Efficiency Series Paper 01/2005

Abstract: A meta-regression analysis including 167 farm level technical efficiency (TE) studies of developing and developed countries was undertaken. The econometric results suggest that stochastic frontier models generate lower mean TE (MTE) estimates than non-parametric deterministic models, while parametric deterministic frontier models yield lower estimates than the stochastic approach. The primal approach is the most common technological representation. In addition, frontier models based on cross-sectional data produce lower estimates than those based on panel data whereas the relationship between functional form and MTE is inconclusive. On average, studies for animal production show a higher MTE than crop farming. The results also suggest that the studies for countries in Western Europe and Oceania present, on average, the highest levels of MTE among all regions after accounting for various methodological features. In contrast, studies for Eastern European countries exhibit the lowest estimate followed by those from Asian, African, Latin American, and North American countries. Additional analysis reveals that MTEs are positively and significantly related to the average income of the countries in the data set but this pattern is broken by the upper middle income group which displays the lowest MTE.

Key words: Meta-Regression, Technical Efficiency, International Agriculture

1. Introduction

As is well established in the literature, productivity growth can be decomposed into technological change (TC) and technical efficiency (TE). This decomposition makes it possible to study the sources of productivity growth from different points of view (Nishimizu and Page, 1982). Specifically, TE can be interpreted as a relative measure of managerial ability for a given technology, while TC evaluates the effect in productivity from the adoption of new production practices. In other words, gains in TE are derived from improvements in decision-making, which in turn are related to a host of variables including knowledge, experience and education. By contrast, TC relates to investments in research and technology (Nishimizu and Page, 1982; Ahmad and Bravo-Ureta, 1996).

In measuring TE, different methodologies and strategies have been proposed and considerable controversy has surrounded the choice and merits of a specific methodology and the impact of such choice on the ensuing analysis (Olesen, Petersen and Lovell, 1996; Coelli and Perelman, 2000). Wadud and White (2000) indicate that in most empirical studies the selection of the methodology used to measure TE is arbitrary and mainly based on the objective of the study, the data available and the personal preference of the researcher. Using a simulation analysis comparing the outcomes from parametric and non-parametric techniques, Resti (2000) concludes that there is no clear advantage of one method over the other. However, empirical studies using agricultural data have shown that the selection of a specific methodology can seriously affect the estimated TE scores (e.g., Kalaitzandonakes and Dunn, 1995; Sharma, Leung and Zaleski, 1999; Wadud and White, 2000; Solís, 2005).

The main goal of this paper is to examine the impact of various attributes of a study (e.g., estimation technique, functional form, sample size) on TE estimates. To accomplish the objective set forth, a meta-regression analysis of 167 frontier studies of TE focusing on the agricultural sector is undertaken. Meta-regression analysis is a quantitative method used to evaluate the effect of methodological and other study-specific characteristics on published empirical estimates of some indicator, TE in our case, using differences across these studies as explanatory variables in a regression model (Alston *et al*, 2000).

The rest of this paper is divided into four additional sections. Section 2 discusses the concept of TE followed by a brief review of its measurement. Section 3 describes the data sources and empirical model employed in the study followed by the results and analysis. The last section presents a summary along with some suggestions for further research.

2. An overview of the frontier function methodology

The original frontier function model introduced by Farrell (1957) uses the efficient unit isoquant to measure economic efficiency (EE), and to decompose this measure into TE and allocative efficiency (AE). In this model, TE can be defined as the firm's ability to produce maximum output given a set of inputs and technology. It is important to distinguish TE from TC, where the latter reflects an upward shift of the production function or a downward shift of the unit isoquant. AE (or price efficiency) measures the firm's success in choosing the optimal input proportions, i.e., where the ratio of marginal products for each pair of inputs is equal to the ratio of their market prices. In Farrell's framework, EE is a measure of overall performance and is equal to TE times AE (i.e., $EE = TE \times AE$).

The frontier function methodology has become a widely used tool in applied production analysis due mainly to its consistency with the textbook definition of a production, profit or cost function (i.e., with the notion of maximization or minimization). This popularity is evidenced by the proliferation of methodological and empirical frontier studies over the last two decades as shown in the reviews by Battese (1992), Bravo-Ureta and Pinheiro (1993), Thiam, Bravo-Ureta and Rivas (2001), and Gorton and Davidova (2004).

