{a}_\alpha = \begin{cases} A^c - A^m, & \text{if } \alpha_{n-1} < \alpha \leq 1, \\ A^c - A^m - A^{\ell,n-1} - A^{\ell,n-2} - \ldots - A^{\ell,i+1}, & \text{if } \alpha_i < \alpha \leq \alpha_{i+1} \\ \qquad\qquad (\text{for some } i \in \{1, 2, \ldots, n-2\}), & \\ A^c - A^m - A^{\ell,n-1} - A^{\ell,n-2} - \ldots - A^{\ell,1}, & \text{if } 0 \leq \alpha \leq \alpha_1; \end{cases} \tag{1}$$

$$\overline{a}_\alpha = \begin{cases} A^c + A^m, & \text{if } \alpha_{n-1} < \alpha \leq 1, \\ A^c + A^m + A^{r,n-1} + A^{r,n-2} + \ldots + A^{r,i+1}, & \text{if } \alpha_i < \alpha \leq \alpha_{i+1} \\ \qquad\qquad (\text{for some } i \in \{1, 2, \ldots, n-2\}), & \\ A^c + A^m + A^{r,n-1} + A^{r,n-2} + \ldots + A^{r,1}, & \text{if } 0 \leq \alpha \leq \alpha_1. \end{cases} \tag{2}$$

The FN $\mathcal{A}$ is the unique finite FN whose center is A^c, whose central spread is A^m, whose left spreads are $\{A^{\ell,i}\}_{i=1}^{n-1}$, whose right spreads are $\{A^{r,i}\}_{i=1}^{n-1}$ and whose image is included in $\{\alpha_i\}_{i=0}^n$.

Then, a finite FN can be equivalently determined in the way

$$\mathcal{A} = \text{FN}\left(\{\alpha_i\}_{i=0}^n, A^c, A^m, \left\{A^{\ell,i}\right\}_{i=1}^{n-1}, \left\{A^{r,i}\right\}_{i=1}^{n-1}\right),$$

 ISBN: 978-84-617-8694-7

which has the advantage that all spreads are nonnegative, that is,

$$A^c \in \mathbb{R} \quad \text{but} \quad A^m, A^{\ell,i}, A^{r,i} \geq 0.$$

If we set

$$\Lambda = \{\alpha_0 = 0, \alpha_1, \ldots, \alpha_{n-1}, \alpha_n = 1\} \subset \mathbb{I},$$

then we will use the notation

$$\mathcal{A} = \mathrm{FFN}_\Lambda \left(A^c, A^m, \left\{A^{\ell,i}\right\}_{i=1}^{n-1}, \left\{A^{r,i}\right\}_{i=1}^{n-1} \right) \tag{3}$$

to describe any FN $\mathcal{F}$ in $\mathcal{F}_\Lambda$, where A^c is its center, and A^m, $\left\{A^{\ell,i}\right\}_{i=1}^{n-1}$ and $\left\{A^{r,i}\right\}_{i=1}^{n-1}$ are its (nonnegative) spreads.

4 Ranking FNs with compact support

It is well-known that there is a lack of universally acceptable total ordering between FNs. However, ranking of FNs is a useful tool to deal with decision-making problems. Therefore, many orderings have been proposed by several authors. Next, we show a novel method for ordering FNs using countable FNs. This method has similar properties to a specificity [19, 9].

Let $\Lambda = \{\alpha_i\}_{i\in I}$ be a countable (or finite) and strictly increasing sequence of real numbers such that $0 \leq \alpha_0 < \alpha_1 < \ldots < \alpha_i < \ldots \leq 1$. Given any FN $\mathcal{A}$ with compact support, we may consider the FN $\mathcal{A}^\Lambda$ given, for all $x \in \mathbb{R}$, by:

$$\mathcal{A}^\Lambda(x) = \begin{cases} 1, & \text{if } x \in \mathcal{A}_{[1]}, \\ \alpha_i, & \text{if } x \in \mathcal{A}_{[\alpha_i]} \setminus \mathcal{A}_{[\alpha_{i+1}]} \quad (i \geq 0), \\ 0, & \text{otherwise.} \end{cases}$$

Then $\mathcal{A}^\Lambda$ is a countable (or finite) FN, has compact support, its image is in $\{\alpha_i\}_{i\in I} \cup \{1\}$ and $\mathcal{A}^\Lambda_{[\alpha_i]} = \mathcal{A}_{[\alpha_i]}$ for all $i \in I$. Let $S_\Lambda(\mathcal{A})$ be the area of the histogram given by the plot of $\mathcal{A}^\Lambda$, i.e.,

$$S_\Lambda(\mathcal{A}) = \ell^{\mathcal{A}}_1 + \textstyle\sum_{i\geq 1} \alpha_i (\ell^{\mathcal{A}}_{\alpha_i} - \ell^{\mathcal{A}}_{\alpha_{i+1}}) \qquad \text{for all } \mathcal{A} \in \mathcal{F} \text{ with compact support,}$$

where $\ell^{\mathcal{A}}_{\alpha_i} = \overline{a}_{\alpha_i} - \underline{a}_{\alpha_i}$ is the length of the corresponding α_i-cut $\mathcal{A}_{[\alpha_i]} = [\underline{a}_{\alpha_i}, \overline{a}_{\alpha_i}]$. Notice that $S_\Lambda(\mathcal{A})$ can be interpreted as a Choquet integral [3, 5] corresponding to the Euclidean measure. As