Frontier models can be classified into two basic types: parametric and non-parametric. Furthermore, parametric models can be separated into deterministic and stochastic. The deterministic model assumes that any deviation from the frontier is due to inefficiency, while the stochastic approach allows for statistical noise. Therefore, a fundamental problem with deterministic frontiers is that any measurement error, and any other source of stochastic variation in the dependent variable, is embedded in the one-sided component making the resulting TE estimates sensitive to outliers (Greene,

1993). The stochastic frontier production model addresses this sensitivity problem by incorporating a composed error structure with a two-sided symmetric term and a one-sided component. The one-sided component reflects inefficiency, while the two-sided error captures the random effects outside the control of the production unit.

Econometric models for the estimation of efficiency can also be separated into primal and dual approaches, depending on the underlying behavioral assumptions that are made. The primal approach has been more common in frontier estimation although dual cost and particularly profit function models have gained increasing attention in recent years (Kumbhakar, 2001). The estimation of frontier functions can also be categorized, according to the type of data, as cross-section or panel data studies. The estimation of stochastic frontiers with panel data is very appealing because it can overcome several limitations present in cross-sectional studies (Schmidt and Sickles, 1984).

Non-parametric technical efficiency models, also referred to as data envelopment analysis (DEA), are based on mathematical programming techniques. The main feature of DEA methods is that they do not require the specification of a functional form for the technology as is the case for parametric models. Nevertheless, a major drawback of these methods is that they are deterministic and thus are affected by extreme observations. Another characteristic of DEA methods is the potential sensitivity of efficiency scores to the number of observations as well as to the dimensionality of the frontier (Ramanathan, 2003).

Recent work has focused on extending the stochastic frontier approach in order to deal with multi-output technologies within a primal framework. To this end, the stochastic distance function approach has been proposed and is now becoming widely used in the efficiency literature. The main advantage of using a distance function is that price information is not needed and the production frontier can be estimated without assuming separability of inputs and outputs (Kumbhakar *et al*, 2003).

Despite significant advances in the frontier function literature, many methodological questions remain. Examples of these questions include the effect of functional form on parametric models, the lack of *a priori* justification for the selection of a particular distributional form for the one-sided inefficiency term in stochastic frontiers, potential

simultaneous equation bias in primal models, and the validity of dual models, particularly when profit maximization is the maintained hypothesis in the context of developing country agriculture. Several authors have discussed the advantages and limitations of the different methodological approaches available to measure efficiency (e.g., Coelli, 1995; Hjalmarsson, Kumbhakar and Heshmati, 1996; and Alvarez and Orea, 2002); however, the extent to which efficiency estimates are sensitive to model specification is a matter of on going debate.

This paper contributes to the existing literature by conducting a systematic analysis of the effects that different methodologies and study-specific characteristics have on mean TE estimates using a data set created from 167 published papers that have relied on farm level data from around the world. Specific issues examined include: (1) whether parametric deterministic or parametric stochastic frontiers produce different TE estimates than non-parametric studies; (2) whether functional form has a discernable effect on TE; (3) whether panel data frontier models produce the same mean TE than cross-sectional data frontier models; (4) whether TE from studies using a primal approach differ from those using a dual approach; (5) whether model dimensionality (sample size and the number of variables) has a significant impact on TE; (6) whether TE varies with the type of product under analysis; (7) whether geographical location generates a significant variation on mean TE; and (8) whether the income level of the country under study has an impact on TE estimates. The work reported here constitutes a significant extension of the study by Thiam, Bravo-Ureta and Rivas (2001) that provided an analysis focusing on 34 articles covering only developing countries.

3. Data and methodology

An important consideration in studies using the meta-regression analysis framework is to define a clear approach to be followed when searching the relevant literature. To this end, in the present paper a thorough review was made in the following databases: Agricola; Agris International; Ingenta; Science Direct; Social Science Citation Index; and the World Agricultural Economics and Rural Sociology Abstracts. In addition, a complementary search was performed in the following Journals (J): Agricultural (Ag.) and Resource Economics (Econ.) Review; American J. of Ag. Econ.; Australian J. of Ag. Econ.; Canadian J. of Ag. Econ.; European J. of Operational Research; European

Review of Ag. Econ.; J. of Ag. and Applied Econ; J. of Ag. Econ.; J. of Comparative Econ.; J. of Econometrics; and J. of Productivity Analysis.

The literature search yielded a total of 167 published papers, which include the type of information required for the present study¹. This search was done for studies published between January 1979 and June 2005. Given that many of the papers report multiple TE estimates, the data set under analysis comprises a total of 569 observations. An overview of all the papers used in this evaluation, including the first author, year of publication, country and product analyzed, average number of observations and mean TE, is presented in Table 1. In addition, all these papers are sorted by the methodology implemented in the studies. To save space on the table, for those studies that reported more than one estimate using the same methodology, both the average number of observations and mean TE are presented. However, for studies reporting multiple estimators using different methodologies, both the average number of observations and mean TE by methodology are displayed. Nevertheless, the data used in the analysis incorporates all observations found in the sources cited that contain the variables necessary to undertake the meta-regression analysis reported below.

Table 2 presents the methodological features of these studies. As indicated, a total of 167 studies are included in the analysis out of which 68 apply deterministic models and 117 stochastic models. As can be noticed, the sum of deterministic and stochastic studies (185) is larger than the reported number of papers (167) because in some studies both techniques are implemented. In general, most of the studies rely on parametric models, panel data, the Cobb-Douglas functional form, and a primal representation of the technology.

Table 2 also shows that the average mean TE (AMTE) for all deterministic models is 74.6% compared to 77.3% for all stochastic models. A comparison of AMTEs between the parametric and non-parametric estimates shows that the former are lower (76.3%) than the latter (78.3%) but these differences are not statistically significant, which is contrary to what would be expected on conceptual grounds, given that non-parametric

¹ Several other papers were found in the databases and journals included in the search but they did not contain all the variables needed; thus, they had to be excluded from the analysis.

studies usually present several TE indexes equal to 100% (Kumbhakar and Lovell, 2000).²

An interesting pattern is observed regarding the effect of functional form. For the deterministic models, the Cobb-Douglas form yields a higher AMTE (72.6%) than the translog (68.1%) while the opposite pattern is observed for the stochastic models, but these differences are not statistically significant. Only within stochastic frontier models, studies specifying a translog functional form (79.7%) produce a significantly higher AMTE than studies using a Cobb-Douglas function (76.3%). Another interesting difference for deterministic studies is that primal models produce a higher AMTE than dual models. Although a similar pattern was reported by Thiam, Bravo-Ureta and Rivas (2001), there is no clear explanation for this result (Greene, 1993).

Finally, Table 2 suggests that studies using panel data display a significantly higher AMTE (77.5%) than studies with cross sectional data (72.8%) among deterministic models. This result is consistent with the findings by Thiam, Bravo-Ureta and Rivas (2001). Even though Greene (1993) argues that models relying on panel data are likely to yield more accurate efficiency estimates, there are no *a priori* expectations regarding the impact of data type (i.e. cross-sectional versus panel) on the magnitude of efficiency scores.

Table 3 summarizes the AMTE measures according to the geographical region where the studies were conducted. The largest number of cases is for Asia (189), followed by Western Europe and Oceania (157), North America (United States and Canada, 103), Latin America and the Caribbean (47), Eastern Europe (45) and Africa (28). The highest AMTE when stochastic and deterministic studies are combined is for Western Europe and Oceania at 82.0%, while the lowest is for Eastern Europe at 70.0%. The differences across geographic regions are significant at the 10% level or better. When the deterministic and stochastic AMTEs are calculated separately, Western Europe and Oceania still exhibit the highest level but some change is found in the rankings for the rest of the regions.

² Independent t-tests and One-Way ANOVA are used to compare AMTEs. The former is used to compare means between two groups whereas the latter is applied when comparing more than two groups (Field, 2005).