$$\sum_{i\geq 1} \alpha_i (\ell^{\mathcal{A}}_{\alpha_i} - \ell^{\mathcal{A}}_{\alpha_{i+1}}) \leq \sum_{i\geq 1} \left[\ell^{\mathcal{A}}_{\alpha_i} - \ell^{\mathcal{A}}_{\alpha_{i+1}} \right] = \ell^{\mathcal{A}}_{\alpha_1} - \lim_i \ell^{\mathcal{A}}_{\alpha_i} \leq \ell^{\mathcal{A}}_{\alpha_1} \leq \mathrm{length}(\mathrm{supp}(\mathcal{A})) < \infty,$$

 ISBN: 978-84-617-8694-7

then the real number $S_\Lambda(\mathcal{A})$ is well-defined. This function allows us to induce an ordering (depending on Λ) on the set of all FNs with compact support given by

$$\mathcal{A} \prec_\Lambda \mathcal{B} \text{ if, and only if, } S_\Lambda(\mathcal{A}) < S_\Lambda(\mathcal{B}); \quad \mathcal{A} \sim_\Lambda \mathcal{B} \text{ if, and only if, } S_\Lambda(\mathcal{A}) = S_\Lambda(\mathcal{B}).$$

We will write $\mathcal{A} \preccurlyeq_\Lambda \mathcal{B}$ if $\mathcal{A} \prec_\Lambda \mathcal{B}$ or $\mathcal{A} \sim_\Lambda \mathcal{B}$. Some basic properties of the previous ordering are as follows.

- If $\mathcal{A} \preccurlyeq_\Lambda \mathcal{B}$ then $\mathcal{A}+\mathcal{C} \preccurlyeq_\Lambda \mathcal{B}+\mathcal{C}$ for all $\mathcal{C}$.
- If $\mathcal{A} \preccurlyeq_\Lambda \mathcal{B}$ then $r\mathcal{A} \preccurlyeq_\Lambda r\mathcal{B}$ for all $r \geq 0$.
- If $\mathcal{A}_{[\alpha]} = \mathcal{B}_{[\alpha]}$ for all $\alpha \in \Lambda$, then $\mathcal{A} \sim_\Lambda \mathcal{B}$.
- If $\mathcal{A} \leq \mathcal{B}$ (that is, $\mathcal{A}(x) \leq \mathcal{B}(x)$ for all $x \in \mathbb{R}$), then $\mathcal{A} \preccurlyeq_\Lambda \mathcal{B}$ for all Λ.
- If $\mathcal{A} \leq \mathcal{B}$ and $\mathcal{A} \sim_\Lambda \mathcal{B}$, then $\mathcal{A}_{[\alpha]} = \mathcal{B}_{[\alpha]}$ for all $\alpha \in \Lambda$.
- $\mathcal{A} \sim_\Lambda \mathcal{A}^\Lambda$.

Although $\mathcal{A} \mapsto S_\Lambda(\mathcal{A})$ does not define a measure of specificity (see [19, 9, 8, 20]), $S_\Lambda(\mathcal{A})$ can be seen as a measure of the imprecision associated to a FN because the property of the fourth bullet recalls one of its main characteristic: the specificity measure of a normal fuzzy set decreases when the membership degree of its elements increases. Therefore, the above process can be interpreted as a specificity-type method. Most authors use triangular or trapezoidal FNs in order to describe their ordering methods. In that cases, the following properties may be useful.

- If $n \in \mathbb{N}$ and $\Lambda_n = \{0, 1/n, 2/n, \ldots, (n-1)/n, 1\}$ then

$$S_{\Lambda_n}(\mathcal{A}) = \frac{n-1}{n}\, S(\mathcal{A}) + \frac{\ell_1^{\mathcal{A}}}{n} \qquad \text{for all trapezoidal FN } \mathcal{A},$$

  where $S(\mathcal{A})$ denotes the area under $\mathcal{A}$ and $\ell_1^{\mathcal{A}} = \ell(\ker \mathcal{A})$ is the length of its kernel.

- If $\mathcal{A}$ and $\mathcal{B}$ are trapezoidal FNs such that $\operatorname{supp}(\mathcal{A}) \subseteq \operatorname{supp}(\mathcal{B})$, $\ker(\mathcal{A}) \subseteq \ker(\mathcal{B})$ and $\mathcal{A} \sim_\Lambda \mathcal{B}$ for some $\Lambda \subset [0,1]$ with, at least, three points, then $\mathcal{A} = \mathcal{B}$.

5 Numerical examples

In [13], the authors proposed a method for ranking FNs using areas. In this work, they showed several examples and compared their results with the methods used by other authors. We illustrated our decision rule using the FNs considered in [13, Example 4].

$$\mathcal{A}_1 = (1/2/5) \text{ (triangular)}, \quad \mathcal{A}_2(x) = \begin{cases} [1-(x-2)^2]^{1/2}, & \text{if } 1 \leq x \leq 2, \\ [1-(x-2)^2/4]^{1/2}, & \text{if } 2 \leq x \leq 4, \\ 0, & \text{otherwise.} \end{cases}$$