Also displayed in Table 3 is the AMTE for all Lower Income Countries (LICs), Lower Middle Income Countries (LMICs), Upper Middle Income Countries (UMICs) and Higher Income Countries (HICs).³ The AMTEs, when the deterministic and stochastic measures are combined, is 74.1%, 75.7%, 68.3%, and 78.8% for the LICs, LMICs, UMICs and HICs, respectively. By comparison, the AMTE, using a deterministic approach, is 68.7%, 64.8%, 68.0% and 76.9% for LICs, LMICs, UMICs and HICs, respectively. The AMTEs for the stochastic approach follow a slightly different pattern equal to 74.7%, 76.8%, 69.2% and 80.3% for LICs, LMICs, UMICs and HICs, respectively. The only statistically significant difference is within the stochastic group where HICs exhibit a higher AMTE than LICs.

Table 4 displays the AMTEs by product type. As shown in this table, Other Crops is the dominant category with 51 studies, followed by Dairy and Cattle (46), Rice (28), Whole Farm (23), Other Grains (20), Maize (10), and Other Animals (6). The highest AMTE is reported for Other Animals (84.5%) followed closely by Dairy and Cattle (80.6%), while the lowest result is found for Rice (72.4%). The statistical test of comparisons of means shows that studies analyzing Other Animal and Dairy Cattle exhibit a significantly higher AMTE than studies for Rice. Studies of Other Grains and of Other Crops produce a lower AMTE than those of Other Animals, while Dairy and Cattle studies generate a significantly higher AMTE than those for Other Crops.

The basic hypothesis of this paper is that the variation in the mean TE (MTE) indices reported in the literature can be explained by the attributes of the studies, including functional form, sample size, product analyzed, dimensionality, estimation technique and geographical region or income level for the region where the farm data for the study was collected. To investigate this issue formally, the following three models are estimated:

Model 1:

³ Based on the World Bank (2005), the LICs that are included in this study are Bangladesh, Cameroon, Cote d'Ivoire, Ethiopia, Ghana, India, Kenya, Lesotho, Mali, Nepal, Nicaragua, Nigeria, Pakistan, Papua New Guinea, Tanzania, Uganda and Vietnam. The LMICs include Brazil, China, Dominican Republic, Ecuador, Guatemala, Indonesia, Iran, Jamaica, Paraguay, Philippines, Sri Lanka and the Ukraine. The UMICs include Costa Rica, Malaysia and Turkey. The HICs comprise Australia, Canada, Finland, France, Germany, Greece, Italy, Netherlands, New Zealand, Poland, Portugal, Republic of Korea, Slovenia, Spain, Sweden, United Kingdom and the United States.

$$MTE = f(PSTO, PDET, TL, CD, CS, PRI, VARSIZE, GRAIN) \quad (1)$$

Model 2:

$$MTE = f(PSTO, PDET, TL, CD, CS, PRI, VARSIZE, GRAIN, ASIA, NAMR, AFRI, LTCR, EAST) \quad (2)$$

Model 3:

$$MTE = f(PSTO, PDET, TL, CD, CS, PRI, VARSIZE, GRAIN, LIC, LMIC, UMIC) \quad (3)$$

where the dependent variable *MTE* is mean technical efficiency as reported in the studies. *PSTO* is a dummy variable equal to one if the model is a parametric stochastic frontier, *PDET* is a dummy variable equal to one for parametric deterministic frontiers and the omitted category is the non-parametric studies. *TL* is a dummy variable equal to one if the translog functional form is used, *CD* is a dummy variable for the Cobb-Douglas functional form and the excluded category is Other Functional forms along with the non-parametric studies. *CS* is a dummy variable equal to one if the data is cross-sectional and zero otherwise; *PRI* is a dummy variable equal to one if a primal model is estimated and zero otherwise; *VARSIZE* is the ratio between the number of explanatory variables and the number of observations included in the study; and *GRAIN* is a dummy variable equal to one if the model is for grains (rice, maize and other grains) and zero otherwise.⁴

The regional variables are *ASIA* which is a dummy equal to one if the study used data for that part of the world; *NAMR* is a dummy variable equal to one if the data comes from North America (United States and Canada); *AFRI* is a dummy variable equal to one if the study used data from Africa; *LTCR* is a dummy variable equal to one if the study used data from Latin America or the Caribbean; and *EAST* is a dummy variable equal to one if the study used data from Eastern Europe. The omitted region is Western Europe and Oceania. Finally, the income level dummies are *LIC*, which is equal to one for low income countries; *LMIC* which is equal to one for lower-middle income countries; and *UMIC*, a dummy that takes the value of one for upper-middle

⁴ As suggested by one of the referees, it would be interesting to include the orientation of the efficiency measures (i.e., input- versus output-oriented) and, for panel data studies, whether TE is time variant or not, and if time variant then the specification used. The former factor is not included, however, because very few studies are input oriented and almost all of them are non-parametric so not much would be gained by including a separate variable for orientation. In terms of the second comment, the models already have a control for panel data but the inclusion of further related effects would be more appropriate if the analysis was restricted to panel data studies with sufficient variability in the behavior of TE overtime.

income countries. The excluded category in this case is the high income country studies or HICs.

Given that the efficiency scores are bounded between zero and one, Models I, II and III are estimated using the two-limit (i.e., doubly censored) Tobit procedure (Greene, 2002). However, for comparison, these models are also estimated using the Ordinary Least Square (OLS). However, Judge *et al* (1988) show that when an econometric model contains a ratio form as the dependent variable OLS could suffer heteroskedasticity problems. Therefore, we use a robust covariance matrix to correct for heteroskedasticity.

4. Results and analysis

Table 5 contains the econometric results for Models I, II and III using the OLS and the two-limit Tobit approach. Generally speaking, both procedures display similar patterns. However, given the characteristics of the data used in this analysis the Tobit technique is the most appropriate one from a methodological point of view. Consequently, the discussion below is based on the results obtained using the latter procedure. With respect to the empirical specifications, Model I ignores the possible presence of a regional effect, Model II introduces a set of five dummy variables to capture potential regional effects, while Model III includes three dummies to account for the effect of income level on MTE. As shown in Table 5, most of the parameters of Models I through III are significant at the 5% level or better.

The variables *PSTO* and *PDET* capture the effect of the methodology used to estimate the frontier on MTE estimates (the excluded category for this group of dummies is the non-parametric frontier approach). The negative sign and statistical significance of the parameter for *PSTO* indicates that parametric stochastic models consistently yield lower MTEs than non-parametric deterministic ones. This result can be explained by the fact that non-parametric deterministic studies typically yield numerous TE indexes equal to 100% and such high measures increase the reported MTEs. The estimated parameter for *PDET* is also negative, significant and higher in absolute value than the parameter for *PSTO* which is consistent with *a priori* expectations based on the fact that parametric deterministic models consider all variations from the frontier as

inefficiency, while stochastic models make it possible to disentangle random shocks from inefficiency (Kumbhakar and Lovell, 2000).

The effect of functional form on TE displays mixed results across the three estimated models (the excluded category for this group of dummies is Other Functional forms). The translog (*TL*) specification is statistically significant in Models I and III, and the Cobb-Douglas (*CD*) is only significant in Model III. The *TL* yields higher MTEs than both the *CD* and Other Functional forms in Models I and III, while the *CD* does so in Model II (but the parameter is not significant). These results suggest that a more flexible functional form (*TL*) tends to yield a higher MTE. These findings are similar to those reported by Ahmad and Bravo-Ureta (1996), Resti (2000) and Thiam (2003), among others.

The parameter for *CS* (Cross Sectional data) displays a negative and highly significant effect on MTE. This result suggests that frontier models using cross-sectional data produce lower MTE estimates than models based on panel data; this is consistent across the three model specifications. In addition, the parameter for *GRAIN* is also consistently negative suggesting that frontier models for grain crops present, on average, lower levels of MTE than those for Dairy and Cattle, Other Crops or Whole Farm. However, whether the model relies on a primal (*PR1*) or dual representation of the technology does not have a significant effect on MTE.

The econometric results indicate that the ratio used to analyze the effect of model dimensionality (*VARSIZE*) does have a significant effect on the MTE measures in the Tobit equations for Models II and III, which is consistent with Thomas and Tauer (1994) and Chavas, Petrie and Roth (2005).

Models II and III introduce additional variables where the former incorporates the geographical region where the studied country is located, while Model III includes the country's average income level on the estimated MTE. It is important to indicate that based on generalized likelihood ratio tests, the Tobit estimates of Models II and III are preferred over Model I, indicating that regional/country effects are indeed important in analyzing the estimated MTEs.

The coefficients for all the regional dummies included in Model II are negative and statistically significant. Given that the excluded category for this group of dummies is for countries located in Western Europe and Oceania, these results imply that countries in these regions present, on average, the highest levels of MTE among all regions after controlling for methodological features of the studies. By contrast, the results show that Eastern European countries exhibit, on average, the lowest estimate of MTE followed by Asian, African, Latin American and North American countries. The joint statistical significance of the parameters associated with the regional dummies was also confirmed by using a generalized likelihood ratio test.

Lastly, to examine whether the country's income level is associated with the estimated MTEs, the data is separated in four groups of countries, HICs, UMICs, LMICs and LICs, and three dummy variables are introduced to capture this effect, as explained earlier (HICs is the excluded category). The results, shown in Table 5 under Model III, indicate that the coefficients for the dummies for the LICs, LMICs and UMICs are all negative and highly significant. These results suggest that, on average and controlling for all other effects included in the model, studies from HICs present the highest MTE estimates followed by LMICs and LICs, while studies from UMICs display the lowest.

5. Summary and conclusions

The objective of this study was to undertake a meta-regression analysis seeking to explain the variation in Mean Technical Efficiency (MTE) for studies focusing on the agricultural sector. The MTE estimates reported in 167 published papers were explained by major methodological characteristics of the studies. In addition, alternative models incorporated regional and income dummy variables to capture the country effect on MTE. This study contributes to the cross-country productivity literature because the existing body of work in this area typically uses aggregate (i.e., national) level data to estimate total factor productivity and has ignored the TE component of productivity.

The econometric results suggest that non-parametric deterministic models generate higher MTE estimates than stochastic frontier models, while parametric deterministic frontier models yield lower estimates. The effect of functional form on TE is

inconclusive. In addition, frontier models based on cross-sectional data produce lower estimates than those based on panel data. In addition, the studies focusing on countries in Western Europe and Oceania present, on average, the highest levels of MTE while studies for Eastern European countries exhibit the lowest, after accounting for key methodological features. Additional analysis reveals that MTE tends to be positively and significantly related to the average income of the countries in the data set. However, this pattern is broken by the UMICs group which displays the lowest MTE.

The large body of published articles included in this study focusing on TE suggests that, given the state of technology prevailing in the various regions/countries at the time that the studies were conducted, the shortfall in TE and thus in managerial ability, is most significant in Eastern European countries followed by Asia, Africa and Latin America. By contrast, managerial improvements as a means to increase productivity are least promising in Western Europe and Oceania, followed by North American countries. More conclusive statements on this matter will need refinements on the data used and further analysis.

In conclusion, in this study we have attempted to organize the 'flood of numbers' (Heckman, 2001) stemming from a substantial body of literature that has emerged over the past few decades on technical efficiency measurement in agriculture. The empirical studies and the conceptual literature reveal mixed results and conflicting views concerning the merits of the various methodologies that have been developed. Thus, the meta-regression analysis presented here seeks to integrate a wide range of empirical findings to shed light in a systematic fashion on the effects of alternative methodological assumptions on farm level TE measures. The authors hope that this work will make this vast literature more accessible to researchers while also providing a broad frame of reference for those that seek to evaluate the sensitivity of their results to the choice of method.

Table 1. Overview of Empirical Studies of Technical Efficiency in Farming*

First Author	Year	Country	Product(s)	No. Obser.	Mean TE

Mean **77.3**

OVERALL MEAN **76.6**

* It is important to notice that several studies computed TE using more than one methodology.

Therefore, in this table a study is presented each time a different methodology is applied.

Table 2. Average Mean Technical Efficiency by Methodological Characteristics

Category	No. of Cases	Deterministic			Stochastic			AMTE
		Avg.	Max.	Min.	Avg.	Max.	Min.	
Approach								
Parametric	482	70.2	95.5	26.0	77.3	100.0	17.0	76.3
Non-Parametric	87	78.3	100.0	35.0	--	--	--	78.3
